N3. [Compare K_i:K_j.] If $K_i > K_j$, go to step N8. If $i = j$, set $R_k \leftarrow R_i$ and go to N13.

N4. [Transmit R_i.] (Steps N4–N7 are analogous to steps M3–M4 of Algorithm M.) Set $R_k \leftarrow R_i$, $k \leftarrow k + d$.

N5. [Stepdown?] Increase i by 1. Then if $K_{i-1} \leq K_i$, go back to step N3.

N6. [Transmit R_j.] Set $R_k \leftarrow R_j$, $k \leftarrow k + d$.

N7. [Stepdown?] Decrease j by 1. Then if $K_{j+1} \leq K_j$, go back to step N6; otherwise go to step N12.

N8. [Transmit R_j.] (Steps N8–N11 are dual to steps N4–N7.) Set $R_k \leftarrow R_j$, $k \leftarrow k + d$.

N9. [Stepdown?] Decrease j by 1. Then if $K_{j+1} \leq K_j$, go back to step N3.

N10. [Transmit R_i.] Set $R_k \leftarrow R_i$, $k \leftarrow k + d$.

N11. [Stepdown?] Increase i by 1. Then if $K_{i-1} \leq K_i$, go back to step N10.

N12. [Switch sides.] Set $f \leftarrow 0$, $d \leftarrow -d$, and interchange $k \leftrightarrow l$. Return to step N3.

N13. [Switch areas.] If $f = 0$, set $s \leftarrow 1 - s$ and return to N2. Otherwise sorting is complete; if $s = 0$, set $(R_1, \ldots, R_N) \leftarrow (R_{N+1}, \ldots, R_{2N})$. (This last copying operation is unnecessary if it is acceptable to have the output in $(R_{N+1}, \ldots, R_{2N})$ at times.) ∎

This algorithm contains one tricky feature which is explained in exercise 5.

It would not be difficult to program Algorithm N for MIX, but we can deduce the essential facts of its behavior without constructing the entire program. The number of ascending runs in the input will be about $\frac{1}{2}N$, under random conditions, since we have $K_i > K_{i+1}$ with probability $\frac{1}{2}$; detailed information about the number of runs, under slightly different hypotheses, has been derived in Section 5.1.3. Each pass cuts the number of runs in half (except in unusual cases such as the situation in exercise 6). So the number of passes will usually be about $\log_2 N$. Each pass requires us to transmit each of the N records, and by exercise 2 most of the time is spent in steps N3, N4, N5, N8, N9. We can sketch the time in the inner loop as follows, if we assume that there is low probability of equal keys:

	Step	Operations	Time
	N3	CMPA, JG, JE	$3.5u$
Either	N4	STA, INC	$3u$
	N5	INC, LDA, CMPA, JGE	$6u$
Or	N8	STX, INC	$3u$
	N9	DEC, LDX, CMPX, JGE	$6u$

Thus about $12.5u$ is spent on each record in each pass, and the total running time will be asymptotically $12.5N \log_2 N$, for both the average case and the worst case. This is slower than quicksort's average time, and it may not be enough better than heapsort to justify taking twice as much memory space, since the asymptotic running time of Program 5.2.3H is $16N \log_2 N$.

The boundary lines between runs are determined in Algorithm N entirely by "step-downs." This has the possible advantage that input files with a preponderance of increasing *or decreasing* order can be handled very quickly; but it slows down the main loop of the calculation. Instead of testing step-downs, we can determine the length of runs artifically, by saying that all runs in the input have length 1, all runs after the first pass (except possibly the last run) have length 2, . . . , all runs after k passes (except possibly the last run) have length 2^k. This is called a *straight* two-way merge, as opposed to the "natural" merge in Algorithm N.

Straight two-way merging is very similar to Algorithm N, and it has essentially the same flowchart; but things are just different enough to make it worth while to write down the whole algorithm again:

Algorithm S (*Straight two-way merge sort*). Records $R_1, \ldots, R_N$ are sorted using two memory areas as in Algorithm N.

S1. [Initialize.] Set $s \leftarrow 0$, $p \leftarrow 1$. (For the significance of variables s, i, j, k, l, d, see Algorithm N. Here p represents the size of ascending runs to be merged on the current pass; q and r keep track of the number of unmerged items in a run.)

S2. [Prepare for pass.] If $s = 0$, set $i \leftarrow 1$, $j \leftarrow N$, $k \leftarrow N$, $l \leftarrow 2N + 1$; if $s = 1$, set $i \leftarrow N + 1$, $j \leftarrow 2N$, $k \leftarrow 0$, $l \leftarrow N + 1$. Then set $d \leftarrow 1$, $q \leftarrow p$, $r \leftarrow p$.

S3. [Compare K_i:K_j.] If $K_i > K_j$, go to step S8.

S4. [Transmit R_i.] Set $k \leftarrow k + d$, $R_k \leftarrow R_i$.

S5. [End of run?] Set $i \leftarrow i + 1$, $q \leftarrow q - 1$. If $q > 0$, go back to step S3.

S6. [Transmit R_j.] Set $k \leftarrow k + d$. Then if $k = l$, go to step S13; otherwise set $R_k \leftarrow R_j$.

S7. [End of run?] Set $j \leftarrow j - 1$, $r \leftarrow r - 1$. If $r > 0$, go back to step S6; otherwise go to S12.

S8. [Transmit R_j.] Set $k \leftarrow k + d$, $R_k \leftarrow R_j$.

S9. [End of run?] Set $j \leftarrow j - 1$, $r \leftarrow r - 1$. If $r > 0$, go back to step S3.

S10. [Transmit R_i.] Set $k \leftarrow k + d$. Then if $k = l$, go to step S13; otherwise set $R_k \leftarrow R_i$.

S11. [End of run?] Set $i \leftarrow i + 1$, $q \leftarrow q - 1$. If $q > 0$, go back to step S10.

S12. [Switch sides.] Set $q \leftarrow p$, $r \leftarrow p$, $d \leftarrow -d$, and interchange $k \leftrightarrow l$. Return to step S3.

S13. [Switch areas.] Set $p \leftarrow p + p$. If $p < N$, set $s \leftarrow 1 - s$ and return to S2. Otherwise sorting is complete; if $s = 0$, set

$$(R_1, \ldots, R_N) \leftarrow (R_{N+1}, \ldots, R_{2N}).$$

(The latter copying operation will be done if and only if $\lceil \log_2 N \rceil$ is odd, regardless of the distribution of the input. Therefore it is possible to predict the location of the sorted output in advance, and copying will usually be unnecessary.) ∎

For an example of this algorithm, see Table 2. It is somewhat amazing that the method works properly when N is not a power of 2; the runs being merged are not all of length 2^k, yet no provision has apparently been made for the exceptions! (See exercise 8.) The former tests for step-downs have been replaced by decrementing q or r and testing the result for zero; this reduces the asymptotic MIX running time to $11N \log_2 N$ units, slightly faster than we were able to achieve with Algorithm N.

Table 2

STRAIGHT TWO-WAY MERGE SORTING

503	087	512	061	908	170	897	275	653	426	154	509	612	677	765	703

087	503	703	765	154	170	509	908	897	653	426	275	677	612	512	061
061	087	503	512	612	677	703	765	908	897	653	509	426	275	170	154
061	087	154	179	275	426	503	509	512	612	653	677	703	765	897	908

In practice it would be worth while to combine Algorithm S with straight insertion; we can sort groups of, say, 16 items using straight insertion, in place of the first four passes of Algorithm S, thereby avoiding the comparatively wasteful bookkeeping operations involved in short merges. As we saw with quicksort, such a combination of methods does not affect the asymptotic running time, but it gives us a reasonable improvement nevertheless.

Let us now study Algorithms N and S from the standpoint of data structures. Why did we need $2N$ record locations instead of N? The reason is comparatively simple: We are dealing with four lists of varying size (two "source" lists and two "destination" lists on each pass); and we are using the standard "growing together" idea discussed in Section 2.2.2, for each pair of sequentially allocated lists. But half of the memory space is always unused, and a little reflection shows that we should really make use of a *linked* allocation for the four lists. If we add one link field to each of the N records, we can do everything required by the merging algorithms using simple link manipulations without moving the records at all! Adding N link fields is generally better than adding the space needed for N more records, and the reduced record movement may also save us time. Therefore we ought to consider a merging algorithm like the following one:

Algorithm L (*List merge sort*). Records $R_1, \ldots, R_N$ are assumed to contain keys $K_1, \ldots, K_N$, and "link fields" $L_1, \ldots, L_N$ capable of holding the numbers $-(N+1)$ through $(N+1)$. There are two auxiliary link fields L_0 and L_{N+1} in artificial records R_0 and R_{N+1} at the beginning and end of the file. This algorithm is a "list sort" which sets the link fields so that the records are linked together in ascending order. After sorting is complete, L_0 is the index of the record with the smallest key; and for $1 \le k \le N$, L_k is the index of the record which follows R_k, or $L_k = 0$ if R_k is the record with the largest key. (See Eq. 5.2.1–9.)

During the course of this algorithm, R_0 and R_{N+1} serve as "list heads" for two linear lists whose sublists are being merged. A negative link denotes the end of a sublist known to be ordered; a zero link denotes the end of the entire list. We assume that $N \ge 2$.

The notation "$|L_s| \leftarrow p$" means "Set L_s to p or $-p$, retaining the previous sign of L_s." This operation is well-suited to MIX, but unfortunately not to most computers; it is possible to modify the algorithm in straightforward ways to obtain an equally efficient method for most other machines.

L1. [Prepare two lists.] Set $L_0 \leftarrow 1$, $L_{N+1} \leftarrow 2$, $L_i \leftarrow -(i+2)$ for $1 \leq i \leq N-2$, and $L_{N-1} \leftarrow L_N \leftarrow 0$. (We have created two lists containing R_1, R_3, $R_5, \ldots$ and R_2, R_4, $R_6, \ldots$, respectively; the negative links indicate that each ordered "sublist" consists of one element only. For another way to do this step, taking advantage of ordering which may be present in the initial data, see exercise 12.)

L2. [Begin new pass.] Set $s \leftarrow 0$, $t \leftarrow N+1$, $p \leftarrow L_s$, $q \leftarrow L_t$. If $q = 0$, the algorithm terminates. (During each pass, p and q traverse the lists being merged; s usually points to the most recently processed record of the current sublist, while t points to the end of the previously output sublist.)

L3. [Compare K_p:K_q.] If $K_p > K_q$, go to L6.

L4. [Advance p.] Set $|L_s| \leftarrow p$, $s \leftarrow p$, $p \leftarrow L_p$. If $p > 0$, return to L3.

L5. [Complete the sublist.] Set $L_s \leftarrow q$, $s \leftarrow t$. Then set $t \leftarrow q$ and $q \leftarrow L_q$, one or more times, until $q \leq 0$. Finally go to L8.

L6. [Advance q.] (Steps L6 and L7 are dual to L4 and L5.) Set $|L_s| \leftarrow q$, $s \leftarrow q$, $q \leftarrow L_q$. If $q > 0$, return to L3.

L7. [Complete the sublist.] Set $L_s \leftarrow p$, $s \leftarrow t$. Then set $t \leftarrow p$ and $p \leftarrow L_p$, one or more times, until $p \leq 0$.

L8. [End of pass?] (At this point, $p \leq 0$ and $q \leq 0$, since both pointers have moved to the end of their respective sublists.) Set $p \leftarrow -p$, $q \leftarrow -q$. If $q = 0$, set $|L_s| \leftarrow p$, $|L_t| \leftarrow 0$ and return to L2. Otherwise return to L3. ∎

An example of this algorithm in action appears in Table 3, where we can see the link settings each time step L2 is encountered. It is possible to rearrange the records $R_1, \ldots, R_N$ at the end of this algorithm, so that their keys are in order, using the method of exercise 5.2–12. There is an interesting similarity between list merging and the addition of sparse polynomials (see Algorithm 2.2.4A).

Table 3

LIST MERGE SORTING

j	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17
K_j	—	503	087	512	061	908	170	897	275	653	426	154	509	612	677	765	703	—
L_j	1	−3	−4	−5	−6	−7	−8	−9	−10	−11	−12	−13	−14	−15	−16	0	0	2
L_j	2	−6	1	−8	3	−10	5	−11	7	−13	9	12	−16	14	0	0	15	4
L_j	4	3	1	−11	2	−13	8	5	7	0	12	10	9	14	16	0	15	6
L_j	4	3	6	7	2	0	8	5	1	14	12	10	13	9	16	0	15	11
L_j	4	12	11	13	2	0	8	5	10	14	1	6	3	9	16	7	15	0

Let us now construct a MIX program for Algorithm L, to see whether the list manipulation is advantageous from the standpoint of speed as well as space:

Program L (*List merge sort*). For convenience, we assume that records are one word long, with L_j in the (0:2) field and K_j in the (3:5) field of location INPUT+j; rI1 $\equiv p$, rI2 $\equiv q$, rI3 $\equiv s$, rI4 $\equiv t$, rA $\equiv R_q$. $N \geq 2$.

```
01    L       EQU   0:2                                  Definition of field names
02    ABSL    EQU   1:2
03    KEY     EQU   3:5
04    START   ENT1  N-2                        1         L1. Prepare two lists.
05            ENNA  2,1                        N - 2
06            STA   INPUT,1(L)                 N - 2     L_i ← -(i+2).
07            DEC1  1                          N - 2
08            J1P   *-3                        N - 2     N - 2 ≥ i > 0.
09            ENTA  1                          1
10            STA   INPUT(L)                   1         L_0 ← 1.
11            ENTA  2                          1
12            STA   INPUT+N+1(L)               1         L_{N+1} ← 2.
13            STZ   INPUT+N-1(L)               1         L_{N-1} ← 0.
14            STZ   INPUT+N(L)                 1         L_N ← 0.
15            JMP   L2                         1         To L2. (See next page.)
16    L3Q     LDA   INPUT,2                    C'' + B'  L3. Compare K_p:K_q.
17    L3P     CMPA  INPUT,1(KEY)               C
18            JL    L6                         C         To L6 if K_q < K_p.
19    L4      ST1   INPUT,3(ABSL)              C'        L4. Advance p. |L_s| ← p.
20            ENT3  0,1                        C'        s ← p.
21            LD1   INPUT,1(L)                 C'        p ← L_q.
22            J1P   L3P                        C'        To L3 if p > 0.
23    L5      ST2   INPUT,3(L)                 B'        L5. Complete the sublist. L_s ← q.
24            ENT3  0,4                        B'        s ← t.
25            ENT4  0,2                        D'        t ← q.
26            LD2   INPUT,2(L)                 D'        q ← L_q.
27            J2P   *-2                        D'        Repeat if q > 0.
28            JMP   L8                         B'        To L8.
29    L6      ST2   INPUT,3(ABSL)              C''       L6. Advance q. |L_s| ← q.
30            ENT3  0,2                        C''       s ← q.
31            LD2   INPUT,2(L)                 C''       q ← L_q.
32            J2P   L3Q                        C''       To L3 if q > 0.
33    L7      ST1   INPUT,3(L)                 B''       L7. Complete the sublist. L_s ← p.
34            ENT3  0,4                        B''       s ← t.
35            ENT4  0,1                        D''       t ← p.
36            LD1   INPUT,1(L)                 D''       p ← L_p.
37            J1P   *-2                        D''       Repeat if p > 0.
38    L8      ENN1  0,1                        B         L8. End of pass? p ← -p.
39            ENN2  0,2                        B         q ← -q.
40            J2NZ  L3Q                        B         To L3 if q ≠ 0.
41            ST1   INPUT,3(ABSL)              A         |L_s| ← p.
42            STZ   INPUT,4(ABSL)              A         |L_t| ← 0.
```

```
43    L2    ENT3  0                 A+1    L2. Begin new pass.  s ← 0.
44          ENT4  N+1               A+1    t ← N+1.
45          LD1   INPUT(L)          A+1    p ← L_s.
46          LD2   INPUT+N+1(L)      A+1    q ← L_t.
47          J2NZ  L3Q               A+1    To L3 if q ≠ 0. ∎
```

The running time of this program can be deduced using techniques we have seen many times before (see exercises 13, 14); it comes to approximately $(10N \log_2 N + 4.92N)u$ on the average, with a small standard deviation of order $\sqrt{N}$. Exercise 15 shows that the running time can be reduced to about $9N \log_2 N$ at the expense of a somewhat longer program.

Thus we have a clear victory for linked-memory techniques over sequential allocation, when internal merging is being done: Less memory space is required, and the program runs about 10 to 20 percent faster. Similar algorithms have been published by L. J. Woodrum [*IBM Systems J.* **8** (1969), 189–203] and A. D. Woodall [*Comp. J.* **13** (1970), 110–111].

EXERCISES

1. [*20*] Generalize Algorithm M to a *k-way merge* of the input files $x_{i1} \le \cdots \le x_{im_i}$ for $i = 1, 2, \ldots, k$.

2. [*M24*] Assuming that each of the $\binom{m+n}{m}$ possible arrangement of m x's among n y's is equally likely, find the mean and standard deviation of the number of times step M2 is performed during Algorithm M. What are the maximum and minimum values of this quantity?

▸ **3.** [*20*] (*Updating.*) Given records $R_1, \ldots, R_M$ and $R'_1, \ldots, R'_N$ whose keys are distinct and in order, so that $K_1 < \cdots < K_M$ and $K'_1 < \cdots < K'_N$, show how to modify Algorithm M to obtain a merged file in which records R_i of the first file have been *discarded* if their key appears also in the second file.

4. [*21*] The text observes that merge sorting may be regarded as a generalization of insertion sorting. Show that merge sorting is also strongly related to tree selection sorting as depicted in Fig. 23.

▸ **5.** [*21*] Prove that i can never be equal to j in steps N6 or N10. (Therefore it is unnecessary to test for a possible jump to N13 in those steps.)

6. [*22*] Find a permutation $K_1 K_2 \ldots K_{16}$ of $\{1, 2, \ldots, 16\}$ such that

$$K_2 > K_3, \quad K_4 > K_5, \quad K_6 > K_7, \quad K_8 > K_9,$$
$$K_{10} < K_{11}, \quad K_{12} < K_{13}, \quad K_{14} < K_{15},$$

yet Algorithm N will sort the file in only two passes. (Since there are eight or more runs, we would expect to have at least four runs after the first pass, two runs after the second pass, and sorting would ordinarily not be complete until after at least three passes. How can we get by with only two passes?)

7. [*16*] Give a formula for the exact number of passes required by Algorithm S, as a function of N.

8. [*22*] During Algorithm S, the variables q and r are supposed to represent the lengths of the unmerged elements in the runs currently being processed; q and r both start out equal to p, while the runs are not always this long. How can this possibly work?

9. [*24*] Write a MIX program for Algorithm S. Specify the instruction frequencies in terms of quantities analogous to A, B', B'', C', ... in Program L.

10. [*25*] (D. A. Bell.) Show that sequentially-allocated straight two-way merging can be done with at most $\frac{3}{2}N$ memory locations, instead of $2N$ as in Algorithm S.

11. [*21*] Is Algorithm L a "stable" sorting method?

▸**12.** [*22*] Revise step L1 of Algorithm L so that the two-way merge is "natural," taking advantage of ascending runs which are initially present. (In particular, if the input is already sorted, step L2 should terminate the algorithm immediately after your step L1 has acted.)

▸**13.** [*M34*] Give an analysis of the average running time of Program L, in the style of other analyses in this chapter: Interpret the quantities A, B, B', ..., and explain how to compute their exact average values. How long does Program L take to sort the 16 numbers in Table 3?

14. [*M24*] Let the binary representation of N be $2^{e_1} + 2^{e_2} + \cdots + 2^{e_t}$, where $e_1 > e_2 > \cdots > e_t \geq 0$, $t \geq 1$. Prove that the maximum number of key comparisons performed by Algorithm L is $1 - 2^{e_t} + \sum_{1 \leq k \leq t} (e_k + k - 1)2^{e_k}$.

15. [*20*] Hand simulation of Algorithm L reveals that it occasionally does redundant operations; the assignments $|L_s| \leftarrow p$, $|L_s| \leftarrow q$ in steps L4 and L6 are unnecessary about half of the time, since we have $L_s = p$ (or q) each time step L4 (or L6) returns to L3. How can Program L be improved so that this redundancy disappears?

16. [*28*] Design a list merging algorithm like Algorithm L but based on three-way merging.

17. [*20*] (J. McCarthy.) Let the binary representation of N be as in exercise 14, and assume that we are given N records arranged in t ordered subfiles of respective sizes $2^{e_1}, 2^{e_2}, \ldots, 2^{e_t}$. Show how to maintain this state of affairs when a new $(N+1)$st record is added and $N \leftarrow N + 1$. (The resulting algorithm may be called an "on-line" merge sort.)

18. [*40*] (M. A. Kronrod.) Given a file on N records containing only two runs,

$$K_1 \leq \cdots \leq K_M \quad \text{and} \quad K_{M+1} \leq \cdots \leq K_N,$$

is it possible to sort the file in $O(N)$ operations in a random-access memory, *using only a small fixed amount of additional memory space* regardless of the size of M and N? (All of the merging algorithms described in this section make use of extra memory space proportional to N.)

19. [*26*] Consider a railway switching network with n "stacks", as shown in Fig. 31 when $n = 5$; such a network has some aspects relevant to n-pass sorting algorithms. We considered one-stack networks in exercises 2.2.1–2 through 2.2.1–5. If N railroad cars enter at the right, we observed that only comparatively few of the $N!$ permutations of those cars could appear at the left, in the one-stack case.

In the n-stack network, assume that 2^n cars enter at the right. Prove that each of the $2^n!$ possible permutations of these cars *is* achievable at the left, by a suitable

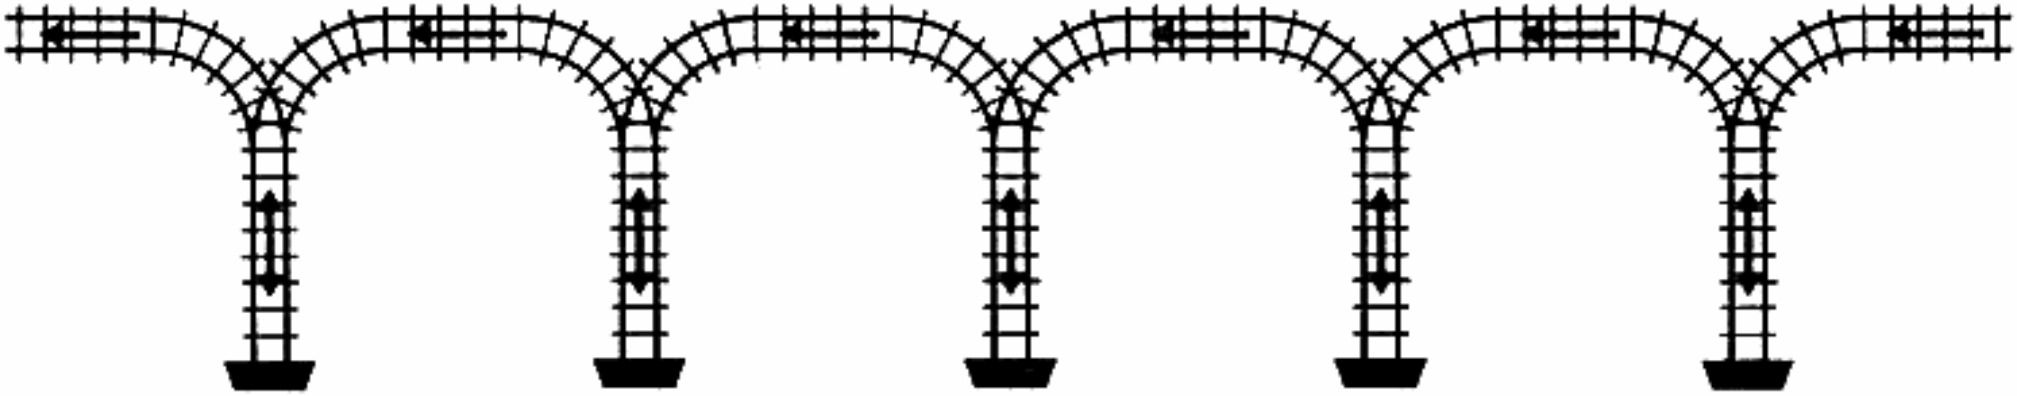

Fig. 31. A railway network with five "stacks."

sequence of operations. (Each stack is big enough to accommodate all the cars, if necessary.)

20. [*47*] In the notation of exercise 2.2.1–4, at most a_N^n permutations of N elements can be produced with an n-stack railway network; hence the number of stacks needed to obtain all $N!$ permutations is at least $\log N!/\log a_N \approx \log_4 N$. Exercise 19 shows that at most $\lceil \log_2 N \rceil$ stacks are needed. What is the true rate of growth of the necessary number of stacks, as $N \to \infty$?

21. [*23*] (A. J. Smith.) Explain how to extend Algorithm L so that, in addition to sorting, it computes the number of *inversions* present in the input permutation.

5.2.5. Sorting by Distribution

We come now to an interesting class of sorting methods, which is shown in Section 5.4.7 to be essentially the exact *opposite* of merging. Readers who are familiar with punched card equipment are well aware of the efficient procedure used on card sorters, based on the digits of the keys; the same idea can be adapted to computer programming, and it is generally known as "radix sorting," "digital sorting," or "pocket sorting."

Suppose we want to sort a 52-card deck of playing cards. We may define

$$\texttt{A} < \texttt{2} < \texttt{3} < \texttt{4} < \texttt{5} < \texttt{6} < \texttt{7} < \texttt{8} < \texttt{9} < \texttt{10} < \texttt{J} < \texttt{Q} < \texttt{K},$$

as an ordering of the face values, and for the suits we may define

$$\clubsuit < \diamondsuit < \heartsuit < \spadesuit$$

One card is to precede another if either (i) its suit is less than the other suit, or (ii) the suits are equal but its face value is less. (This is a particular case of a *lexicographic ordering* between ordered pairs of objects; cf. exercise 5–2). Thus

$$\texttt{A}\clubsuit < \texttt{2}\clubsuit < \cdots < \texttt{K}\clubsuit < \texttt{A}\diamondsuit < \cdots < \texttt{Q}\spadesuit < \texttt{K}\spadesuit.$$

We could sort the cards by any of the methods already discussed; people generally use a technique somewhat analogous to the idea behind radix exchange. It is natural to sort the cards first by their suits into four piles, then to fiddle with each of the individual piles until they are in order.

But there is a faster way to do the trick! First deal the cards face up into 13 piles, one for each face value. Then collect these piles by putting the aces

on the bottom, the 2's face up on top of them, then the 3's, etc., finally putting the kings (face up) on top. Turn the deck face down and deal again, this time into four piles for the four suits. By putting the resulting piles together, with clubs on the bottom, then diamonds, hearts, and spades, the deck will be in perfect order.

The same idea applies to the sorting of numbers and alphabetic data. Why does it work? Because (in our playing card example) if two cards go into different piles in the final deal, they have different suits, so the one with the lower suit is lowest. But if two cards have the same suit (and consequently go into the same pile), they are already in proper order because of the previous sorting. In other words, the face values will be in increasing order on each of the four piles as we deal the cards on the second pass. The same proof can be abstracted to show that any lexicographic ordering can be sorted in this manner; for details, see the answer to exercise 5–2, at the beginning of this chapter.

The sorting method just described is not immediately obvious, and it isn't clear who first discovered the fact that it works so conveniently. A 19-page pamphlet entitled "The Inventory Simplified," published by the Tabulating Machines Company division of IBM in 1923, presents an interesting Digit Plan method for forming sums of products on their Electric Sorting Machine: Suppose, for example, that we want to multiply the number punched in columns 1–10 by the number punched in columns 23–25, and to sum all of these products for a large number of cards. We can sort first on column 25, then use the Tabulating Machine to find the quantities $a_1, a_2, \ldots, a_9$, where a_k is the total of columns 1–10 summed over all cards having k in column 25. Then we can sort on column 24, finding the analogous totals $b_1, b_2, \ldots, b_9$; also on column 23, obtaining $c_1, c_2, \ldots, c_9$. The desired sum of products is easily seen to be

$$a_1 + 2a_2 + \cdots + 9a_9 + 10b_1 + 20b_2 + \cdots + 90b_9 + 100c_1 + 200c_2 + \cdots + 900c_9.$$

This punched-card tabulating method leads naturally to the discovery of least-significant-digit-first radix sorting, so it probably became known to the operators of the machines. The first published reference to this principle for sorting appears in L. J. Comrie's early discussion of punched-card equipment [*Transactions of the Office Machinery Users' Assoc., Ltd.* (1929), 25–37, esp. p. 28].

In order to handle radix sorting inside a computer, we must decide what to do with the piles. Suppose that there are M piles; we could set aside M areas of memory, moving each record from an input area into its appropriate pile area. But this is unsatisfactory, since each area must be large enough to hold N items, and $(M + 1)N$ record spaces would be required. Such an excessive memory requirement originally caused most people to reject the idea of radix sorting within a computer, until H. H. Seward [Master's thesis, M.I.T. Digital Computer Laboratory Report R-232 (Cambridge, Mass.: 1954), 25–28] pointed out that we can achieve the same effect with only $2N$ record areas and M count

fields. We simply count how many elements will lie in each of the M piles, by making a preliminary pass over the data; this tells us precisely how to allocate memory for the piles. We have already made use of the same idea in the "distribution sort," Algorithm 5.2D.

Thus radix sorting can be carried out as follows: Start with a distribution sort based on the *least significant digit* of the keys (in radix M notation), moving records from the input area to an auxiliary area. Then do another distribution sort, on the next least significant digit, moving the records back into the original input area; and so on, until the final pass (on the most significant digit) puts all records into the desired order.

If we have a decimal computer with 12-digit keys, and if N is rather large, we can choose $M = 1000$ (considering three decimal digits as one radix-1000 digit); sorting will be complete in four passes, regardless of the size of N. Similarly, if we have a binary computer and a 40-bit key, we can set $M = 1024$ and complete the sorting in four passes. Actually each "pass" consists of three parts (counting, allocating, moving); Friend [*JACM* **3** (1956), 151] has suggested combining two of these parts at the expense of M more memory locations, by accumulating the counts for pass $k + 1$ while moving the records in pass k.

Table 1 shows how such a radix sort can be applied to our 16 example numbers, with $M = 10$. Radix sorting is generally not useful for such small N, so a small example like this is intended to illustrate the sufficiency rather than the efficiency of the method.

Table 1

RADIX SORTING

Input area contents:	503	087	512	061	908	170	897	275	653	426	154	509	612	677	765	703
Counts for units digit distribution:					1	1	2	3	1	2	1	3	1	1		
Storage allocations based on these counts:					1	2	4	7	8	10	11	14	15	16		
Auxiliary area contents:	170	061	512	612	503	653	703	154	275	765	426	087	897	677	908	509
Counts for tens digit distribution:					4	2	1	0	0	2	2	3	1	1		
Storage allocations based on these counts:					4	6	7	7	7	9	11	14	15	16		
Input area contents:	503	703	908	509	512	612	426	653	154	061	765	170	275	677	087	897
Counts for hundreds digit distribution:					2	2	1	0	1	3	3	2	1	1		
Storage allocations based on these counts:					2	4	5	5	6	9	12	14	15	16		
Auxiliary area contents:	061	087	154	170	275	426	503	509	512	612	653	677	703	765	897	908

An alert, "modern" reader will note, however, that the whole idea of making digit counts for the storage allocation is tied to "old-fashioned" ideas about sequential data representation; we know that *linked* allocation is specifically

designed to handle multiple tables of variable size, so it is natural to choose a linked data structure for radix sorting. Since we traverse each pile serially, all that is necessary is a single link from each item to its successor. Furthermore, we never need to move the records, we merely adjust the links and proceed merrily down the lists. The amount of memory required is $(1 + \epsilon)N + 2\epsilon M$ records, where ϵ is the amount of space taken up by a link field. Formal details of this procedure are rather interesting since they furnish an excellent example of typical data structure manipulations, combining sequential and linked allocation:

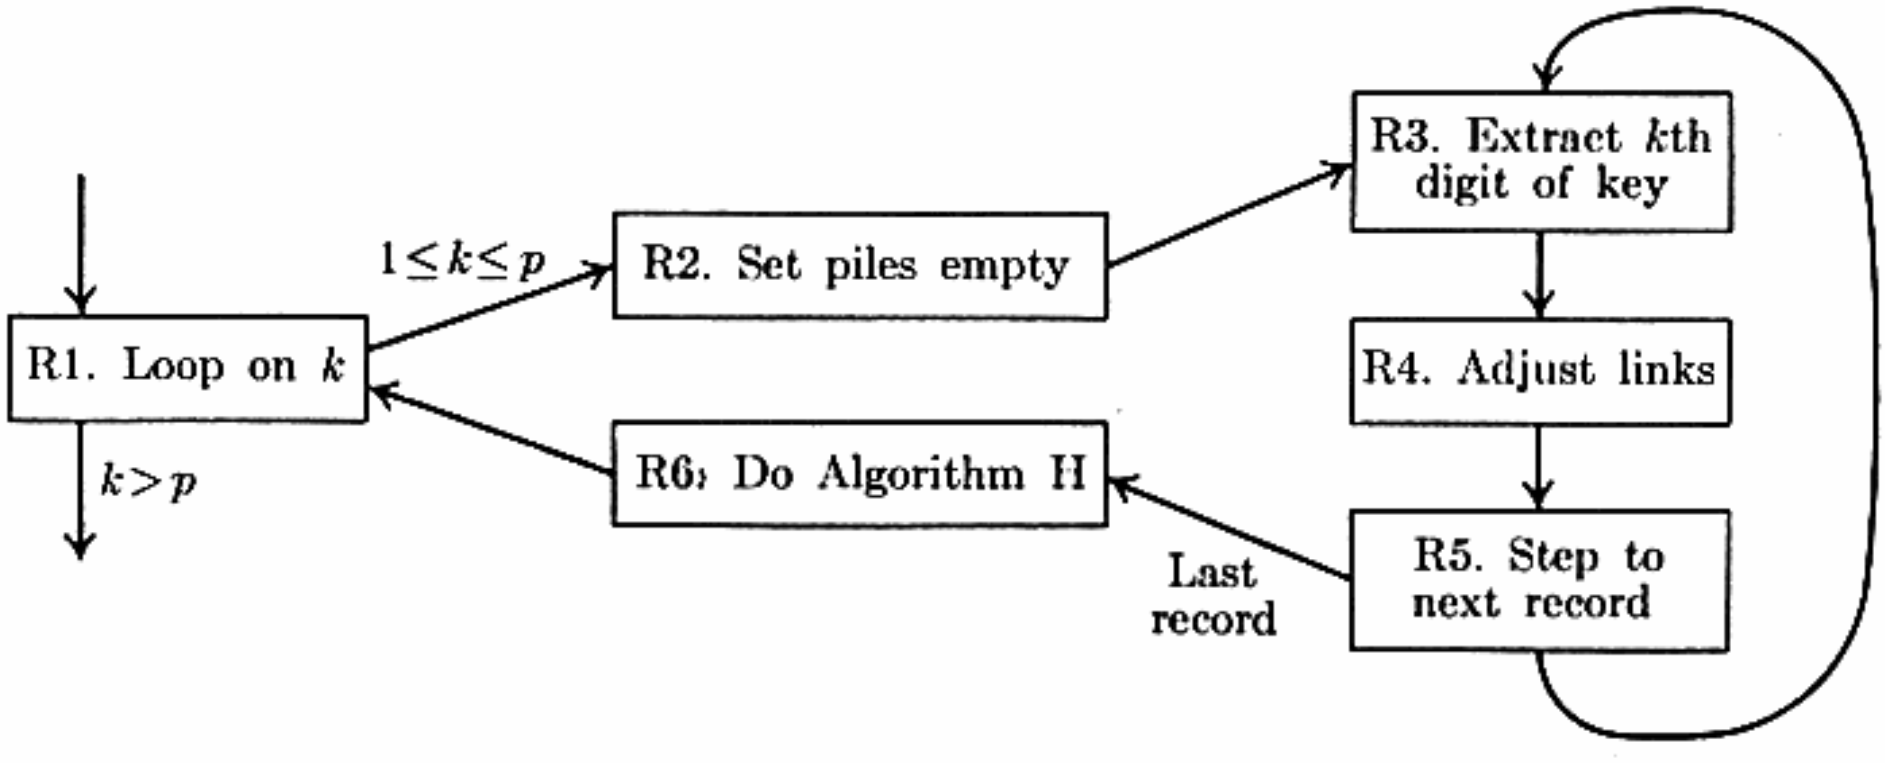

Fig. 32. Radix list sort.

Algorithm R (*Radix list sort*). Records $R_1, \ldots, R_N$ are each assumed to contain a LINK field. Their keys are assumed to be p-tuples

$$(a_p, \ldots, a_2, a_1), \qquad 0 \le a_i < M,$$

where the order is defined lexicographically so that

$$(a_p, \ldots, a_2, a_1) < (b_p, \ldots, b_2, b_1)$$

if and only if for some j, $1 \le j \le p$, we have

$$a_i = b_i \quad \text{for all} \quad i > j, \quad \text{but} \quad a_j < b_j.$$

The keys may, in particular, be thought of as numbers written in radix M notation,

$$a_p M^{p-1} + \cdots + a_2 M + a_1,$$

and in this case lexicographic order corresponds to the normal ordering of nonnegative numbers. The keys may also be strings of alphabetic letters, etc.

Sorting is done by keeping M "piles" of records, in a manner that exactly parallels the action of a card sorting machine. The piles are really queues in the sense of Chapter 2, since we link them together so that they are traversed

in a first-in-first-out manner. There are two pointer variables TOP[i] and BOTM[i] for each pile, $0 \le i < M$, and we assume as in Chapter 2 that

$$\texttt{LINK(LOC(BOTM([}i\texttt{]))))} \equiv \texttt{BOTM[}i\texttt{]}.$$

R1. [Loop on k.] In the beginning, set P $\leftarrow$ LOC(R_N), a pointer to the last record. Then perform steps R2 through R6 for $k = 1, 2, \ldots, p$. (Steps R2 through R6 constitute one "pass.") Then the algorithm terminates, with P pointing to the record with smallest key, LINK(P) to the record with next smallest, then LINK(LINK(P)), etc.; the LINK in the final record will be Λ.

R2. [Set piles empty.] Set TOP[i] $\leftarrow$ LOC(BOTM[i]) and BOTM[i] $\leftarrow \Lambda$, for $0 \le i < M$.

R3. [Extract kth digit of key.] Let KEY(P), the key in the record referenced by P, be $(a_p, \ldots, a_2, a_1)$; set $i \leftarrow a_k$, the kth least significant digit of this key.

R4. [Adjust links.] Set LINK(TOP[i]) $\leftarrow$ P, then set TOP[i] $\leftarrow$ P.

R5. [Step to next record.] If $k = 1$ (the first pass) and if P = LOC(R_j), for some $j \neq 1$, set P $\leftarrow$ LOC(R_{j-1}) and return to R3. If $k > 1$ (subsequent passes), set P $\leftarrow$ LINK(P), and return to R3 if P $\neq \Lambda$.

R6. [Do Algorithm H.] (We are now done distributing all elements onto the piles.) Perform Algorithm H below, which "hooks together" the individual piles into one list, in preparation for the next pass. Then set P $\leftarrow$ BOTM[0], a pointer to the first element of the hooked-up list. (See exercise 3.) ∎

Algorithm H (*Hooking-up of queues*). Given M queues, linked according to the conventions of Algorithm R, this algorithm adjusts at most M links so that a single queue is created, with BOTM[0] pointing to the first element, and with pile 0 preceding pile 1 $\cdots$ preceding pile $(M - 1)$.

H1. [Initialize.] Set $i \leftarrow 0$.

H2. [Point to top of pile.] Set P $\leftarrow$ TOP[i].

H3. [Next pile.] Increase i by 1. If $i = M$, set LINK(P) $\leftarrow \Lambda$ and terminate the algorithm.

H4. [Is pile empty?] If BOTM[i] $= \Lambda$, go back to H3.

H5. [Tie piles together.] Set LINK(P) $\leftarrow$ BOTM[i]. Return to H2. ∎

Figure 33 shows the contents of the piles after each of the three passes, when our 16 example numbers are sorted with $M = 10$. Algorithm R is very easy to program for MIX, once a suitable way to treat the pass-by-pass variation of steps R3 and R5 has been found. The following program does this without sacrificing any speed in the inner loop, by overlaying two of the instructions. Note that TOP[i] and BOTM[i] can be packed into the same word.

Program R (*Radix list sort*). The input in locations INPUT+1 through INPUT+N is assumed to have $p = 3$ components (a_3, a_2, a_1), stored respectively in the (1:1), (2:2), and (3:3) fields. (Thus M is assumed to be less than or equal to

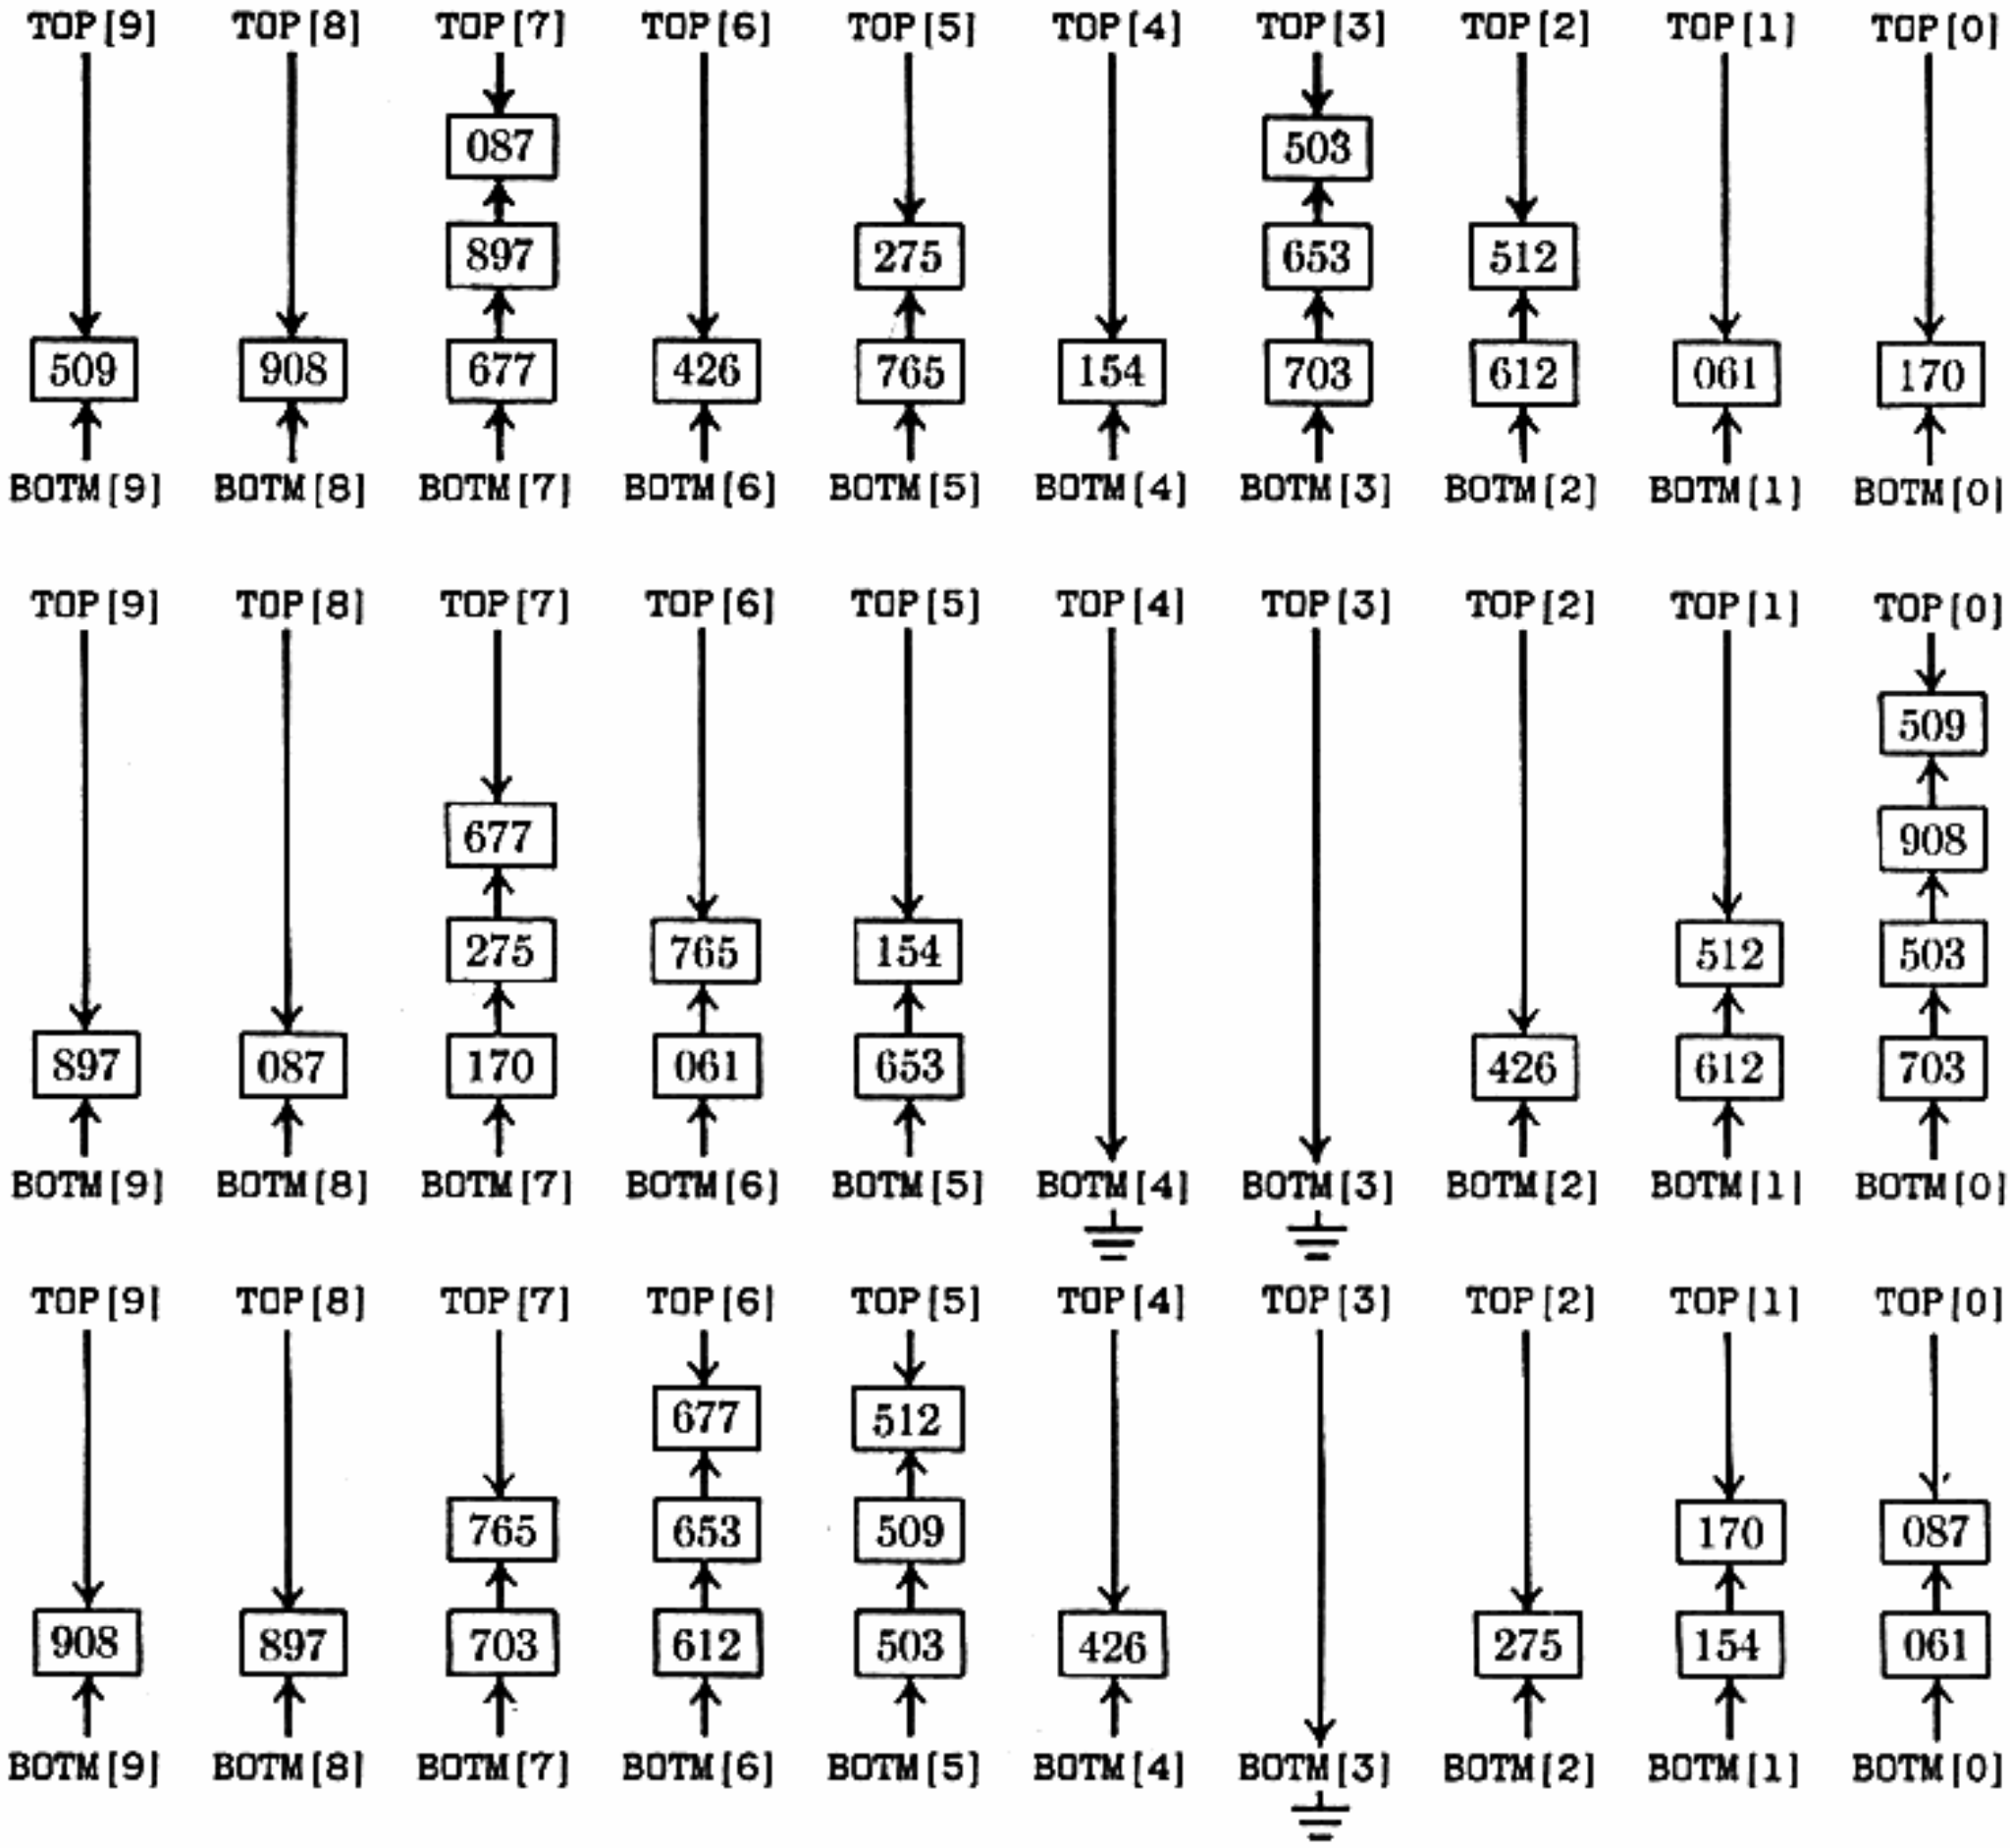

Fig. 33. Radix sort using linked allocation: contents of the ten piles after each pass.

the byte size of MIX.) The (4:5) field of each record is its LINK. We let TOP[i] ≡ PILES+i(1:2) and BOTM[i] ≡ PILES+i(4:5), for $0 \le i < M$. It is convenient to make links relative to location INPUT, so that LOC(BOTM[i]) = PILES + i − INPUT; to avoid negative links we therefore want the PILES table to be in higher locations than the INPUT table. Index registers are assigned as follows: rI1 ≡ P, rI2 ≡ i, rI3 ≡ 3 − k, rI4 ≡ TOP[i]; during Algorithm H, rI2 ≡ $i - M$.

```
01    LINK   EQU   4:5
02    TOP    EQU   1:2
03    START  ENT1  N                1     R1. Loop on k.  P ← LOC(R_N).
04           ENT3  2                1     k ← 1.
05    2H     ENT2  M-1              3     R2. Set piles empty.
06           ENTA  PILES-INPUT,2    3M    LOC(BOTM[i])
07           STA   PILES,2(TOP)     3M        → TOP[i]
08           STZ   PILES,2(LINK)    3M    BOTM[i] ← Λ.
09           DEC2  1                3M
10           J2NN  *-4              3M    M > i ≥ 0.
```

```

```

The running time of Program R is $32N + 48M + 38 - 4E$, where N is the number of input records, M is the radix (the number of piles), and E is the number of occurrences of empty piles. This compares very favorably with other programs we have constructed based on similar assumptions (Programs 5.2.1M, 5.2.4L). A p-pass version of the program would take $(11p - 1)N + O(pM)$ units of time; the critical factor in the timing is the inner loop, which involves five references to memory and one branch. On a typical computer we will have $M = b$ and $p = \lceil t/r \rceil$, where t is the number of radix-b digits in the keys; increasing r will decrease p, so the formulas can be used to determine a "best" value of r.

The only variable in the timing is E, the number of empty piles observed in step H4. If we consider each of the M^N sequences of radix-M digits to be equally probable, we know from our study of the "poker test" in Section 3.3.2D that there are $M - r$ empty piles with probability

$$\frac{M(M-1)\cdots(M-r+1)}{M^N}\left\{{N \atop r}\right\}$$

on each pass, where $\{{N \atop r}\}$ is a Stirling number of the second kind. By exercise 5,

$$E = \left(\min\ \max(M-N,0)p, \qquad \text{ave}\ M\left(1-\frac{1}{M}\right)^N p, \qquad \max\,(M-1)p\right).$$

An ever-increasing number of "pipeline" or "number crunching" computers have appeared in recent years. These machines have multiple arithmetic units

and "look-ahead" circuitry so that memory references and computation can be highly overlapped; but their efficiency deteriorates noticeably in the presence of conditional branch instructions unless the branch almost always goes the same way. The inner loop of a radix sort is well adapted to such machines, because it is a straight iterative calculation of typical "number crunching" form. Therefore *radix sorting is usually more efficient than any other known method for internal sorting on such machines*, provided that N is not too small and the keys are not too long.

Of course, radix sorting is not very efficient when the keys are extremely long. For example, imagine sorting cards on an 80-column key; very few pairs of cards will tend to have identical keys in their first five columns, so the first 75 passes accomplish very little. In our analysis of radix-exchange sorting, we found that it was unnecessary to inspect many bits of the key, when we approach the keys from the left instead of the right. Let us therefore reconsider the idea of a radix sort which starts at the most significant digit (MSD) instead of the least significant digit (LSD).

We have already remarked that an MSD-first radix method suggests itself naturally; in fact, it is not hard to see why the post office uses such a method to sort mail. A large collection of letters can be sorted into separate bags for different geographical areas; each of these bags then contains a smaller number of letters which can be sorted independently of the other bags, into finer and finer geographical divisions. (Indeed, they can be transported nearer to their destinations before they are sorted further.) This principle of "divide and conquer" is quite appealing, and the only reason it doesn't work especially well for sorting punched cards is that the multiplicity of piles tends to become confusing. The same phenomenon accounts for the relative efficiency of Algorithm R, even though it considers LSD first, since we never have more than M piles, and they need to be hooked together only p times. On the other hand, it would not be difficult to design an MSD-first radix method using linked memory, with negative links as in Algorithm 5.2.4L to denote the boundaries between piles. (See exercise 10.)

Perhaps the best compromise has been suggested by M. D. MacLaren [*JACM* **13** (1966), 404–411], who recommends an LSD-first sort as in Algorithm R, but *applied only to the most significant digits*. This does not completely sort the file, but it usually brings the file very nearly into order so that very few inversions remain; therefore straight insertion can be used to finish up. Our analysis of Algorithm 5.2.1M applies also to this situation, so that if the keys are uniformly distributed we will have an average of

$$\tfrac{1}{4}N(N-1)M^{-p}$$

inversions remaining in the file after sorting on the leading p digits. (See Eq. 5.2.1–14 and exercise 5.2.1–38.) MacLaren has computed the average number of memory references per item sorted, and the optimum choice of M and p (assuming that M is a power of 2, that the keys are uniformly distributed,

and that $N/M^p \leq 0.1$ so that deviations from uniformity are tolerable) turns out to be given by the following table:

$N =$	100	1000	5000	10000	50000	100000
best $M =$	32	128	256	512	1024	1024
best $p =$	2	2	2	2	2	2
$\tilde{\beta}(N) =$	19.3	18.5	18.2	18.2	18.1	18.0

Here $\tilde{\beta}(N)$ denotes the average number of memory references per item sorted; it is bounded as $N \to \infty$, if we take $p = 2$ and $M > \sqrt{N}$, so the average sorting time is actually $O(N)$ instead of order $N \log N$. This method is an improvement over multiple list insertion (Algorithm 5.2.1M) which is essentially the case $p = 1$. Exercise 12 gives MacLaren's interesting procedure for final rearrangement of a partially list-sorted file.

It is also possible to avoid the link fields, using the methods of Algorithm 5.2D and exercise 5.2–13, so that only $O(\sqrt{N})$ memory locations are needed in addition to the space required for the records themselves. The average sorting time is proportional to N if the input records are uniformly distributed.

EXERCISES

▶ **1.** [*20*] The algorithm of exercise 5.2–13 shows how to do a distribution sort with only N record areas (and M count fields), instead of $2N$ record areas. Does this lead to an improvement over the radix sorting algorithm illustrated in Table 1?

2. [*13*] Is Algorithm R a "stable" sorting method?

3. [*15*] Explain why Algorithm H makes `BOTM[0]` point to the first record in the "hooked-up" queue, *even though pile* 0 *might be empty*.

▶ **4.** [*23*] Algorithm R keeps the M piles linked together as queues (first-in-first-out). Explore the idea of linking the piles as *stacks* instead. (The arrows in Fig. 33 would go downward instead of upward, and the `BOTM` table would be unnecessary.) Show that if the piles are "hooked together" in an appropriate order, it is possible to achieve a valid sorting method. Does this lead to a simpler or a faster algorithm?

5. [*M24*] Let $g_{MN}(z) = \sum p_{MNk} z^k$, where p_{MNk} is the probability that exactly k empty piles are present after a random radix-sort pass puts N elements into M piles. (a) Show that $g_{M,N+1}(z) = g_{MN}(z) + ((1 - z)/M) g'_{MN}(z)$. (b) Use this relation to find simple expressions for the mean and variance of this probability distribution, as a function of M and N.

6. [*20*] What changes are necessary to Program R so that it sorts eight-byte keys instead of three-byte keys? Assume that the most significant bytes of K_i are stored in location `KEY+`i`(1:5)`, while the three least significant bytes are in location `INPUT+`i`(1:3)` as presently. What is the running time of the program, after these changes have been made?

7. [*20*] Discuss the similarities and differences between Algorithm R and radix-exchange sorting (Algorithm 5.2.2R).

▸ **8.** [*20*] The radix-sorting algorithms discussed in the text assume that all keys being sorted are nonnegative. What changes should be made to the algorithms when the keys are numbers expressed in *two's complement* or *ones' complement* notation?

9. [*20*] Continuing exercise 8, what changes should be made to the algorithms when the keys are numbers expressed in *signed-magnitude* notation?

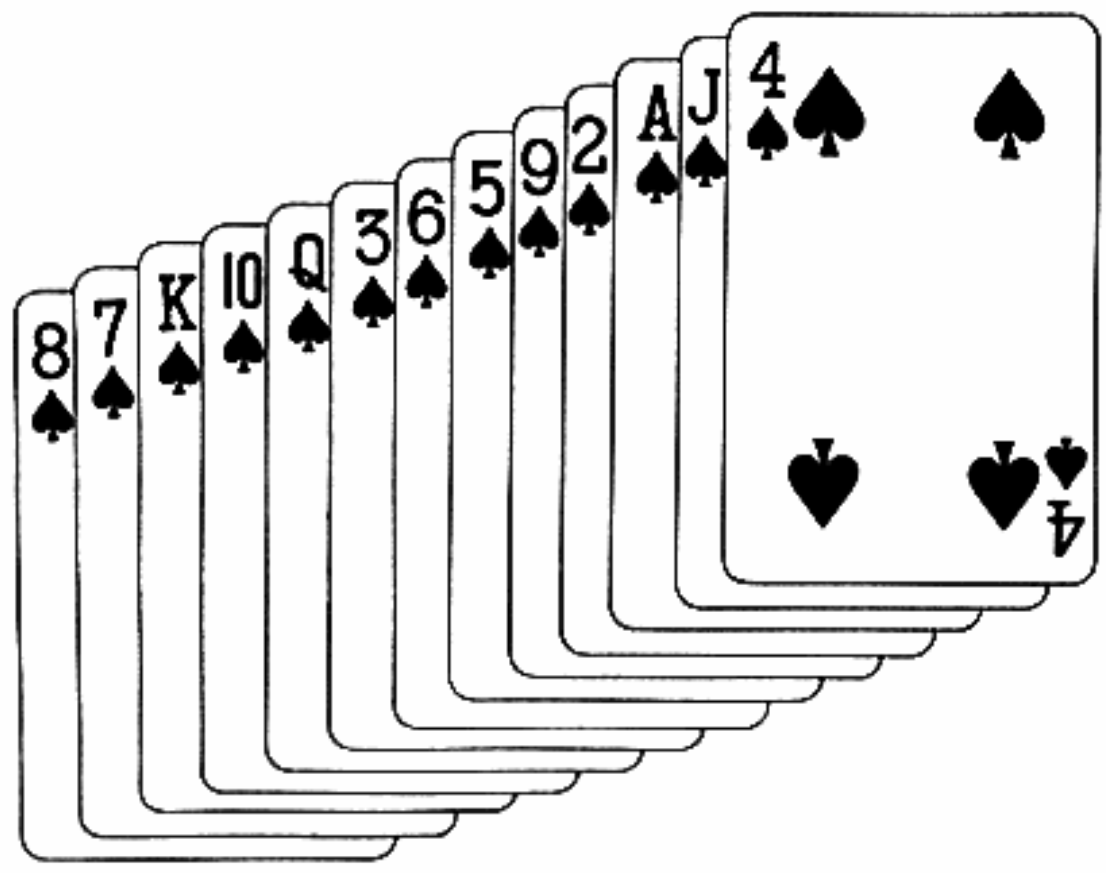
10. [*30*] Design an efficient most-significant-digit-first radix-sorting algorithm which uses linked memory. (As the size of the subfiles decreases, it is wise to decrease M, and to use a nonradix method on the really short subfiles.)

11. [*16*] The sixteen input numbers shown in Table 1 start with 41 inversions; after sorting is complete, of course, there are no inversions remaining. How many inversions would be present in the file if we omitted pass 1, doing a radix sort only on the tens and hundreds digits? How many inversions would be present if we omitted both pass 1 and pass 2?

12. [*24*] (M. D. MacLaren.) Suppose that Algorithm R has been applied only to the p leading digits of the actual keys; thus the file is nearly sorted when we read it in the order of the links, but keys which agree in their first p digits may be out of order. Design an algorithm which rearranges the records in place so that their keys are in order, $K_1 \leq K_2 \leq \ldots \leq K_N$. [*Hint:* The special case that the file is perfectly sorted appears in the answer to exercise 5.2–12; it is possible to combine this with straight insertion without loss of efficiency, since few inversions remain in the file.]

13. [*40*] Implement the internal sorting method suggested in the text at the close of this section, producing a subroutine which sorts random data in $O(N)$ units of time with only $O(\sqrt{N})$ additional memory locations.

14. [*22*] The sequence of playing cards



can be sorted into increasing order A 2 . . . J Q K from top to bottom in two passes, using just two piles for intermediate storage: Deal the cards face down into two piles containing respectively A 2 9 3 10 and 4 J 5 6 Q K 7 8 (from bottom to top); then put the second pile on the first, turn the deck face up, and deal into two piles A 2 3 4 5 6 7 8, 9 10 J Q K. Combine these piles, turn them face up, and you're done.

Prove that the above sequence of cards cannot be sorted into *decreasing* order K Q J . . . 2 A from top to bottom in two passes, even if you are allowed to use up to three piles for intermediate storage. (Dealing must always be from the top of the deck, turning the cards face down as they are dealt. Top to bottom is right to left in the illustration.)

15. [*M25*] Consider the problem of exercise 14 when all cards must be dealt face up instead of face down. Thus, one pass can be used to convert increasing order into decreasing order. How many passes are required?

As soon as an Analytical Engine exists,
it will necessarily guide the future course of the science.
Whenever any result is sought by its aid,
the question will then arise—
By what course of calculation can these
results be arrived at by the machine
in the shortest time?

—CHARLES BABBAGE (1864)

5.3. OPTIMUM SORTING

Now that we have analyzed a great many methods for internal sorting, it is time to turn to a broader question: *What is the best possible way to sort?* Can we place limits on the maximum sorting speeds that will ever be achievable, no matter how clever a programmer might be?

Of course there *is* no best possible way to sort; we must define precisely what is meant by "best," and there is no best possible way to define "best." We have discussed similar questions about the theoretical optimality of algorithms in Sections 4.3.3, 4.6.3, and 4.6.4, where high-precision multiplication and polynomial evaluation were considered. In each case it was necessary to formulate a rather simple definition of a "best possible" algorithm, in order to give sufficient structure to the problem to make it workable. And in each case we ran into interesting problems that are so difficult they still haven't been completely resolved. The same situation holds for sorting; some very interesting discoveries have been made, but there are many fascinating questions still unanswered.

Studies of the inherent complexity of sorting have usually been directed towards minimizing the number of times we make comparisons between keys while sorting n items, or merging m items with n, or selecting the tth largest of an unordered set of n items. Sections 5.3.1, 5.3.2, and 5.3.3 discuss these questions in general, and Section 5.3.4 deals with similar issues under the interesting restriction that the pattern of comparisons must essentially be fixed in advance. Some other types of interesting theoretical questions related to optimum sorting appear in the exercises for Section 5.3.4, and in the discussion of external sorting in Section 5.4.4.

5.3.1. Minimum-Comparison Sorting

The minimum number of key comparisons needed to sort n elements is obviously *zero*, because we have seen radix methods that do no comparisons at all. In fact, it is possible to write MIX programs that are able to sort, although they contain no conditional jump instructions at all! (See exercise 5–6 at the beginning of this chapter.) We have also seen several sorting methods which are based essentially on comparisons of keys, yet their running time in practice is dominated by other considerations such as data movement, housekeeping operations, etc.

Therefore it is clear that comparison counting is not the only way to measure the effectiveness of a sorting method. But it is fun to scrutinize the number of comparisons anyway, since a theoretical study of this subject gives us a good deal of useful insight into the nature of sorting processes, and it also helps us to sharpen our wits for the more mundane problems that may confront us at other times.

In order to rule out radix-sorting methods, which do no comparisons at all, we shall restrict our discussion to sorting techniques which are based solely on

an abstract linear ordering relation "$<$" between keys, as discussed at the beginning of this chapter. For simplicity, we shall also confine our discussion to the case of *distinct* keys, so that there are only two possible outcomes of any comparison of K_i vs. K_j: either $K_i < K_j$ or $K_i > K_j$. (For an extension of the theory to the general case where equal keys are allowed, see exercises 3 through 12.)

The problem of sorting by comparisons can also be expressed in other equivalent ways. Given a set of n distinct weights and a balance scale, we can ask for the least number of weighings necessary to completely rank the weights in order of magnitude, when the pans of the balance scale can each accommodate only one weight. Alternatively, given a set of n players in a tournament, we can ask for the smallest number of games which suffice to rank all contestants, assuming that the strengths of the players can be linearly ordered (with no ties).

All n-element sorting methods which satisfy the above constraints can be represented in terms of an extended binary tree structure such as that shown in Fig. 34. Each *internal node* (drawn as a circle) contains two indices "$i:j$" denoting a comparison of K_i versus K_j. The left subtree of this node represents the subsequent comparisons to be made if $K_i < K_j$, and the right subtree represents the actions to be taken when $K_i > K_j$. Each *external node* of the tree (drawn as a box) contains a permutation $a_1\, a_2 \ldots a_n$ of $\{1, 2, \ldots, n\}$, denoting the fact that the ordering

$$K_{a_1} < K_{a_2} < \cdots < K_{a_n}$$

has been established. (If we look at the path from the root to this external node, each of the $n - 1$ relationships $K_{a_i} < K_{a_{i+1}}$ for $1 \leq i < n$ will be the result of some comparison $a_i:a_{i+1}$ or $a_{i+1}:a_i$ on this path.)

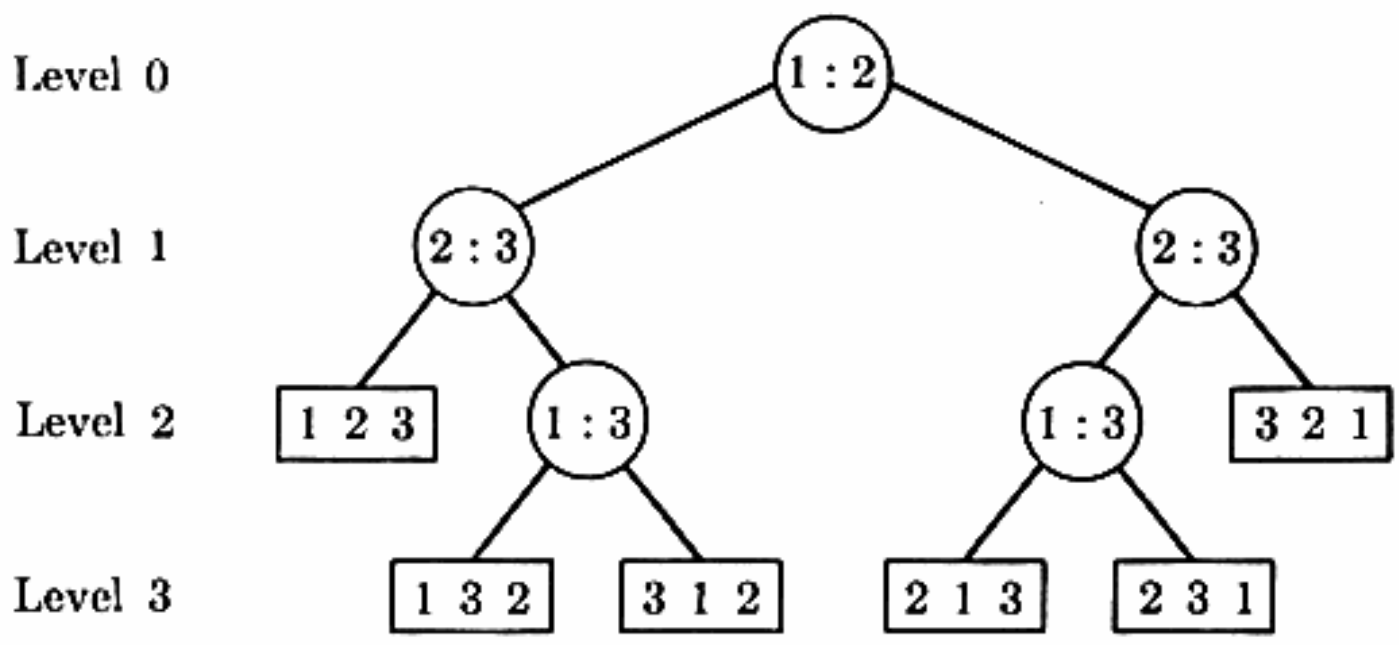


Fig. 34. A comparison tree for sorting three elements.

Thus Fig. 34 represents a sorting method which first compares K_1 with K_2; if $K_1 > K_2$, it goes on (via the right subtree) to compare K_2 with K_3, and then if $K_2 < K_3$ it compares K_1 with K_3; finally if $K_1 > K_3$ it knows that $K_2 < K_3 < K_1$. An actual sorting algorithm will usually also move the keys around in the file, but we are interested here only in the comparisons, so we ignore

all data movement. A comparison of K_i with K_j in this tree always means the *original* keys K_i and K_j, not the keys which might currently occupy the ith and jth positions of the file after the records have been shuffled around.

It is possible to make redundant comparisons; for example, in Fig. 35 there is no reason to compare 3:1, since $K_1 < K_2$ and $K_2 < K_3$ implies that $K_1 < K_3$. No permutation can possibly correspond to the left subtree of node (3:1) in Fig. 35, so that part of the algorithm will never be performed! Since we are interested in minimizing the number of comparisons, we may assume that no redundant comparisons are made; hence we have an extended binary tree structure in which every external node corresponds to a permutation. All permutations of the input keys are possible, and every permutation defines a unique path from the root to an external node; it follows that *there are exactly $n!$ external nodes in a comparison tree which sorts n elements with no redundant comparisons.*

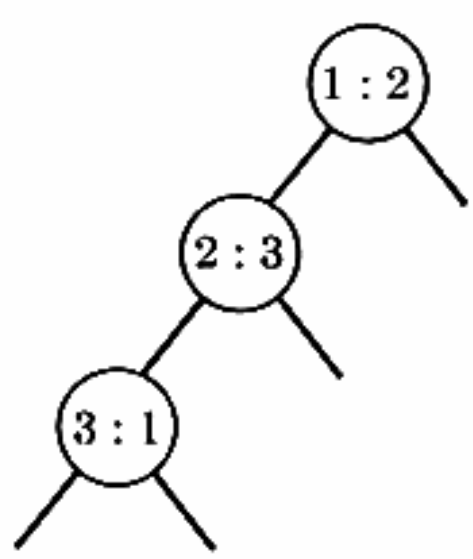

Fig. 35. Example of a redundant comparison.

The best worst case. The first problem that naturally arises is to find comparison trees which minimize the *maximum* number of comparisons made. (Later we shall consider the *average* number of comparisons.)

Let $S(n)$ be the minimum number of comparisons which will suffice to sort n elements. If all the internal nodes of a comparison tree are at levels $< k$, it is obvious that there can be at most 2^k external nodes in the tree. Hence, letting $k = S(n)$, we have

$$n! \le 2^{S(n)}.$$

Since $S(n)$ is an integer, we can rewrite this formula to obtain the lower bound

$$S(n) \ge \lceil \log_2 n! \rceil. \tag{1}$$

Note that by Stirling's approximation,

$$\lceil \log_2 n! \rceil = n \log_2 n - n/(\ln 2) + \tfrac{1}{2} \log_2 n + O(1), \tag{2}$$

so that about $n \log_2 n$ comparisons are needed.

Relation (1) is often called the "information theoretic lower bound," since cognoscenti of information theory would say that $(\log_2 n!)$ "bits of information" are being acquired during a sorting process; each comparison yields at most one "bit of information." Trees such as Fig. 34 have also been called "questionnaires," and their mathematical properties have been explored in Claude Picard's book *Théorie des questionnaires* (Paris: Gauthier-Villars, 1965).

Of all the sorting methods we have seen, the three that require fewest comparisons are binary insertion (cf. Section 5.2.1), tree selection (cf. Section 5.2.3), and straight two-way merging as reflected in Algorithm 5.2.4L. The maximum number of comparisons for binary insertion is readily seen to be

$$B(n) = \sum_{1\le k\le n} \lceil \log_2 k \rceil = n\lceil \log_2 n \rceil - 2^{\lceil \log_2 n \rceil} + 1 \tag{3}$$

(cf. exercise 1.2.4–42), and the maximum number of comparisons in Algorithm 5.2.4L is given in exercise 5.2.4–14. It turns out (see Section 5.3.3) that tree selection has the same bound on its comparisons as either binary insertion or two-way merging, depending on how the tree is set up. In all three cases we achieve an asymptotic value of $n \log_2 n$; combining these lower and upper bounds for $S(n)$ proves that

$$\lim_{n\to\infty} \frac{S(n)}{n \log_2 n} = 1. \tag{4}$$

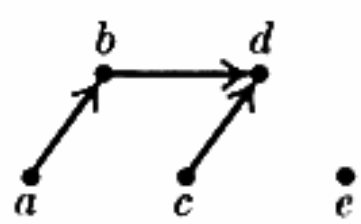
Thus we have an approximate formula for $S(n)$, but it is desirable to obtain more precise information. The following table gives exact values of the above quantities, for small n:

$n =$	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17
$\lceil \log_2 n! \rceil =$	0	1	3	5	7	10	13	16	19	22	26	29	33	37	41	45	49
$B(n) =$	0	1	3	5	8	11	14	17	21	25	29	33	37	41	45	49	54
$L(n) =$	0	1	3	5	9	11	14	17	25	27	30	33	38	41	45	49	65

Here $B(n)$ and $L(n)$ refer respectively to binary insertion and list merging. It can be shown that $B(n) \le L(n)$ for all n (see exercise 2).

From the above table, we can see that $S(4) = 5$, but $S(5)$ might be either 7 or 8. This brings us back to a problem stated at the beginning of Section 5.2: What is the best way to sort five elements? Can five elements be sorted using only seven comparisons?

The answer is yes, but it is not especially easy to find the method. We begin as if we were sorting four elements by merging, first comparing $K_1{:}K_2$, then $K_3{:}K_4$, then the larger elements of these pairs. This produces a configuration which may be diagramed as



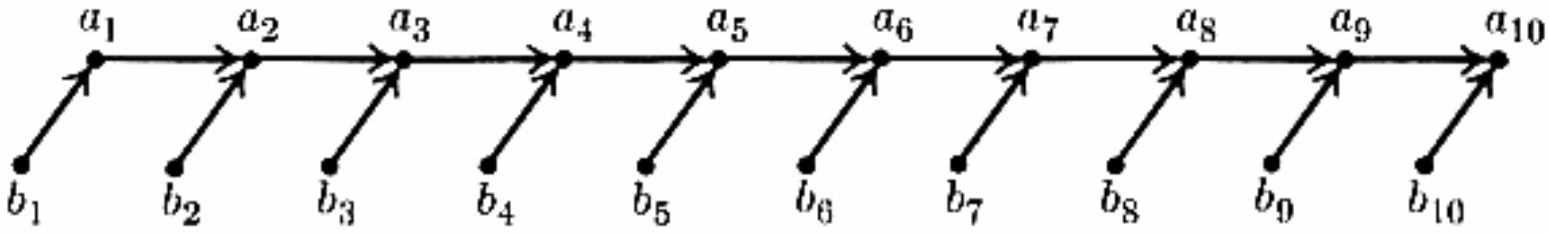
(5)

indicating that $a < b < d$ and $c < d$. (It is convenient to represent known ordering relations between elements by drawing directed graphs such as this, where x is known to be less than y if and only if there is a path from x to y in the graph.) At this point we insert the fifth element $K_5 = e$ into its proper place among $\{a, b, d\}$; only two comparisons are needed, since we may compare it first with b and then with a or d. This leaves one of four possibilities,

(6)

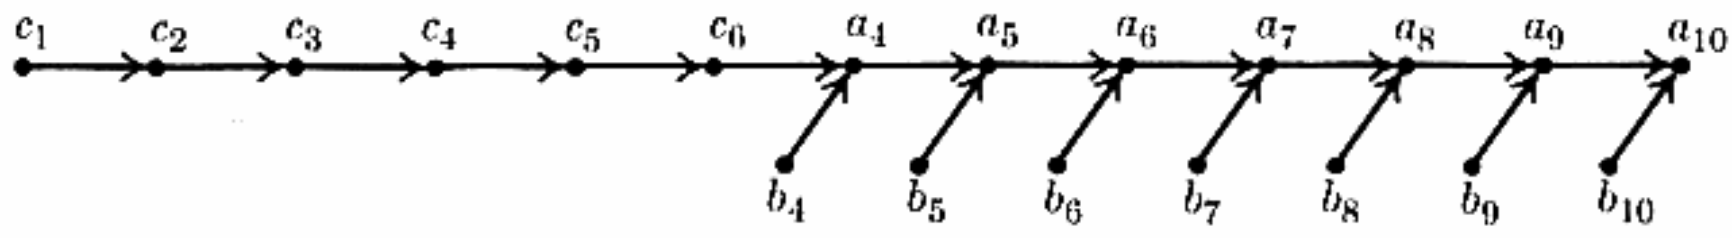
and in each case we can insert c among the remaining elements less than d in two more comparisons. This method for sorting five elements was first discovered by H. B. Demuth [Ph.D. thesis, Stanford University (Oct. 1956), 41–43].

Merge insertion. A pleasant generalization of the above method has been discovered by Lester Ford, Jr. and Selmer Johnson. Since it involves some aspects of merging and some aspects of insertion, we shall call it *merge insertion*. For example, consider the problem of sorting 21 elements. We start by comparing the ten pairs $K_1{:}K_2$, $K_3{:}K_4$, . . . , $K_{19}{:}K_{20}$; then we sort the ten larger elements of the pairs, using merge insertion. As a result we obtain the configuration



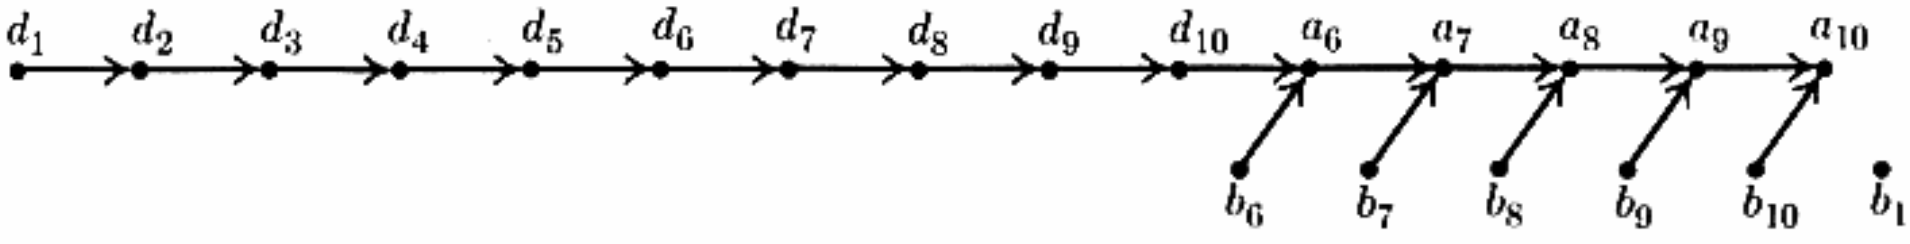
(7)

analogous to (5). The next step is to insert b_3 among $\{b_1, a_1, a_2\}$, then b_2 among the other elements less than a_2; we arrive at the configuration



(8)

Let us call the upper-line-elements the *main chain*. We can insert b_5 into its proper place in the main chain, using three comparisons (first comparing it to c_4, then c_2 or c_6, etc.); then b_4 can be moved into the main chain in three more steps, leading to



(9)

The next step is crucial; is it clear what to do? We insert b_{11} (*not* b_7) into the main chain, using only four comparisons. Then each of b_{10}, b_9, b_8, b_7, b_6 (in this order) can also be inserted into their proper places in the main chain, using at most four comparisons each.

A careful count of the comparisons involved here shows that the 21 elements have been sorted in at most $10 + 22 + 2 + 2 + 3 + 3 + 4 + 4 + 4 + 4 + 4 + 4 = 66$ steps. Since

$$2^{65} < 21! < 2^{66},$$

we also know that no fewer than 66 would be possible in any event; hence

$$S(21) = 66. \tag{10}$$

(Binary insertion would have required 74 comparisons.)

In general, merge insertion proceeds as follows for n elements:

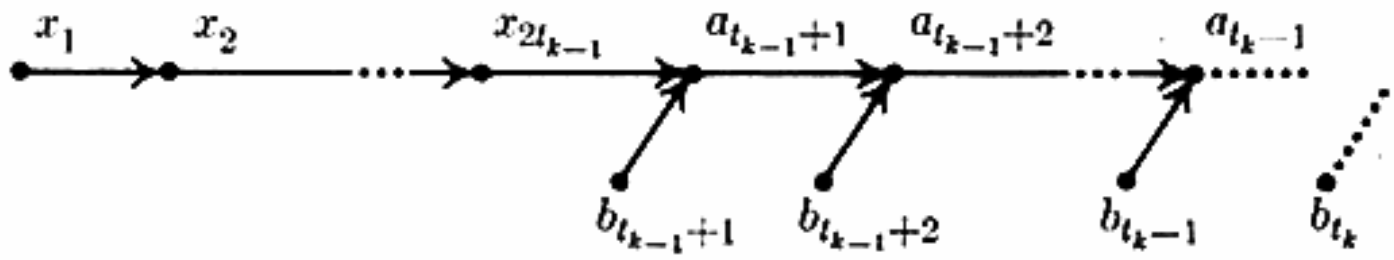
i) Make pairwise comparisons of $\lfloor n/2 \rfloor$ disjoint pairs of elements. (If n is odd, leave one element out.)

ii) Sort the $\lfloor n/2 \rfloor$ larger numbers, found in step (i), by merge insertion.

iii) Name the elements $a_1, a_2, \ldots, a_{\lfloor n/2 \rfloor}, b_1, b_2, \ldots, b_{\lceil n/2 \rceil}$ as in (7), where $a_1 \le a_2 \le \cdots \le a_{\lfloor n/2 \rfloor}$ and $b_i \le a_i$ for $1 \le i \le \lfloor n/2 \rfloor$; call b_1 and the a's the "main chain." Insert the remaining b's into the main chain, using binary insertion, in the following order, leaving out all b_j for $j > \lceil n/2 \rceil$:

$$b_3, b_2; b_5, b_4; b_{11}, b_{10}, \ldots, b_6; \ldots; b_{t_k}, b_{t_k-1}, \ldots, b_{t_{k-1}+1}; \ldots \tag{11}$$

We wish to define the sequence $(t_1, t_2, t_3, t_4, \ldots) = (1, 3, 5, 11, \ldots)$, which appears in (11), in such a way that each of $b_{t_k}, b_{t_k-1}, \ldots, b_{t_{k-1}+1}$ can be inserted into the main chain with at most k comparisons. Generalizing (7), (8), and (9), we obtain the diagram



where the main chain up to and including a_{t_k-1} contains $2t_{k-1} + (t_k - t_{k-1} - 1)$ elements. This number must be less than 2^k; our best bet is to set it equal to $2^k - 1$, so that

$$t_{k-1} + t_k = 2^k. \tag{12}$$

Since $t_1 = 1$, we may set $t_0 = 1$ for convenience, and we find that

$$\begin{aligned} t_k = 2^k - t_{k-1} = 2^k - 2^{k-1} + t_{k-2} = \cdots &= 2^k - 2^{k-1} + \cdots + (-1)^k 2^0 \\ &= (2^{k+1} + (-1)^k)/3 \end{aligned} \tag{13}$$

by summing a geometric series. (Curiously, this same sequence arose in our study of an algorithm for calculating the greatest common divisor of two integers; cf. exercise 4.5.2–27.)

Let $F(n)$ be the number of comparisons required to sort n elements by merge insertion. Clearly

$$F(n) = \lfloor n/2 \rfloor + F(\lfloor n/2 \rfloor) + G(\lceil n/2 \rceil), \tag{14}$$

where G represents the amount of work involved in step (iii). If $t_{k-1} \le m \le t_k$, we have

$$\begin{aligned} G(m) &= \sum_{1 \le j < k} j(t_j - t_{j-1}) + k(m - t_{k-1}) \\ &= km - (t_0 + t_1 + \cdots + t_{k-1}), \end{aligned} \tag{15}$$

summing by parts. Let us set

$$w_k = t_0 + t_1 + \cdots + t_{k-1} = \lfloor 2^{k+1}/3 \rfloor, \tag{16}$$

so that $(w_0, w_1, w_2, w_3, w_4, \ldots) = (0, 1, 2, 5, 10, 21, \ldots)$. Exercise 13 shows that

$$F(n) - F(n-1) = k \quad \text{iff} \quad w_k < n \le w_{k+1}, \tag{17}$$

and the latter condition is equivalent to

$$\frac{2^{k+1}}{3} < n \le \frac{2^{k+2}}{3},$$

$$k + 1 < \log_2 (3n) \le k + 2;$$

hence

$$F(n) - F(n-1) = \lceil \log_2 (\tfrac{3}{4}n) \rceil. \tag{18}$$

(This formula is due to A. Hadian [Ph. D. thesis, Univ. of Minnesota (1969), 38–42].) It follows that $F(n)$ has a remarkably simple expression,

$$F(n) = \sum_{1 \le k \le n} \lceil \log_2 (\tfrac{3}{4}k) \rceil, \tag{19}$$

quite similar to the corresponding formula (3) for binary insertion. A "closed form" for this sum appears in exercise 14.

Equation (19) makes it easy to construct a table of $F(n)$; we have

$n =$	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17
$\lceil \log_2 n! \rceil =$	0	1	3	5	7	10	13	16	19	22	26	29	33	37	41	45	49
$F(n) =$	0	1	3	5	7	10	13	16	19	22	26	30	34	38	42	46	50

$n =$	18	19	20	21	22	23	24	25	26	27	28	29	30	31	32	33
$\lceil \log_2 n! \rceil =$	53	57	62	66	70	75	80	84	89	94	98	103	108	113	118	123
$F(n) =$	54	58	62	66	71	76	81	86	91	96	101	106	111	116	121	126

Note that $F(n) = \lceil \log_2 n! \rceil$ for $1 \le n \le 11$ and for $20 \le n \le 21$, so we know that merge insertion is optimum for these n:

$$S(n) = \lceil \log_2 n! \rceil = F(n) \quad \text{for} \quad 1 \le n \le 11 \quad \text{and} \quad 20 \le n \le 21. \tag{20}$$

Hugo Steinhaus posed the problem of finding $S(n)$ in the second edition of his classic book *Mathematical Snapshots* (Oxford University Press, 1950), pp. 38–39. He described the method of binary insertion, which is the best possible way to sort n objects if we start by sorting $n - 1$ of them first before the nth is considered; and he conjectured that binary insertion is optimum in general. Several years later [*Calcutta Math. Soc. Golden Jubilee Commemoration* **2** (1959), 323–327], he reported that two of his colleagues, S. Trybuła and C. Ping, had "recently" disproved his conjecture, and that they had determined $S(n)$ for $n \le 11$. Trybuła and Ping may have independently discovered the method of merge insertion, which was published soon afterwards by Ford and Johnson [*AMM* **66** (1959), 387–389].

After the discovery of merge insertion, the first unknown value of $S(n)$ was $S(12)$. Table 1 shows that 12! is quite close to 2^{29}, so that the existence of a 29-step sorting procedure for 12 elements is somewhat unlikely. An exhaustive search (about 60 hours on a Maniac II computer) was therefore carried out by Mark Wells, who discovered that $S(12) = 30$ [*Proc. IFIP Congress* 65 **2** (1965), 497–498]. Thus the merge insertion procedure turns out to be optimum for $n = 12$ as well.

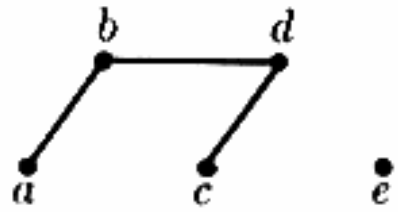
***A slightly deeper analysis.** In order to study $S(n)$ more carefully, let us look more closely at partial ordering diagrams such as (5). After several comparisons

have been made, we can represent the knowledge we have gained in terms of a directed graph. This directed graph contains no cycles, in view of the transitivity of the $<$ relation, so we can draw it in such a way that all arcs go from left to right; it is therefore convenient to leave arrows off the diagram. In this way (5) becomes



(21)

If G is such a directed graph, let $T(G)$ be the number of permutations consistent with G, i.e., the number of ways to assign the integers $\{1, 2, \ldots, n\}$ to the vertices of G so that the number on vertex x is less than the number on vertex y whenever $x \longrightarrow y$ in G. For example, one of the permutations consistent with (21) has $a = 1$, $b = 4$, $c = 2$, $d = 5$, $e = 3$. We have studied $T(G)$ for various G in Section 5.1.4, where we observed that $T(G)$ is the number of ways in which G can be "topologically sorted."

If G is a graph on n elements which can be obtained after k comparisons, we define the *efficiency* of G to be

$$E(G) = \frac{n!}{2^k T(G)}. \tag{22}$$

(This idea is due to Frank Hwang and Shen Lin.) Strictly speaking, the efficiency is not a function of the graph G alone, it depends on the way we arrived at G during a sorting process, but it is convenient to be a little careless in our language. After making one more comparison, between elements i and j, we obtain two graphs G_1 and G_2, one for the case $K_i < K_j$ and one for the case $K_i > K_j$. Clearly

$$T(G) = T(G_1) + T(G_2).$$

If $T(G_1) \geq T(G_2)$, we have

$$T(G) \leq 2T(G_1),$$

$$E(G_1) = \frac{n!}{2^{k+1} T(G_1)} = \frac{E(G)T(G)}{2T(G_1)} \leq E(G). \tag{23}$$

Therefore each comparison leads to a graph of less or equal efficiency; we can't improve the efficiency by making further comparisons.

Note that when G has no arcs at all, we have $k = 0$ and $T(G) = n!$, so the initial efficiency is 1. And when G is a graph representing the final result of sorting, G looks like a straight line, and $T(G) = 1$. Thus, for example, if we want to find a sorting procedure that sorts five elements in seven or less steps, we must obtain the linear graph  whose efficiency is $5!/(2^7 \times 1) = 120/128 = 15/16$. It follows that all of the graphs arising in the sorting procedure must have efficiency $\geq \frac{15}{16}$; if any less efficient graph were to appear, at least one of its descendants would also be less efficient, and

we would ultimately reach a linear graph whose efficiency is $< \frac{15}{16}$. In general, this argument proves that all graphs corresponding to the tree nodes of a sorting procedure for n elements must have efficiency $\geq n!/2^l$, where $l+1$ is the number of levels of the tree. This is another way to prove that $S(n) \geq \lceil \log_2 n! \rceil$, although the argument is not really much different than what we said before.

The graph (21) has efficiency 1, since $T(G) = 15$ and since G has been obtained in three comparisons. In order to see what vertices should be compared next, we can form the *comparison matrix*

$$C(G) = \begin{array}{c} \\ a \\ b \\ c \\ d \\ e \end{array} \begin{array}{c} \begin{array}{ccccc} a & b & c & d & e \end{array} \\ \begin{pmatrix} 0 & 15 & 10 & 15 & 11 \\ 0 & 0 & 5 & 15 & 7 \\ 5 & 10 & 0 & 15 & 9 \\ 0 & 0 & 0 & 0 & 3 \\ 4 & 8 & 6 & 12 & 0 \end{pmatrix} \end{array}, \tag{24}$$

where C_{ij} is $T(G_1)$ for the graph G_1 obtained by adding the arc $i \longrightarrow j$ to G. For example, if we compare K_c with K_e, the 15 permutations consistent with G split up into $C_{ce} = 6$ having $K_c < K_e$ and $C_{ec} = 9$ having $K_c > K_e$. The latter graph would have efficiency $15/(2 \times 9) = \frac{5}{6} < \frac{15}{16}$, so it could not lead to a seven-step sorting procedure. The next comparison *must* be $K_b : K_c$ in order to keep the efficiency $\geq \frac{15}{16}$.

The concept of "efficiency" is especially useful when we consider the "connected components" of graphs. Consider for example the graph

$G =$ 
;

it has two components,

$G' =$ 
and $G'' =$ 
with no arcs connecting G' to G'', so it has been formed by making some comparisons entirely within G' and others entirely within G''. In general, assume that $G = G' + G''$ has no arcs between G' and G'', where G' and G'' have respectively n' and n'' vertices; it is easy to see that

$$T(G) = \binom{n'+n''}{n'} T(G')T(G''), \tag{25}$$

since each consistent permutation of G is obtained by choosing n' elements to

assign to G' and then making consistent permutations within G' and G'' independently. If k' comparisons have been made within G' and k'' within G'', we have the basic result

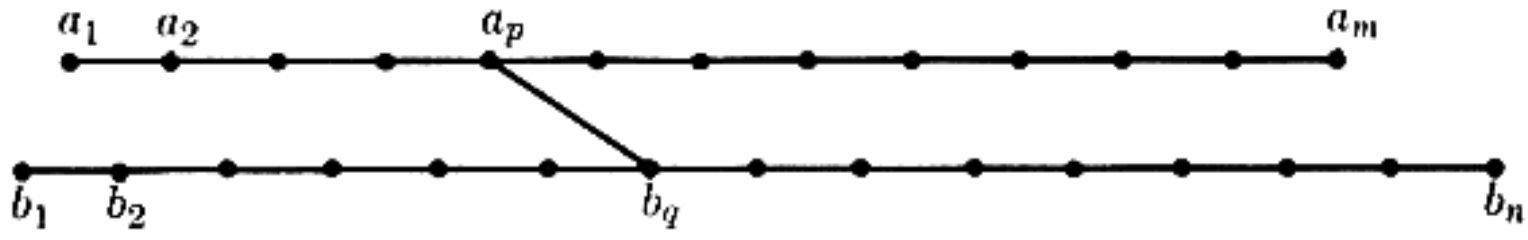
$$E(G) = \frac{(n'+n'')!}{2^{k'+k''}T(G)} = \frac{n'!}{2^{k'}T(G')} \cdot \frac{n''!}{2^{k''}T(G'')} = E(G')E(G''), \tag{26}$$

showing that the efficiency of a graph is related in a simple way to the efficiency of its components. Therefore we may restrict consideration to graphs having only one component.

Now suppose that G' and G'' are one-component graphs, and suppose that we want to hook them together by comparing a vertex x of G' with a vertex y of G''. We want to know how efficient this will be. For this purpose we need a function which can be denoted by

$$\binom{p}{m} < \binom{q}{n}, \tag{27}$$

defined to be the number of permutations consistent with the graph



(28)

Thus $\binom{p}{m}<\binom{q}{n}$ is $\binom{m+n}{m}$ times the probability that the pth smallest of a set of m numbers is less than the qth smallest of an independently chosen set of n numbers. Exercise 17 shows that we can express $\binom{p}{m}<\binom{q}{n}$ in two ways in terms of binomial coefficients,

$$\binom{p}{m} > \binom{q}{n} = \sum_{0\le k<q} \binom{m-p+n-k}{m-p}\binom{p-1+k}{p-1}$$

$$= \sum_{p\le j\le m} \binom{n-q+m-j}{n-q}\binom{q-1+j}{q-1}. \tag{29}$$

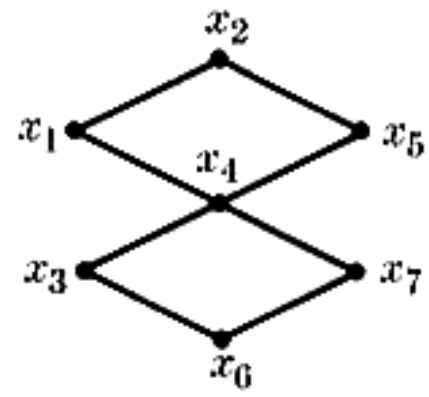
(Incidentally, it is by no means obvious on algebraic grounds that these two sums of products of binomial coefficients should come out to be equal.) We also have the formulas

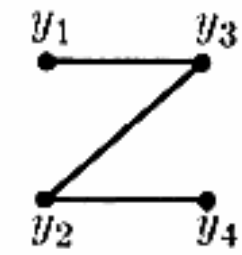
$$\binom{p}{m} < \binom{q}{n} + \binom{q}{n} < \binom{p}{m} = \binom{m+n}{m}, \tag{30}$$

$$\binom{q}{n} < \binom{p}{m} = \binom{m+1-p}{m} < \binom{n+1-q}{n}. \tag{31}$$

For definiteness, let us now consider the two graphs

$$G' = \quad , \qquad G'' = \qquad (32)$$





It is not hard to show by direct enumeration that $T(G') = 42$ and $T(G'') = 5$; so if G is the 11-vertex graph having G' and G'' as components, we have $T(G) = \binom{11}{4} \cdot 42 \cdot 5 = 69300$ by Eq. (25). This is a formidable number of permutations to list, if we want to know how many of them have $x_i < y_j$ for each i and j. But the calculation can be done by hand, in less than an hour, as follows. We form the matrices $A(G')$ and $A(G'')$, where A_{ik} is the number of consistent permutations of G' (or G'') in which x_i (or y_i) is equal to k. Thus the number of permutations of G in which x_i is less than y_j is the (ip) element of $A(G')$ times $\binom{p}{7}<\binom{q}{4}$ times the (jq) element of $A(G'')$, summed over $1 \le p \le 7$ and $1 \le q \le 4$. In other words, we want to form the matrix product $A(G') \cdot L \cdot A(G'')^T$, where $L_{pq} = \binom{p}{7}<\binom{q}{4}$. This comes to

$$\begin{pmatrix} 21 & 16 & 5 & 0 & 0 & 0 & 0 \\ 0 & 5 & 10 & 12 & 10 & 5 & 0 \\ 21 & 16 & 5 & 0 & 0 & 0 & 0 \\ 0 & 0 & 12 & 18 & 12 & 0 & 0 \\ 0 & 0 & 0 & 0 & 5 & 16 & 21 \\ 0 & 5 & 10 & 12 & 10 & 5 & 0 \\ 0 & 0 & 0 & 0 & 5 & 16 & 21 \end{pmatrix} \begin{pmatrix} 210 & 294 & 322 & 329 \\ 126 & 238 & 301 & 325 \\ 70 & 175 & 265 & 315 \\ 35 & 115 & 215 & 295 \\ 15 & 65 & 155 & 260 \\ 5 & 29 & 92 & 204 \\ 1 & 8 & 36 & 120 \end{pmatrix} \begin{pmatrix} 2 & 3 & 0 & 0 \\ 2 & 2 & 0 & 1 \\ 1 & 0 & 2 & 2 \\ 0 & 0 & 3 & 2 \end{pmatrix} = \begin{pmatrix} 48169 & 42042 & 66858 & 64031 \\ 22825 & 16005 & 53295 & 46475 \\ 48169 & 42042 & 66858 & 64031 \\ 22110 & 14850 & 54450 & 47190 \\ 5269 & 2442 & 27258 & 21131 \\ 22825 & 16005 & 53295 & 46475 \\ 5269 & 2442 & 27258 & 21131 \end{pmatrix}.$$

Thus the "best" way to hook up G' and G'' is to compare x_1 with y_2; this gives 42042 cases with $x_1 < y_2$ and $69300 - 42042 = 27258$ cases with $x_1 > y_2$. (By symmetry, we could also compare x_3 with y_2, x_5 with y_3, or x_7 with y_3, leading to essentially the same results.) The efficiency of the resulting graph for $x_1 < y_2$ is

$$\frac{69300}{84084} E(G')E(G''),$$

which is none too good; hence it is probably a bad idea to hook G' up with G'' in any sorting method! The point of this example is that we are able to make such a decision without excessive calculation.

These ideas can be used to provide independent confirmation of Mark Well's proof that $S(12) = 30$. Starting with a graph containing one vertex, we can repeatedly try to add a comparison to one of our graphs G or to a pair of graph components G' and G'' in such a way that the two resulting graphs have 12 or less vertices and efficiency $\ge 12!/2^{29} \approx 0.89221$. Whenever this is possible, we take the resulting graph of least efficiency and add it to our set, unless it is isomorphic to a graph we already have included (or to the dual of such a graph, obtained by reversing the order). If both of the resulting graphs

have the same efficiency, we arbitrarily choose one of them. The first 24 graphs obtained in this way are displayed in Fig. 36 together with their efficiencies.

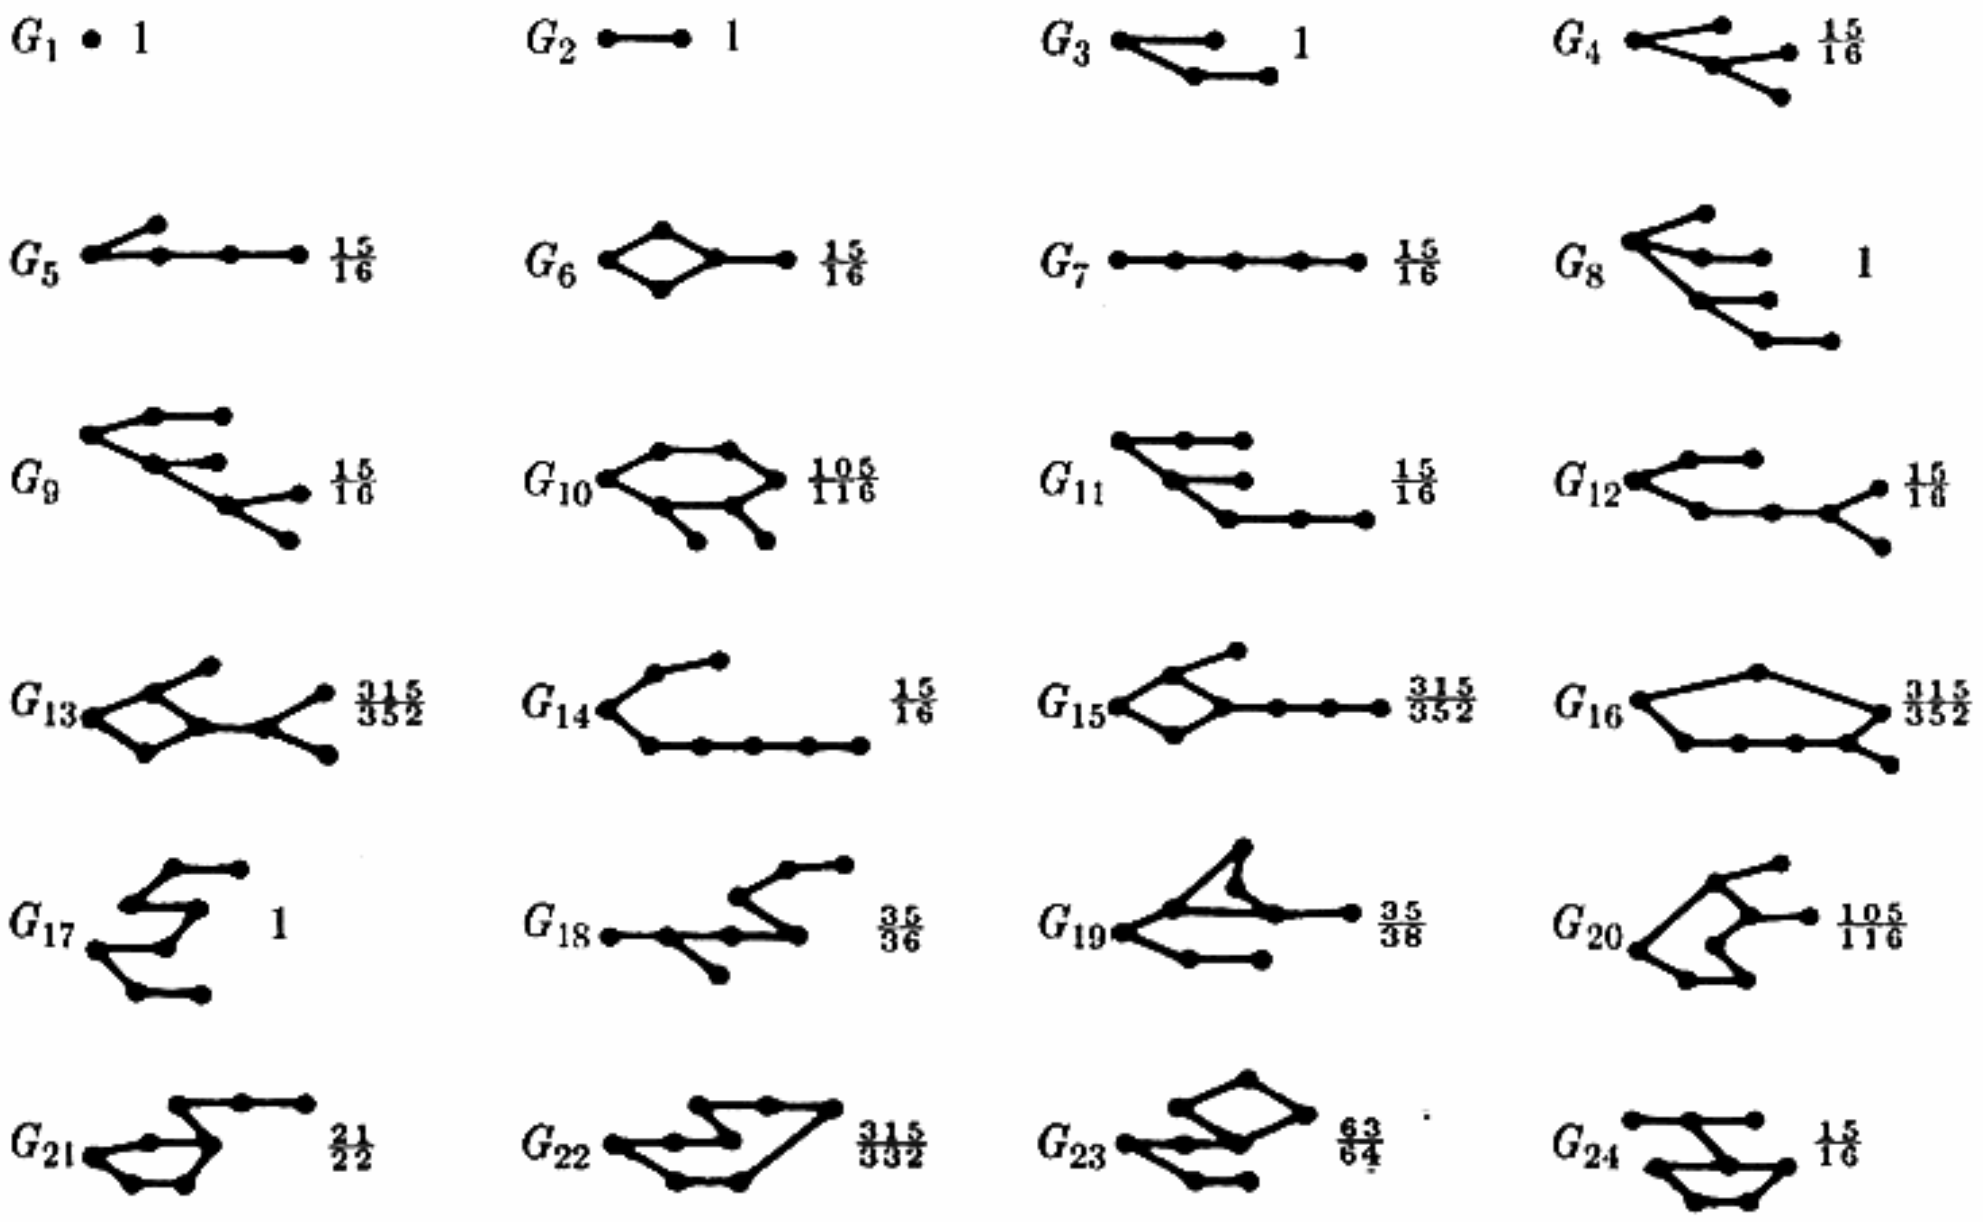


Fig. 36. Some graphs and their efficiencies, obtained at the beginning of a long proof that $S(12) > 29$.

Exactly 1594 graphs were generated, by computer, before this process terminated. Since the graph  was not obtained, we may conclude that $S(12) > 29$. It is plausible that a similar experiment could be performed to deduce that $S(22) > 70$ in a fairly reasonable amount of time, since $22!/2^{70} \approx 0.952$ requires extremely high efficiency to sort in 70 steps. (Only 92 of the 1594 graphs found on 12 or less vertices had such high efficiency.)

The intermediate results suggest strongly that $S(13) = 33$, so that merge insertion would not be optimum when $n = 13$. But as yet nobody has discovered *any* n such that $S(n) < F(n)$.

It should certainly be possible to prove that $S(16) < F(16)$, since $F(16)$ takes no fewer comparisons than sorting ten elements with $S(10)$ comparisons and then inserting six others by binary insertion, one at a time. There must be a way to improve upon such a method!

The average number of comparisons. So far we have been considering procedures which are best possible in the sense that their worst case isn't bad; we have looked for "minimax" procedures which minimize the *maximum* number of comparisons. Now let us look for a "minimean" procedure which minimizes the *average* number of comparisons, assuming that the input is random so that each permutation is equally likely.

Consider once again the tree representation of a sorting procedure, as shown in Fig. 34. The average number of comparisons in that tree is

$$\frac{2+3+3+3+3+2}{6} = 2\tfrac{2}{3},$$

averaging over all permutations. In general, the average number of comparisons in a sorting method is the *external path length of the tree* divided by $n!$. (Recall that the external path length is the sum of the distances from the root to each of the external nodes; see Section 2.3.4.5.) It is easy to see from the considerations in Section 2.3.4.5 that the minimum external path length occurs in a binary tree with N external nodes if there are $2^q - N$ external nodes at level $q-1$ and $2N - 2^q$ at level q, where $q = \lceil \log_2 N \rceil$. (The root is at level zero.) The minimum external path length is therefore

$$(q-1)(2^q - N) + q(2N - 2^q) = (q+1)N - 2^q. \tag{33}$$

The minimum path length can also be characterized in another interesting way: *An extended binary tree has minimum external path length if and only if there is a number l such that all external nodes appear on levels l and $l+1$.* (See exercise 20.)

If we set $q = \log_2 N + \theta$, where $0 \le \theta < 1$, the formula for minimum external path length becomes

$$N(\log_2 N + 1 + \theta - 2^\theta). \tag{34}$$

The function $1 + \theta - 2^\theta$ is shown in Fig. 37; for $0 < \theta < 1$ it is positive but very small, never exceeding

$$1 - (1 + \ln \ln 2)/(\ln 2) = 0.08607\ 13320\ 55934+. \tag{35}$$

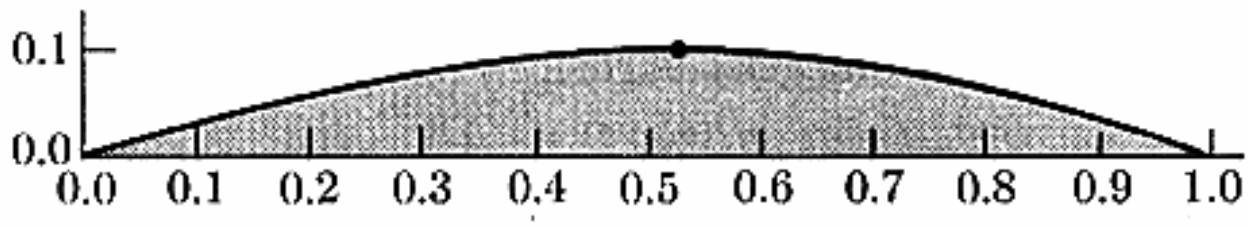

Fig. 37. The function $1 + \theta - 2^\theta$.

Thus the minimum possible average path length, obtained by dividing (34) by N, is never less than $\log_2 N$ and never more than $\log_2 N + 0.0861$. (This result was first obtained by A. Gleason in an unpublished memorandum (1956).)

Now if we set $N = n!$ we get a lower bound for the average number of comparisons in any sorting scheme. Note that this lower bound is $\log_2 n! + O(1) = n \log_2 n - n/(\ln 2) + O(\log n)$.

Let $\overline{F}(n)$ be the average number of comparisons performed by the merge insertion algorithm; we have

$n =$	1	2	3	4	5	6	7	8
lower bound (33) $=$	0	2	16	112	832	6896	62368	619904
$n!\,\overline{F}(n) =$	0	2	16	112	832	6912	62784	623232

Thus merge insertion is optimum in both senses for $n \leq 5$, but for $n = 6$ it averages $6912/720 = 9.6$ comparisons while our lower bound says that an average of $6896/720 = 9.577777\cdots$ comparisons may be possible. A moment's reflection shows why this is true: Some "fortunate" permutations of six elements are sorted after only eight comparisons by merge insertion, so the comparison tree has external nodes appearing on three levels instead of two. This forces the overall path length to be higher. Exercise 24 shows that it is possible to construct a six-element sorting procedure which requires nine or ten comparisons in each case; it follows that this method is superior to merge insertion, on the average, and no worse than merge insertion in its worst case.

When $n = 7$, Y. Césari [thesis (Paris, 1968), p. 37] has shown that no sorting method can attain the lower bound 62368 on external path length. (It is possible to prove this fact by hand, using the results of exercise 22.) On the other hand, he has constructed procedures which do achieve the lower bound (33) when $n = 9$ or 10. In general, the problem of minimizing the average number of comparisons turns out to be substantially more difficult than the problem of determining $S(n)$. It may even be true that, for some n, all methods which minimize the *average* number of comparisons require *more* than $S(n)$ comparisons in their worst case.

EXERCISES

1. [*20*] Draw the comparison trees for sorting four elements by the method of (a) binary insertion; (b) straight two-way merging. What are the external path lengths of these trees?

2. [*M24*] Prove that $B(n) \leq L(n)$, and find all n for which equality holds.

3. [*M22*] When equality between keys is allowed, there are 13 possible outcomes when sorting three elements:

$$K_1 = K_2 = K_3 \qquad K_1 = K_2 < K_3 \qquad K_1 = K_3 < K_2$$
$$K_2 = K_3 < K_1 \qquad K_1 < K_2 = K_3 \qquad K_2 < K_1 = K_3$$
$$K_3 < K_1 = K_2 \qquad K_1 < K_2 < K_3 \qquad K_1 < K_3 < K_2$$
$$K_2 < K_1 < K_3 \qquad K_2 < K_3 < K_1 \qquad K_3 < K_1 < K_2 \qquad K_3 < K_2 < K_1.$$

Let P_n denote the number of possible outcomes when n elements are sorted with ties allowed, so that $(P_0, P_1, P_2, P_3, P_4, P_5, \ldots) = (1, 1, 3, 13, 75, 541, \ldots)$. Prove that the generating function $P(z) = \sum_{n\geq 0} P_n z^n/n!$ is equal to $1/(2 - e^z)$. *Hint:* Show that

$$P_n = \sum_{k>0} \binom{n}{k} P_{n-k} \qquad \text{when} \qquad n > 0.$$

4. [*HM27*] (O. A. Gross.) Determine the asymptotic value of the numbers P_n of exercise 3, as $n \to \infty$. [*Possible hint:* Consider the partial fraction expansion of cot z.]

5. [*16*] When keys can be equal, each comparison may have three results instead of two: $K_i < K_j$, $K_i = K_j$, $K_i > K_j$. Sorting algorithms for this general situation can be represented as extended *ternary* trees, in which each internal node $i{:}j$ has three subtrees; the left, middle, and right subtrees correspond respectively to the three possible outcomes of the comparison.

Draw an extended ternary tree which defines a sorting algorithm for $n = 3$, when equal keys are allowed. There should be 13 external nodes, corresponding to the 13 possible outcomes listed in exercise 3.

▸ **6.** [*M22*] Let $S'(n)$ be the minimum number of comparisons necessary to sort n elements and to determine all equalities between keys, when each comparison has three outcomes as in exercise 5. The "information theory" argument of the text can readily be generalized to show that $S'(n) \geq \lceil \log_3 P_n \rceil$, where P_n is the function studied in exercises 3 and 4; but prove that, in fact, $S'(n) = S(n)$.

7. [*20*] Draw an extended ternary tree in the sense of exercise 5 for sorting four elements, when it is known that all keys are either 0 or 1. (Thus if $K_1 < K_2$ and $K_3 < K_4$, we know that $K_1 = K_3$ and $K_2 = K_4$!) Use the minimum average number of comparisons, assuming that the 2^4 possible inputs are equally likely.

8. [*26*] Draw an extended ternary tree as in exercise 7, for sorting four elements, when it is known that all keys are either -1, 0, or $+1$. Use the minimum average number of comparisons, assuming that the 3^4 possible inputs are equally likely.

9. [*M20*] When sorting n elements as in exercise 7, knowing that all keys are 0 or 1, what is the minimum number of comparisons in the worst case?

▸ **10.** [*M25*] When sorting n elements as in exercise 7, knowing that all keys are 0 or 1, what is the minimum *average* number of comparisons as a function of n?

11. [*HM25*] When sorting n elements as in exercise 5, and knowing that all keys are members of the set $\{1, 2, \ldots, m\}$, let $S_m(n)$ be the minimum number of comparisons needed in the worst case. [Thus by exercise 6, $S_n(n) = S(n)$.] Prove that, for fixed m, $S_m(n)$ is asymptotically $n \log_2 m$ as $n \to \infty$.

▸ **12.** [*M25*] (W. G. Bouricius, circa 1954.) Suppose that equal keys may occur, but we merely want to sort the elements $\{K_1, K_2, \ldots, K_n\}$ so that a permutation $a_1\, a_2 \ldots a_n$ is determined with $K_{a_1} \leq K_{a_2} \leq \cdots \leq K_{a_n}$; we do not need to know whether or not equality occurs between K_{a_i} and $K_{a_{i+1}}$.

Let us say that a comparison tree sorts a sequence of keys *strongly* if it will sort the sequence in the above sense no matter which branch is taken below the nodes $i{:}j$ for which $K_i = K_j$. (The tree is binary, not ternary.)

a) Prove that a comparison tree with no redundant comparisons sorts every sequence of keys strongly if and only if it sorts every sequence of distinct keys.

b) Prove that a comparison tree sorts every sequence of keys strongly if and only if it sorts every sequence of zeros and ones strongly.

13. [*M28*] Prove (17).

14. [*M24*] Find a "closed form" for the sum (19).

15. [*M21*] Determine the asymptotic behavior of $B(n)$ and $F(n)$ up to $O(\log n)$. [*Hint:* Show that in both cases the coefficient of n involves the function shown in Fig. 37.]

16. [*HM26*] (F. Hwang and S. Lin.) Prove that $F(n) > \lceil \log_2 n! \rceil$ for $n \geq 22$.

17. [*M20*] Prove (29).

18. [*20*] If the procedure which starts in Fig. 36 had produced the graph  with efficiency $12!/2^{29}$, would this have proved that $S(12) = 29$?

19. [*40*] Experiment with the following heuristic rule for deciding which pair of elements to compare next while designing a comparison tree: At each stage of sorting $\{K_1, \ldots, K_n\}$, let u_i be the number of keys known to be $\leq K_i$ as a result of the comparisons made so far, and let v_i be the number of keys known to be $\geq K_i$, for $1 \leq i \leq n$. Renumber the keys in terms of increasing u_i/v_i, so that $u_1/v_1 \leq u_2/v_2 \leq \cdots \leq u_n/v_n$. Now compare $K_i{:}K_{i+1}$ for some i which minimizes $|u_i v_{i+1} - u_{i+1} v_i|$. (Although this method is based on far less information than a full comparison matrix as in (24), it appears to give optimum results in many cases.)

▸**20.** [*M26*] Prove that an extended binary tree has minimum external path length if and only if there is a number l such that all external nodes appear on levels l and $l+1$ (or perhaps all on a single level l).

21. [*M21*] The *height* of an extended binary tree is the maximum level number of its external nodes. If x is an internal node of an extended binary tree, let $t(x)$ be the number of external nodes below x, and let $l(x)$ denote the root of x's left subtree. If x is an external node, let $t(x) = 1$. Prove that an extended binary tree has minimum height among all binary trees with the same number of nodes if and only if

$$|t(x) - 2t(l(x))| \leq 2^{\lceil \log_2 t(x) \rceil} - t(x)$$

for all internal nodes x.

22. [*M24*] Continuing exercise 21, prove that a binary tree has minimum external path length among all binary trees with the same number of nodes if and only if

$$|t(x) - 2t(l(x))| \leq 2^{\lceil \log_2 t(x) \rceil} - t(x) \qquad \text{and} \qquad |t(x) - 2t(l(x))| \leq t(x) - 2^{\lfloor \log_2 t(x) \rfloor}$$

for all internal nodes x. [Thus, for example, if $t(x) = 67$, we must have $t(l(x)) = 32$, 33, 34, or 35. If we merely wanted to minimize the height of the tree we could have $3 \leq t(l(x)) \leq 64$, by the preceding exercise.]

23. [*10*] The text proves [cf. (34)] that the average number of comparisons made by any sorting method for n elements must be at least $\lceil \log_2 n! \rceil \approx n \log_2 n$. But multiple list insertion (Algorithm 5.2.1M) takes only $O(n)$ units of time on the average. How can this be?

24. [*27*] (C. Picard.) Find a sorting tree for six elements such that all external nodes appear on levels 10 and 11.

25. [*11*] If there were a sorting procedure for seven elements which achieves the minimum average number of comparisons predicted by the use of Eq. (34), how many external nodes would there be on level 13?

26. [*M42*] Find a sorting procedure for seven elements which minimizes the average number of comparisons performed.

▸**27.** [*20*] Suppose it is known that the configurations ($K_1 < K_2 < K_3$, $K_1 < K_3 < K_2$, $K_2 < K_1 < K_3$, $K_2 < K_3 < K_1$, $K_3 < K_1 < K_2$, $K_3 < K_2 < K_1$) occur with respective probabilities (.01, .25, .01, .24, .25, .24). Find a comparison tree which sorts these three elements with the smallest average number of comparisons.

28. [*40*] Write a MIX program which sorts five one-word keys in the minimum possible amount of time, and halts. (See the beginning of Section 5.2 for ground rules.)

29. [*M25*] (S. M. Chase.) Let $a_1 a_2 \ldots a_n$ be a permutation of $\{1, 2, \ldots, n\}$. Prove that any algorithm which decides whether this permutation is even or odd (i.e., whether it has an even or odd number of inversions), based solely on comparisons between the a's, must make at least $n \log_2 n$ comparisons, even though the algorithm has only two possible outcomes.

30. [*M23*] (*Optimum exchange sorting.*) Every exchange sorting algorithm as defined in Section 5.2.2 can be represented as a *comparison-exchange tree*, namely a binary tree structure whose internal nodes have the form $\textcircled{i:j}$ for $i < j$, interpreted as the following operation: "If $K_i \leq K_j$, continue by taking the left branch of the tree; if $K_i > K_j$, continue by interchanging records i and j and then taking the right branch of the tree." When an external node is encountered, it must be true that $K_1 \leq K_2 \leq \cdots \leq K_n$. Thus, a comparison-exchange tree differs from a comparison tree in that it specifies data movement as well as comparison operations.

Let $S_e(n)$ denote the minimum number of comparison-exchanges needed, in the worst case, to sort n elements by means of a comparison-exchange tree. Prove that $S_e(n) \leq S(n) + n - 1$.

31. [*M38*] Continuing exercise 30, prove that $S_e(5) = 8$.

32. [*M42*] Continuing exercise 31, investigate $S_e(n)$ for small values of $n > 5$.

33. [*M30*] (T. N. Hibbard.) A *real-valued search tree* of order x and resolution δ is an extended binary tree in which all nodes contain a nonnegative real value, such that (i) the value in each external node is $\leq \delta$; (ii) the value in each internal node is $\leq$ the sum of the values in its two sons; (iii) the value in the root is x. The *weighted path length* of such a tree is defined to be the sum, over all external nodes, of the level of that node times the value it contains.

Prove that a real-valued search tree of order x and resolution 1 has minimum weighted path length, taken over all such trees of the same order and resolution, if and only if equality holds in (ii) and the following further conditions hold for all pairs of values x_0 and x_1 that are contained in brother nodes: (iv) There is no integer $k \geq 0$ such that $x_0 < 2^k < x_1$ or $x_1 < 2^k < x_0$; (v) $\lceil x_0 \rceil - x_0 + \lceil x_1 \rceil - x_1 < 1$. (In particular if x is an integer, condition (v) implies that all values in the tree are integers, and condition (iv) is equivalent to the result of exercise 22.)

Also prove that the corresponding minimum weighted path length is $x\lceil \log_2 x \rceil + \lceil x \rceil - 2^{\lceil \log_2 x \rceil}$.

34. [*M50*] Determine the exact value of $S(n)$ for infinitely many n.

*5.3.2. Minimum-Comparison Merging

Let us now consider a related question: What is the best way to merge an ordered set of m elements with an ordered set of n? Denoting the elements to be merged by

$$A_1 < A_2 < \cdots < A_m,$$
$$B_1 < B_2 < \cdots < B_n, \tag{1}$$

we shall assume as in Section 5.3.1 that the $m + n$ elements are distinct. The

A's may appear among the B's in $\binom{m+n}{m}$ ways, so the arguments we have used for the sorting problem tell us immediately that at least

$$\left\lceil \log_2 \binom{m+n}{m} \right\rceil \tag{2}$$

comparisons are required. If we set $m = \alpha n$ and let $n \to \infty$, while α is fixed, Stirling's approximation tells us that

$$\log_2 \binom{\alpha n + n}{\alpha n} = n((1+\alpha)\log_2 (1+\alpha) - \alpha \log_2 \alpha) - \tfrac{1}{2}\log_2 n + O(1). \tag{3}$$

The normal merging procedure, Algorithm 5.2.4M, takes $m + n - 1$ comparisons in its worst case.

Let $M(m, n)$ denote the function analogous to $S(n)$, namely the minimum number of comparisons which will always suffice to merge m things with n. By the observations we have just made,

$$\left\lceil \log_2 \binom{m+n}{m} \right\rceil \le M(m, n) \le m + n - 1 \qquad \text{for all} \qquad m, n \ge 1. \tag{4}$$

Formula (3) shows how far apart this lower bound and upper bound can be. When $\alpha = 1$ (i.e., $m = n$), the lower bound is $2n - \frac{1}{2}\log_2 n + O(1)$, so both bounds have the right order of magnitude but the difference between them can be arbitrarily large. When $\alpha = 0.5$ (i.e., $m = \frac{1}{2}n$), the lower bound is

$$\tfrac{3}{2}n(\log_2 3 - \tfrac{2}{3}) + O(\log n),$$

which is about $\log_2 3 - \frac{2}{3} \approx 0.918$ times the upper bound. And as α decreases, the bounds get farther and farther apart, since the standard merging algorithm is primarily designed for files with $m \approx n$.

When $m = n$, the merging problem has a fairly simple solution; it turns out that the *lower* bound of (4), not the upper bound, is at fault. The following theorem was discovered independently by R. L. Graham and R. M. Karp about 1968:

Theorem M. $M(m, m) = 2m - 1$, *for* $m \ge 1$.

Proof. Consider any algorithm which merges $A_1 < \cdots < A_m$ with $B_1 < \cdots < B_m$. When it compares $A_i{:}B_j$, take the branch $A_i < B_j$ if $i < j$, the branch $A_i > B_j$ if $i \ge j$. Merging must eventually terminate with the configuration

$$B_1 < A_1 < B_2 < A_2 < \cdots < B_m < A_m, \tag{5}$$

since this is consistent with all of the branches taken. And each of the $2m - 1$ comparisons $B_1{:}A_1$, $A_1{:}B_2$, $B_2{:}A_2, \ldots, B_m{:}A_m$ must have been made explicitly, or else there would be at least two configurations consistent with

the known facts. For example, if A_1 has not been compared to B_2, the configuration

$$B_1 < B_2 < A_1 < A_2 < \cdots < B_m < A_m$$

is indistinguishable from (5). ∎

A simple modification of this proof yields the companion formula

$$M(m, m+1) = 2m, \qquad \text{for} \qquad m \geq 0. \tag{6}$$

Oracular lower bounds. Theorem M shows that the "information theoretic" lower bound can be considerably lower than the true lower bound; thus the technique used to prove Theorem M gives us another way to discover lower bounds. It is convenient to regard this proof technique as the construction of an "oracle": When merging by some algorithm, we decide to compare A_i:B_j and we say, "Pray tell me, O thou wise Oracle, which is the larger, A_i or B_j?" After we have made a suitable offering, the answer comes back:

I am Sir Oracle, and I ope my lips to say that A_i is the greater.

If we can construct a suitable oracle, as in the proof of Theorem M, we can ensure that every valid merging algorithm will have to ask a rather large number of questions.

It turns out to be important to consider the idea of a *constrained oracle*, which has been enjoined to give specific answers to certain questions. (The merging method which consults the oracle does not know, of course, that the oracle is constrained, so it may be necessary to ask the question anyway.) The constraints we speak of apply to the left and right ends of the files. Left constraints are symbolized by

. (meaning no left constraint),
\ (meaning that all pronouncements must be consistent with $A_1 < B_1$),
/ (meaning that all pronouncements must be consistent with $A_1 > B_1$);

right constraints are symbolized by

. (meaning no right constraint),
\ (meaning that all pronouncements must be consistent with $A_m < B_n$),
/ (meaning that all pronouncements must be consistent with $A_m > B_n$).

There are nine kinds of oracles, denoted by $\nabla M \phi$, where ∇ is a left constraint and ϕ is a right constraint. For example, a "$\backslash M \backslash$" oracle must say that $A_1 < B_j$ and $A_i < B_n$; a "$.M.$" oracle is unconstrained. For some small m and n, constrained oracles of certain kinds are impossible; when $m = 1$ we obviously can't have a "$\backslash M /$" oracle.

Let us now construct a rather complicated, but very wise, oracle for merging. It does not always produce optimum results, but it gives lower bounds

which cover a lot of interesting cases. Given m, n, and the left and right constraints ∇ and ϕ, suppose the oracle is asked which is the greater of A_i or B_j. The oracle can use six strategies in general which reduce the problem to cases of smaller $m + n$:

Strategy $A(k, l)$, *for* $i \leq k \leq m$ *and* $1 \leq l \leq j$. Say that $A_i < B_j$, and require that subsequent operations merge $\{A_1, \ldots, A_k\}$ with $\{B_1, \ldots, B_{l-1}\}$ and $\{A_{k+1}, \ldots, A_m\}$ with $\{B_l, \ldots, B_n\}$. Thus future questions $A_p{:}B_q$ will be answered $A_p < B_q$ if $p \leq k$ and $q \geq l$; $A_p > B_q$ if $p > k$ and $q < l$; they will be handled by a $(k, l-1, \nabla, .)$ oracle if $p \leq k$ and $q < l$; by an $(m-k, n+1-l, ., \phi)$ oracle if $p > k$ and $q \geq l$.

Strategy $B(k, l)$, *for* $i \leq k \leq m$ *and* $1 \leq l < j$. Say that $A_i < B_j$, and require that subsequent operations merge $\{A_1, \ldots, A_k\}$ with $\{B_1, \ldots, B_l\}$ and $\{A_{k+1}, \ldots, A_m\}$ with $\{B_l, \ldots, B_n\}$, stipulating that $A_k < B_l < A_{k+1}$. (Note that B_l appears in both lists to be merged. The condition $A_k < B_l < A_{k+1}$ ensures that merging one group gives no information that could help to merge the other.) Thus future questions $A_p{:}B_q$ will be answered $A_p < B_q$ if $p \leq k$ and $q \geq l$; $A_p > B_q$ if $p > k$ and $q \leq l$; they will be handled by a $(k, l, \nabla, \backslash)$ oracle if $p \leq k$ and $q \leq l$; by an $(m-k, n+1-l, /, \phi)$ oracle if $p > k$ and $q \geq l$.

Strategy $C(k, l)$ *for* $i < k \leq m$ *and* $1 \leq l \leq j$. Say that $A_i < B_j$, and require that subsequent operations merge $\{A_1, \ldots, A_k\}$ with $\{B_1, \ldots, B_{l-1}\}$ and $\{A_k, \ldots, A_m\}$ with $\{B_l, \ldots, B_n\}$, stipulating that $B_{l-1} < A_k < B_l$. (Analogous to Strategy B, interchanging the roles of A, B.)

Strategy $A'(k, l)$ *for* $1 \leq k \leq i$ *and* $j \leq l \leq n$. Say that $A_i > B_j$ and require the merging of $\{A_1, \ldots, A_{k-1}\}$ with $\{B_1, \ldots, B_l\}$ and $\{A_k, \ldots, A_m\}$ with $\{B_{l+1}, \ldots, B_n\}$. (Analogous to Strategy A.)

Strategy $B'(k, l)$ *for* $1 \leq k \leq i$ *and* $j < l \leq n$. Say that $A_i > B_j$, and require the merging of $\{A_1, \ldots, A_{k-1}\}$ with $\{B_1, \ldots, B_l\}$ and $\{A_k, \ldots, A_m\}$ with $\{B_l, \ldots, B_n\}$, subject to $A_{k-1} < B_l < A_k$. (Analogous to Strategy B.)

Strategy $C'(k, l)$ *for* $1 \leq k < i$ *and* $j \leq l \leq n$. Say that $A_i > B_j$, and require the merging of $\{A_1, \ldots, A_k\}$ with $\{B_1, \ldots, B_l\}$ and $\{A_k, \ldots, A_m\}$ with $\{B_{l+1}, \ldots, B_n\}$, subject to $B_l < A_k < B_{l+1}$. (Analogous to Strategy C.)

Because of the constraints, the above strategies cannot be used in certain cases summarized here:

Strategy	Must be omitted when
$A(k, 1)$, $B(k, 1)$, $C(k, 1)$	$\nabla = /$
$A'(1, l)$, $B'(1, l)$, $C'(1, l)$	$\nabla = \backslash$
$A(m, l)$, $B(m, l)$, $C(m, l)$	$\phi = /$
$A'(k, n)$, $B'(k, n)$, $C'(k, n)$	$\phi = \backslash$

Let $\nabla M\phi(m, n)$ denote the maximum lower bound for merging which is obtainable by an oracle of the class described above. Each strategy, when applicable, gives us an inequality relating these nine functions, when the first comparison is $A_i{:}B_j$, namely,

$$A(k, l): \quad \nabla M\phi(m, n) \geq 1 + \nabla M.(k, l-1) + .M\phi(m-k, n+1-l);$$
$$B(k, l): \quad \nabla M\phi(m, n) \geq 1 + \nabla M\backslash(k, l) + /M\phi(m-k, n+1-l);$$
$$C(k, l): \quad \nabla M\phi(m, n) \geq 1 + \nabla M/(k, l-1) + \backslash M\phi(m+1-k, n+1-l);$$
$$A'(k, l): \quad \nabla M\phi(m, n) \geq 1 + \nabla M.(k-1, l) + .M\phi(m+1-k, n-l);$$
$$B'(k, l): \quad \nabla M\phi(m, n) \geq 1 + \nabla M\backslash(k-1, l) + /M\phi(m+1-k, n+1-l);$$
$$C'(k, l): \quad \nabla M\phi(m, n) \geq 1 + \nabla M/(k, l) + \backslash M\phi(m+1-k, n-l).$$

For fixed i and j, the oracle will adopt a strategy which maximizes the lower bound given by the righthand side; then we define $\nabla M\phi(m, n)$ to be the minimum of these lower bounds taken over $1 \leq i \leq m$ and $1 \leq j \leq n$. When m or n is zero, $\nabla M\phi(m, n)$ is zero.

For example, suppose that $m = 2$ and $n = 3$, and our oracle is unconstrained. If the first comparison is $A_1{:}B_1$, the oracle may adopt strategy $A'(1, 1)$, requiring $.M.(0, 1) + .M.(2, 2) = 3$ further comparisons. If the first comparison is $A_1{:}B_3$, the oracle may adopt strategy $B(1, 2)$, requiring $.M\backslash(1, 2) + /M.(1, 2) = 4$ further comparisons. No matter what comparison $A_i{:}B_j$ is made first, the oracle can guarantee that at least three further comparisons must be made. Hence $.M.(2, 3) = 4$.

It isn't easy to do these calculations by hand, but a computer can grind out tables of the $\nabla M\phi$ functions rather quickly. There are some obvious symmetries, e.g.,

$$/M.(m, n) = .M\backslash(m, n) = \backslash M.(n, m) = .M/(n, m), \tag{7}$$

by means of which we can reduce the nine functions to just four,

$$.M.(m, n), \qquad /M.(m, n), \qquad /M\backslash(m, n), \qquad \text{and} \qquad /M/(m, n).$$

Table 1 shows the resulting values for all $m, n \leq 10$; our merging oracle has been defined in such a way that

$$.M.(m, n) \leq M(m, n) \qquad \text{for all} \qquad m, n \geq 0. \tag{8}$$

This relation includes Theorem M as a special case, because our oracle will use the simple strategy of that theorem when $|m - n| \leq 1$.

Let us now consider some simple relations satisfied by the M function:

$$M(m, n) = M(n, m); \tag{9}$$
$$M(m, n) \leq M(m, n+1); \tag{10}$$
$$M(k+m, n) \leq M(k, n) + M(m, n); \tag{11}$$

$$M(m, n) \leq \max\left(M(m, n-1) + 1, M(m-1, n) + 1\right); \tag{12}$$

$$M(m, n) \leq \max\left(M(m, n-2) + 1, M(m-1, n) + 2\right), \text{ for } m \geq 1, n \geq 2. \tag{13}$$

Relation (12) comes from the usual merging procedure, if we first compare $A_1 : B_1$. Relation (13) is derived similarly, by first comparing $A_1 : B_2$; if $A_1 > B_2$, we need $M(m, n-2)$ more comparisons, but if $A_1 < B_2$, we can insert A_1 into its proper place and merge $\{A_2, \ldots, A_m\}$ with $\{B_1, \ldots, B_n\}$. Generalizing, we can see that

$$M(m, n) \leq \max\left(M(m, n-k) + 1, M(m-1, n) + 1 + \lceil \log_2 k \rceil\right),$$
$$\text{for} \qquad m \geq 1, \qquad n \geq k, \tag{14}$$

by first comparing $A_1 : B_k$ and using binary search if $A_1 < B_k$.

It turns out that $M(m, n) = .M.(m, n)$ for all $m, n \leq 10$, so Table 1 actually gives the optimum values for merging. This can be proved by using (9)–(14) together with special constructions for $(m, n) = (2, 8)$, $(3, 6)$, and $(5, 9)$ which are given in exercises 8, 9, and 10.

On the other hand, our oracle doesn't always give the best possible lower bounds; the simplest example is $m = 3$, $n = 11$, when $.M.(3, 11) = 9$ but $M(3, 11) = 10$. To see where the oracle has "failed" in this case, we must study the reasons for its decisions; further scrutiny reveals that if $(i, j) \neq (2, 6)$, the oracle can find a strategy which demands 10 comparisons; but when $(i, j) = (2, 6)$, no strategy beats Strategy $A(2, 4)$, leading to the lower bound $1 + .M.(2, 3) + .M.(1, 8) = 9$. It is necessary but not sufficient to finish by merging $\{A_1, A_2\}$ with $\{B_1, B_2, B_3\}$ and $\{A_3\}$ with $\{B_4, \ldots, B_{11}\}$, so the lower bound fails to be sharp in this case.

Similarly it can be shown that $.M.(2, 38) = 10$ while $M(2, 38) = 11$, so our oracle isn't good enough to solve the case $m = 2$. But there is an infinite class of values for which it excels:

Theorem K. $M(m, m + 2) = 2m + 1$ *for* $m \geq 2$;
$M(m, m + 3) = 2m + 2$ *for* $m \geq 4$;
$M(m, m + 4) = 2m + 3$ *for* $m \geq 6$.

Proof. We can in fact prove the result with M replaced by $.M.$; for small m the results have been obtained by computer, so we may assume that m is sufficiently large. We may also assume that the first comparison is $A_i:B_j$ where $i \leq \lceil m/2 \rceil$. If $j \leq i$ we use strategy $A'(i, i)$, obtaining

$$.M.(m, m+d) \geq 1 + .M.(i-1, i) + .M.(m+1-i, m+d-i) = 2m + d - 1$$

by induction on d, $d \leq 4$. If $j > i$ we use strategy $A(i, i + 1)$, obtaining

$$.M.(m, m + d) \geq 1 + .M.(i, i) + .M.(m - i, m + d - i) = 2m + d - 1$$

by induction on m. ∎

The first two parts of Theorem K were obtained by F. Hwang and S. Lin in 1969. This proof makes it reasonable to conjecture that $M(m, m + d) = 2m + d - 1$ for all sufficiently large m, when d is fixed. (Cf. exercise 6.)

Upper bounds. Now let us consider *upper* bounds for $M(m, n)$; good upper bounds correspond to efficient merging algorithms.

When $m = 1$ the merging problem is equivalent to an insertion problem, and there are $n + 1$ places in which A_1 might fall among $B_1, \ldots, B_n$. For this case it is easy to see that *any* extended binary tree with $n + 1$ external nodes is the tree for some merging method! (See exercise 2.) Hence we may choose an optimum binary tree, realizing the information-theoretic lower bound

$$1 + \lfloor \log_2 n \rfloor = M(1, n) = \lceil \log_2 (n + 1) \rceil. \tag{15}$$

Binary search (Section 6.2.1) is, of course, a simple way to attain this value.

The case $m = 2$ is extremely interesting, but considerably harder. It has

been solved completely by R. L. Graham, F. K. Hwang, and S. Lin (see exercises 11, 12, 13); we have

$$M(2, n) = \lceil \log_2 \tfrac{7}{12}(n+1) \rceil + \lceil \log_2 \tfrac{14}{17}(n+1) \rceil. \tag{16}$$

We have seen that the usual merging procedure is optimum when $m = n$, and the rather different binary search procedure is optimum when $m = 1$. What we need is an in-between method which combines the normal merging algorithm with binary search in such a way that the best features of both are retained. Formula (14) suggests the following merging algorithm, due to F. K. Hwang and S. Lin [*SIAM J. Computing* **1** (1972), 31–39]:

Algorithm H (*Binary merging*).

H1. If m or n is zero, stop. If $m \le n$, set $t \leftarrow \lfloor \log_2 (n/m) \rfloor$. If $m > n$, set $t \leftarrow \lfloor \log_2 (m/n) \rfloor$ and go to H4.

H2. Compare $A_m : B_{n+1-2^t}$. If A_m is smaller, set $n \leftarrow n - 2^t$ and return to step H1.

H3. Using binary search (which requires exactly t more comparisons), insert A_m into its proper place among $\{B_{n+1-2^t}, \ldots, B_n\}$. If k is maximal such that $B_k < A_m$, set $m \leftarrow m - 1$ and $n \leftarrow k$. Return to H1.

H4. (Steps H4 and H5 are like H2 and H3, interchanging the roles of m, n, A, B.) If $B_n < A_{m+1-2^t}$, set $m \leftarrow m - 2^t$ and return to step H1.

H5. Insert B_n into its proper place among the A's. If k is maximal such that $A_k < B_n$, set $m \leftarrow k$ and $n \leftarrow n - 1$. Return to H1. ∎

As an example of this algorithm, Table 2 shows the process of merging the three keys {087, 503, 512} with thirteen keys {061, 154, . . . , 908}; eight comparisons are required in this example.

Table 2

EXAMPLE OF BINARY MERGING

A (**boldface** elements are compared)			*B*												Output			
{087	503	512}	{051	154	170	275	426	509	612	653	677	703	765	897	908}

{087}			{061	154	170	275	426}		{503	509	512	612	653	677	703	765	897	908}
{087}			{061}		{154	170	275	426	503	509	512	612	653	677	703	765	897	908}
			{061	087	154	170	275	426	503	509	512	612	653	677	703	765	897	908}

Let $H(m, n)$ be the maximum number of comparisons required by Hwang and Lin's algorithm. To calculate $H(m, n)$, we may assume that $k = n$ in step H3 and $k = m$ in step H5, since it is not difficult to prove that $H(m, n) \le H(m, n+1)$ for all $n \ge m$ by induction on n. Thus when $m \le n$ we have

$$H(m, n) = \max\big(H(m, n - 2^t) + 1, \quad H(m - 1, n) + t + 1\big), \quad \text{for} \quad 2^t m \le n < 2^{t+1} m. \tag{17}$$

Replace n by $2n + \epsilon$, $\epsilon = 0$ or 1, to get

$$H(m, 2n + \epsilon) = \max\big(H(m, 2n + \epsilon - 2^{t+1}) + 1, \; H(m - 1, 2n + \epsilon) + t + 2\big), \quad \text{for} \quad 2^t m \le n < 2^{t+1} m;$$

whence it follows by induction on n that

$$H(m, 2n + \epsilon) = H(m, n) + m, \quad \text{for} \quad m \le n, \quad \epsilon = 0 \quad \text{or} \quad 1. \tag{18}$$

It is also easy to see that $H(m, n) = m + n - 1$ when $m \le n < 2m$; hence a repeated application of (18) yields the general formula

$$H(m, n) = m + \lfloor n/2^t \rfloor - 1 + tm, \quad \text{for} \quad m \le n, \quad t = \lfloor \log_2 (n/m) \rfloor. \tag{19}$$

Setting $m = \alpha n$ and $\theta = \log_2 (n/m) - t$ gives

$$H(\alpha n, n) = \alpha n(1 + 2^\theta - \theta - \log_2 \alpha) + O(1), \tag{20}$$

as $n \to \infty$. We know by Eq. 5.3.1–35 that $1.9139 < 1 + 2^\theta - \theta \le 2$; hence (20) may be compared with the information-theoretic lower bound (3). Hwang and Lin have proved (see exercise 17) that

$$H(m, n) < \left\lceil \log_2 \binom{m + n}{m} \right\rceil + \min(m, n). \tag{21}$$

The Hwang-Lin merging algorithm, which might be called "binary merging," does not always give optimum results, but it has the great virtue that it can be programmed rather easily. It reduces to "uncentered binary search" when $m = 1$, and it reduces to the usual merging procedure when $m \approx n$, so it represents an excellent compromise between those two methods. Furthermore, it *is* optimum in many cases (see exercise 16).

Formula (18) suggests that the M function itself might satisfy

$$M(m, n) \le M(m, \lfloor n/2 \rfloor) + m. \tag{22}$$

This is actually true (see exercise 19). Tables of $M(m, n)$ suggest several other plausible relations, such as

$$M(m + 1, n) \ge 1 + M(m, n) \ge M(m, n + 1), \quad \text{for} \quad m \le n; \tag{23}$$

$$M(m + 1, n + 1) \ge 2 + M(m, n); \tag{24}$$

but no proof of these inequalities is known.

EXERCISES

1. [*15*] Find an interesting relation between $M(m, n)$ and the function S defined in Section 5.3.1. [*Hint:* Consider $S(m + n)$.]

▶ **2.** [*22*] When $m = 1$, every merging algorithm without redundant comparisons defines an extended binary tree with $\binom{m+n}{m} = n + 1$ external nodes. Prove that, conversely, every extended binary tree with $n + 1$ external nodes corresponds to some merging algorithm with $m = 1$.

3. [*M24*] Prove that $.M.(1, n) = M(1, n)$ for all n.

4. [*M44*] Is $.M.(m, n) \geq \lceil \log_2 \binom{m+n}{m} \rceil$ for all m and n?

5. [*M30*] Prove that $.M.(m, n) \leq .M\backslash(m, n + 1)$.

6. [*M26*] The stated proof of Theorem K requires that a lot of cases be verified by computer. How can the number of such cases be drastically reduced?

7. [*21*] Prove (11).

▶ **8.** [*24*] Prove that $M(2, 8) \leq 6$, by finding an algorithm which merges two elements with eight others using at most six comparisons.

9. [*27*] Prove that three elements can be merged with six in at most seven steps.

10. [*33*] Prove that five elements can be merged with nine in at most twelve steps. [*Hint:* Experience with the oracle suggests starting by comparing $A_1 : B_2$, then if $A_1 < B_2$ trying $A_5 : B_8$.]

11. [*M40*] (F. Hwang, S. Lin.) Let $g_{2k} = \lfloor 2^k \cdot \frac{17}{14} \rfloor$, $g_{2k+1} = \lfloor 2^k \cdot \frac{12}{7} \rfloor$, for $k \geq 0$, so that we have $(g_0, g_1, g_2, \ldots) = (1, 1, 2, 3, 4, 6, 9, 13, 19, 27, 38, 54, 77, \ldots)$. Prove that it takes more than t comparisons to merge two elements with g_t elements, in the worst case; but two elements can be merged with $g_t - 1$ in at most t steps. [*Hint:* Show that if $n \geq g_{t-1}$ and if we want to merge $\{A_1, A_2\}$ with $\{B_1, B_2, \ldots, B_n\}$ in t comparisons, we can't do better than to compare $A_2 : B_{g_{t-1}}$ on the first step.]

12. [*M21*] Let $R_n(i, j)$ be the least number of comparisons required to sort the distinct objects $\{\alpha, \beta, X_1, X_2, \ldots, X_n\}$, given the relations

$$\alpha < \beta, \qquad X_1 < X_2 < \cdots < X_n, \qquad \alpha < X_{i+1}, \qquad \beta > X_{n-j}.$$

(The condition $\alpha < X_{i+1}$ or $\beta > X_{n-j}$ becomes vacuous when $i \geq n$ or $j \geq n$. Therefore $R_n(n, n) = M(2, n)$.)

Clearly, $R_n(0, 0) = 0$. Prove that

$$R_n(i, j) = 1 + \min\Big(\min_{1 \leq k \leq i} \max\big(R_n(k-1, j), R_{n-k}(i-k, j)\big), \min_{1 \leq k \leq j} \max\big(R_n(i, k-1), R_{n-k}(i, j-k)\big)\Big)$$

for $0 \leq i \leq n$, $0 \leq j \leq n$, $i + j > 0$.

13. [*M42*] (R. L. Graham.) Show that the solution to the recurrence in exercise 12 may be expressed as follows. Define the function $G(x)$, for $0 < x < \infty$, by the rules

$$G(x) = \begin{cases} 1, & 0 < x \leq \frac{5}{7}; \\ \frac{1}{2} + \frac{1}{8}G(8x - 5), & \frac{5}{7} < x \leq \frac{3}{4}; \\ \frac{1}{2}G(2x - 1), & \frac{3}{4} < x \leq 1; \\ 0, & 1 < x < \infty. \end{cases}$$

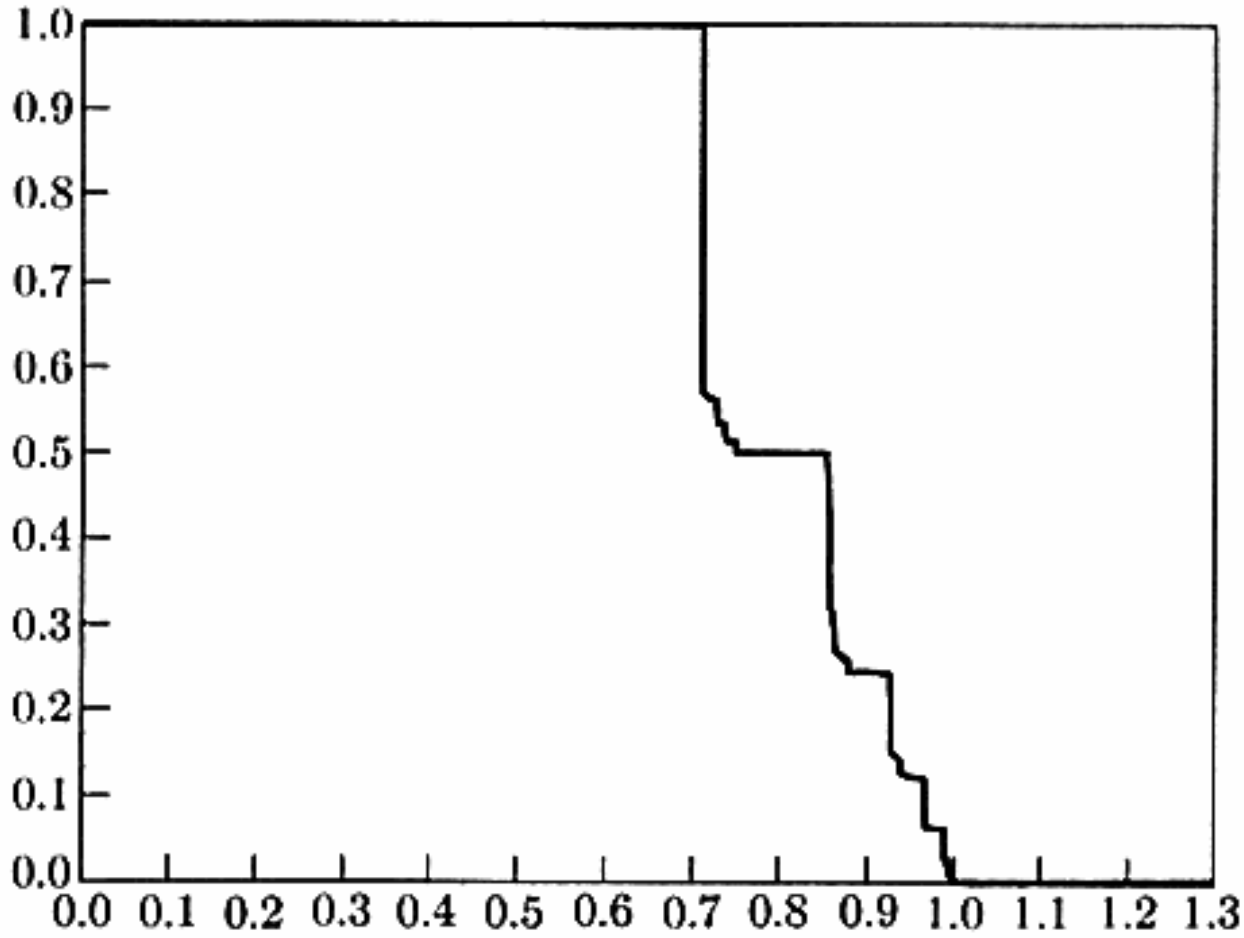

Fig. 38. Graham's function (see exercise 13).

(See Fig. 38.) Since $R_n(i, j) = R_n(j, i)$ and since $R_n(0, j) = M(1, j)$, we may assume that $1 \le i \le j \le n$. Let $p = \lfloor \log_2 i \rfloor$, $q = \lfloor \log_2 j \rfloor$, $r = \lfloor \log_2 n \rfloor$, and let $t = n - 2^r + 1$. Then

$$R_n(i, j) = p + q + S_n(i, j) + T_n(i, j),$$

where S_n and T_n are functions which are either 0 or 1:

$$S_n(i, j) = 1 \quad \text{if and only if } q < r \text{ or } (i - 2^p \ge u \text{ and } j - 2^r \ge u),$$
$$T_n(i, j) = 1 \quad \text{if and only if } p < r \text{ or } (t > \tfrac{6}{7}2^{r-2} \text{ and } i - 2^r \ge v),$$

where $u = 2^p G(t/2^p)$ and $v = 2^{r-2} G(t/2^{r-2})$.

(This may be the most formidable recurrence relation that will ever be solved!)

14. [*46*] (Hwang and Lin.) Let $h_{3k} = 2^k + 2^{k-1} - 1$, $h_{3k+1} = g_{2k} + g_{2k-3} + 2^{k-2}$, $h_{3k+2} = 2g_{2k}$, for $k \ge 2$, except that $h_8 = 9$, with initial values adjusted so that we have $(h_0, h_1, h_2, \ldots) = (1, 1, 2, 2, 3, 4, 5, 7, 9, 11, 14, 18, 23, 29, 38, 47, 59, 76, \ldots)$. Here g_k is the function defined in exercise 11. Prove (or disprove) that $M(3, h_t) > t$, $M(3, h_t - 1) \le t$, for all t.

15. [*12*] Step H1 of the binary merge algorithm may require the calculation of $\lfloor \log_2 (n/m) \rfloor$. Explain how to compute this easily without division or calculation of a logarithm.

16. [*18*] For which m and n is Hwang and Lin's binary merging algorithm optimum, for $1 \le m \le n \le 10$?

17. [*M25*] Prove (21). [*Hint:* The inequality isn't very tight.]

18. [*M40*] Study the *average* number of comparisons used by binary merge.

▶ **19.** [*23*] Prove that the M function satisfies (22).

20. [*20*] Show that if $M(m, n+1) \le M(m+1, n)$ for all $m \le n$, then $M(m, n+1) \le 1 + M(m, n)$ for all $m \le n$.

21. [*M47*] Prove or disprove (23), (24).

22. [*M50*] Study the minimum *average* number of comparisons needed to merge m things with n.

23. [*HM30*] (E. Reingold.) Let $\{A_1, \ldots, A_n\}$ and $\{B_1, \ldots, B_n\}$ be sets containing n elements each. Consider an algorithm which attempts to test *equality* of these two sets solely by making comparisons for equality between elements. Thus, the algorithm asks questions of the form "Is $A_i = B_j$?" for certain i and j, and it branches depending on whether the answer is yes or no.

By defining a suitable oracle, prove that any such algorithm must make at least $\frac{1}{2}n(n+1)$ comparisons in its worst case.

*5.3.3. Minimum-Comparison Selection

A similar class of interesting problems arises when we look for best possible procedures to select the tth largest of n elements.

The history of this question goes back to Rev. C. L. Dodgson's amusing (though serious) essay on lawn tennis tournaments which appeared in *St. James's Gazette*, August 1, 1883, pp. 5–6. Dodgson, who is of course better known as Lewis Carroll, was concerned about the unjust manner in which prizes were (and still are) awarded in tennis tournaments. Consider, for example, Fig. 39 which shows a typical "knockout tournament" between 32 players labeled *01*, *02*, . . . , *32*. In the "finals," player *01* defeats player *05*, so it is clear that player *01* is the champion and he deserves first prize. The inequity arises in connection with the fact that player *05* usually gets second prize, although he may not be the second-best player. It is possible to win second prize even if you are worse than half of the players in the tournament. In fact, as Dodgson observed, the second-best player wins second prize if and only if he and the champion are originally in opposite halves of the tournament; for 2^n players this occurs with probability $2^{n-1}/(2^n - 1)$, so the wrong player receives second prize almost half of the time! If the losers of the semifinal round (players *25* and *17* in Fig. 39) compete for third prize, it is highly unlikely that the third-best player receives third prize.

Dodgson therefore set out to design a tournament that determines the true second- and third-best players, assuming a transitive ranking. (In other words if player A beats player B, and B beats C, then we may assume that A would beat C.) He devised a procedure in which losers are allowed to play further games until they are known to be definitely inferior to three other players. An example of Dodgson's scheme appears in Fig. 40, which is a supplementary tournament to be run in conjunction with Fig. 39. An attempt is made to pair off players with equal records so far, and to avoid matches in which both players have been defeated by the same man. For example, *16* loses to *11* and *13* loses to *12* in Round 1; after *16* loses to *13* in the second round, *16* is eliminated since he is now known to be inferior to *11*, *12*, and *13*. In Round 3 we do not allow *19* to play with *21*, since they have both been defeated by *18* and we could not automatically eliminate the loser of *19* vs. *21*.

It would be nice to report that Lewis Carroll's tournament turns out to be

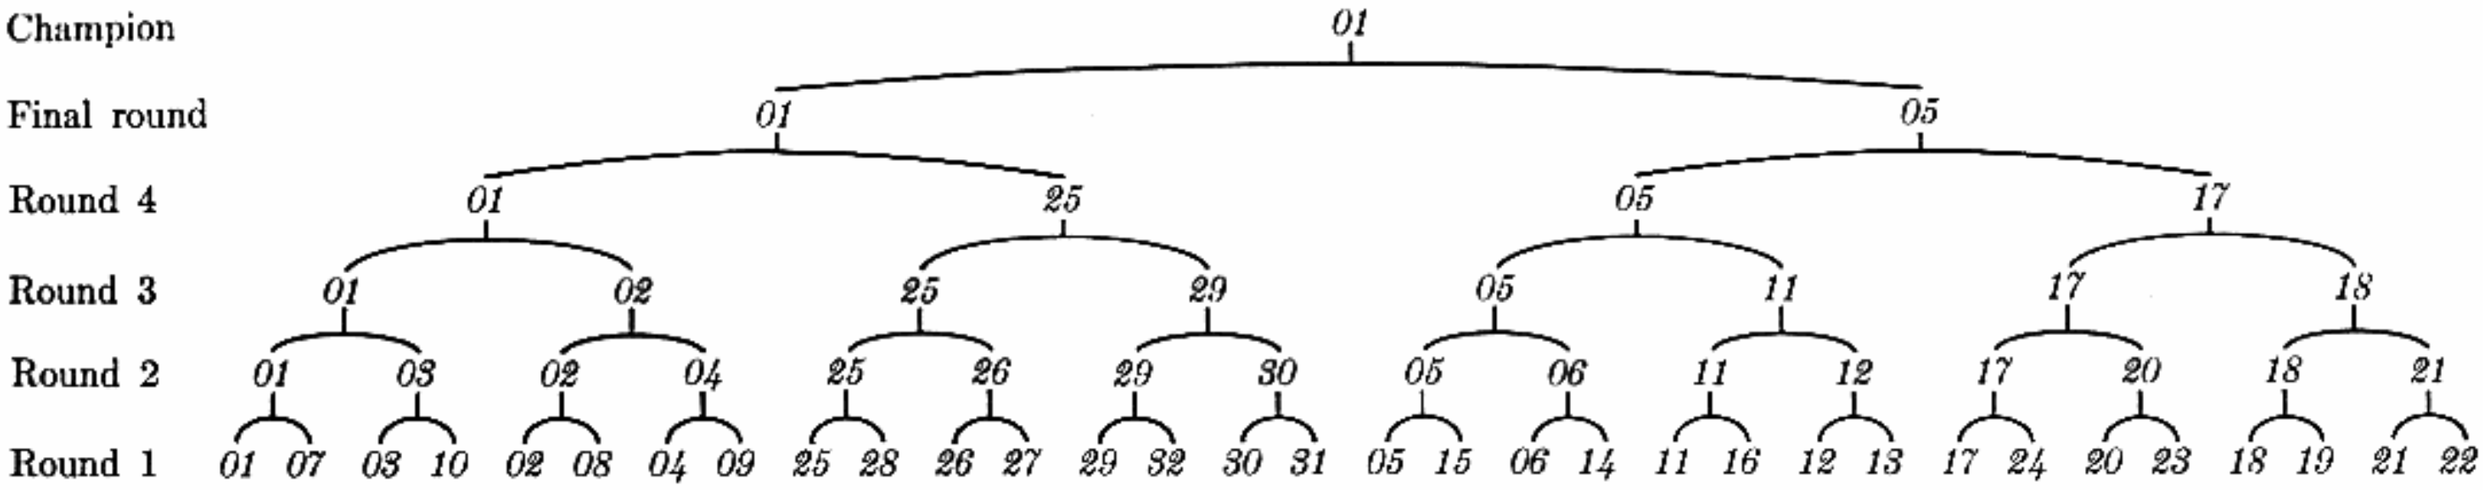

Fig. 39. A knockout tournament with 32 players.

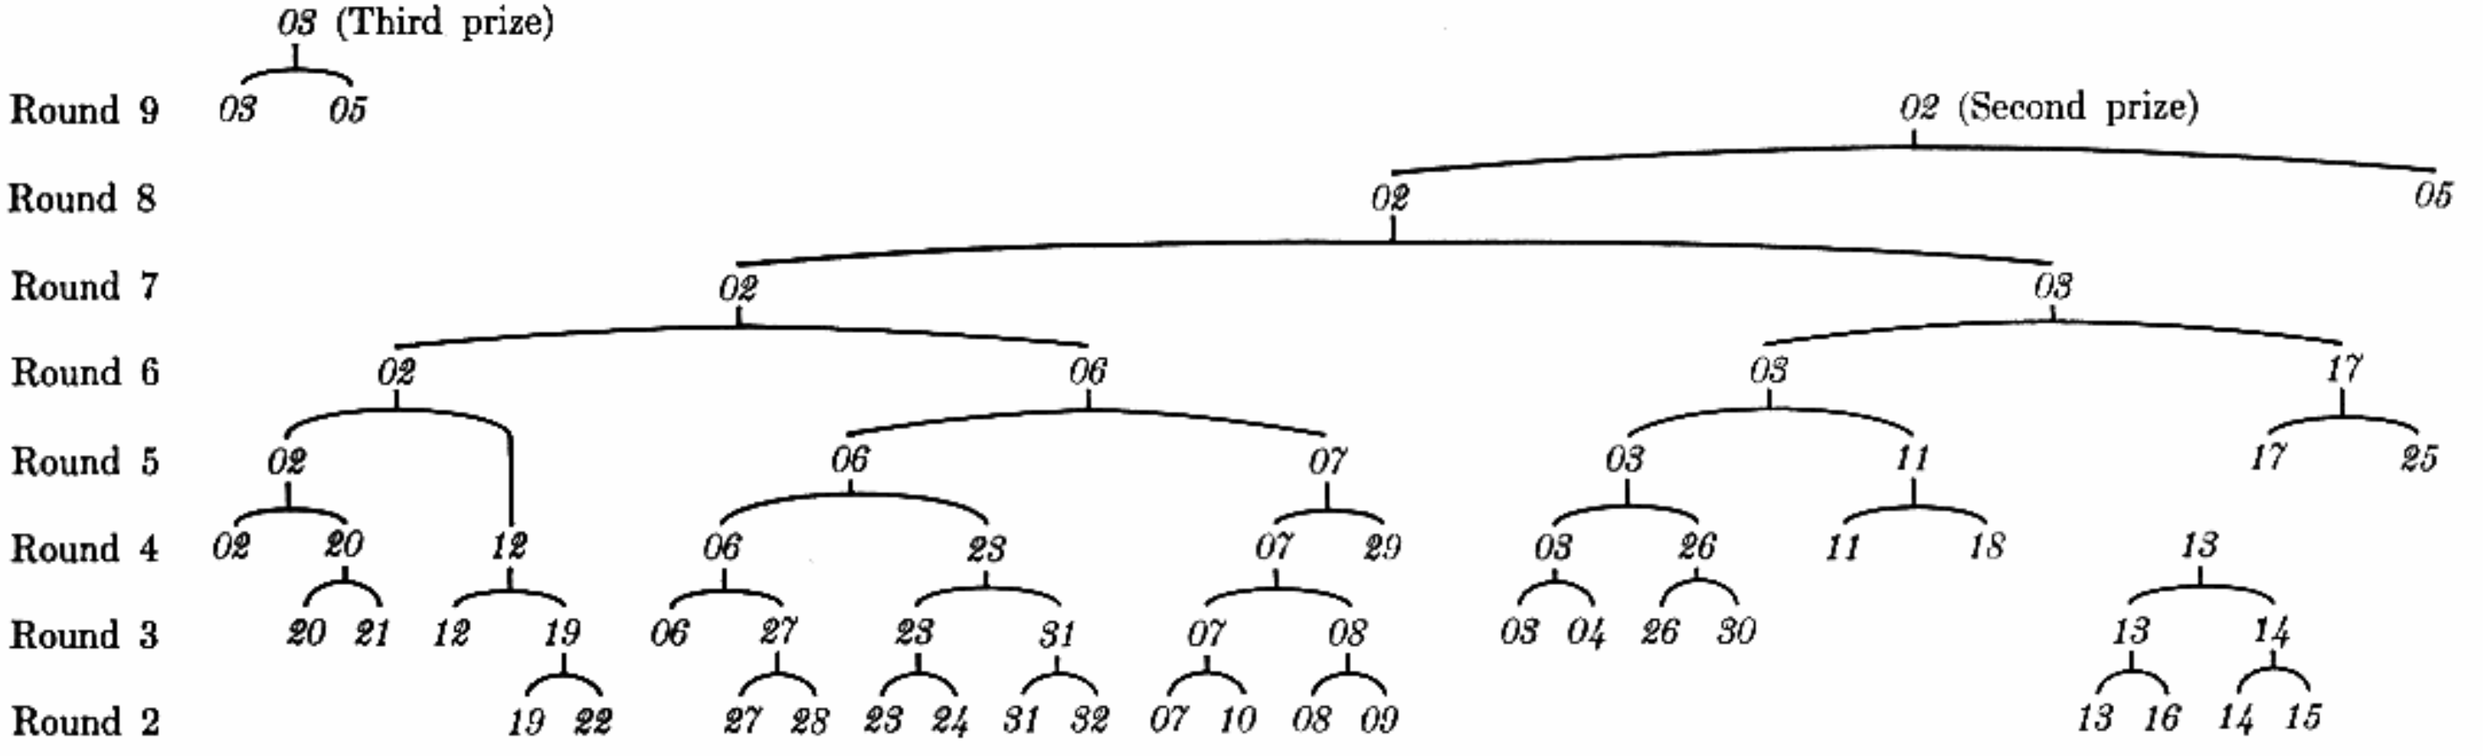

Fig. 40. Lewis Carroll's lawn tennis tournament (played in conjunction with Fig. 39).

optimal, but unfortunately that is not the case. His diary entry for July 23, 1883, says that he composed the essay in about six hours, and he felt "we are now so late in the (tennis) season that it is better it should appear soon than be written well." His procedure makes more comparisons than necessary, and it is not formulated precisely enough to qualify as an algorithm. On the other hand, it has some rather interesting aspects from the standpoint of parallel computation. And it appears to be an excellent plan for a tennis tournament, because he built in some dramatic effects; for example, he specified that the two finalists should sit out round 5, playing an extended match during rounds 6 and 7. But tournament directors presumably thought the proposal was too logical, and so Carroll's system has apparently never been tried. Instead a method of "seeding" is used to keep the best players in different parts of the tree.

In a mathematical seminar during 1929–1930, Hugo Steinhaus posed the problem of finding the *minimum* number of tennis matches required to determine the first and second best players in a tournament, when there are $n \geq 2$ players in all. J. Schreier [*Mathesis Polska* **7** (1932), 154–160] gave a procedure which requires at most $n - 2 + \lceil \log_2 n \rceil$ matches, using essentially the same method as the first two stages in what we have called tree selection sorting (cf. Section 5.2.3, Fig. 23), avoiding redundant comparisons that involve $-\infty$. Schreier also claimed that $n - 2 + \lceil \log_2 n \rceil$ is best possible, but his proof was incorrect, as was another attempted proof by J. Słupecki [*Colloquium Mathematicum* **2** (1951), 286–290]. Thirty-two years went by before a correct, although rather complicated, proof was finally published by S. S. Kislitsyn [*Sibirskiĭ Mat. Zhurnal* **5** (1964), 557–564].

Let $V_t(n)$ denote the minimum number of comparisons needed to determine the tth largest of n elements, for $1 \leq t \leq n$, and let $W_t(n)$ be the minimum number required to determine the largest, second largest, . . . , and tth largest, collectively. By symmetry, we have

$$V_t(n) = V_{n+1-t}(n), \tag{1}$$

and it is obvious that

$$V_1(n) = W_1(n), \tag{2}$$
$$V_t(n) \leq W_t(n), \tag{3}$$
$$W_n(n) = W_{n-1}(n) = S(n). \tag{4}$$

We have observed in Section 5.2.3 that

$$V_1(n) = n - 1. \tag{5}$$

In fact, there is an astonishingly simple proof of this fact, since everyone in a tournament except the champion must lose at least one game! By extending this idea and using an "oracle," we can prove the Schreier-Kislitsyn theorem without much difficulty:

Theorem S. $V_2(n) = W_2(n) = n - 2 + \lceil \log_2 n \rceil$, for $n \geq 2$.

Proof. Assume that n players have participated in a tournament which has determined the second-best player by some given procedure, and let a_j be the number of players who have lost j or more matches. The total number of matches played is then $a_1 + a_2 + a_3 + \cdots$. We cannot determine the second-best player without also determining the champion (cf. exercise 2), so our previous argument shows that $a_1 = n - 1$. To complete the proof, we will show that there is always some sequence of outcomes of the matches which makes $a_2 \geq \lceil \log_2 n \rceil - 1$.

Suppose that at the end of the tournament the champion has played (and beaten) p players; one of these is the second best, and the others must have lost at least one other time, so $a_2 \geq p - 1$. Therefore we can complete the proof by finding an oracle who decides the results of the games in such a way that the champion must play at least $\lceil \log_2 n \rceil$ other people.

Let the oracle declare A to be better than B if A is previously undefeated and B has lost at least once, or if both are undefeated and B has won fewer matches than A at that time. In other circumstances the oracle may make an arbitrary decision consistent with some partial ordering.

Consider the outcome of a complete tournament whose matches have been decided by such an oracle. Let us say that "A supersedes B" if and only if $A = B$ or A supersedes the player who first defeated B. (Only a player's first defeat is relevant in this relation, his subsequent games are ignored. According to the mechanism of the oracle, any player who *first* defeats another must be previously unbeaten.) It follows that a player who won his first p matches supersedes at most 2^p players on the basis of those p contests. (The latter is clear for $p = 0$, and for $p > 0$ the pth match was against someone who was either previously beaten or who supersedes at most 2^{p-1} players.) The champion supersedes everyone, so he must have played at least $\lceil \log_2 n \rceil$ matches. ∎

Thus the problem of finding the second largest is completely resolved in the minimax sense. Exercise 6 shows, in fact, that it is possible to give a simple formula for the minimum number of comparisons needed to find the second largest element of a set when an arbitrary partial ordering of the elements is known.

What if t > 2? In the paper cited above, Kislitsyn went on to consider larger values of t, proving that

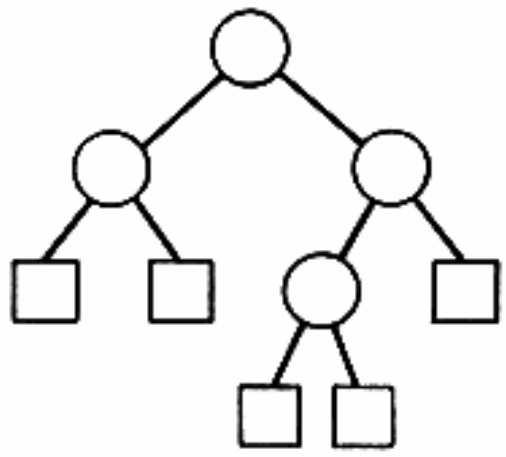
$$W_t(n) \leq n - t + \sum_{n+1-t<j\leq n} \lceil \log_2 j \rceil, \qquad \text{for} \qquad n \geq t. \tag{6}$$

For $t = 1$ and $t = 2$ we have seen that equality actually holds in this formula; for $t = 3$ it can be slightly improved (see exercise 21).

We shall prove Kislitsyn's theorem by showing that the first t stages of *tree selection* require at most $n - t + \sum_{n+1-t<j\leq n} \lceil \log_2 j \rceil$ comparisons (ignoring all of the comparisons which involve $-\infty$). It is interesting to note that the

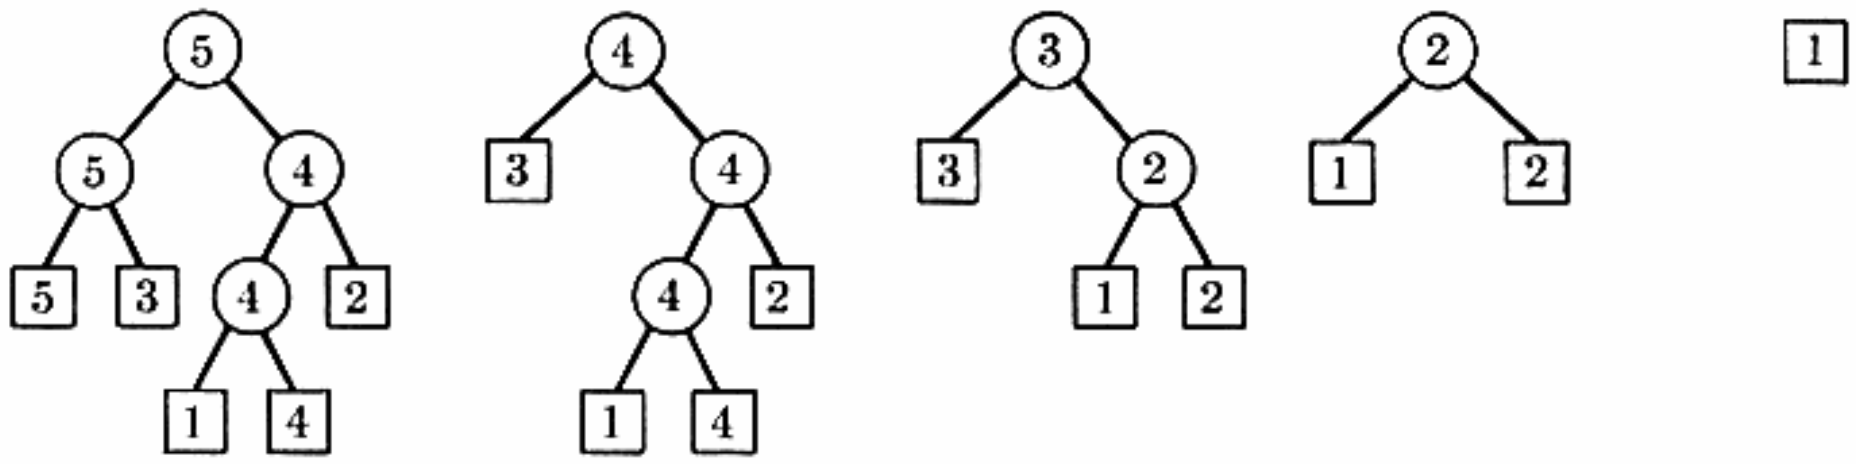
right-hand side of (6) equals $B(n)$ when $t = n - 1$ and $t = n$ (see Eq. 5.3.1–3); hence tree selection and binary insertion yield the same upper bound for the sorting problem, although they are quite different methods.

Let α be an extended binary tree with n external nodes, and let π be a permutation of $\{1, 2, \ldots, n\}$. Place the elements of π into the external nodes, from left to right in symmetric order, and fill in the internal nodes according to the rules of a knockout tournament as in tree selection. When the resulting tree is subjected to repeated selection operations, it defines a sequence $c_{n-1}\ c_{n-2} \ldots c_1$, where c_j is the number of comparisons required to bring element j to the root of the tree when element $j + 1$ has been replaced by $-\infty$. For example, if α is the tree



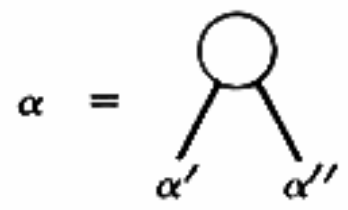
(7)

and if $\pi = 5\ 3\ 1\ 4\ 2$, we obtain the successive trees



If π had been $3\ 1\ 5\ 4\ 2$, the sequence $c_4\ c_3\ c_2\ c_1$ would have been $2\ 1\ 1\ 0$ instead. It is easy to see that c_1 is always zero.

Let $\mu(\alpha, \pi)$ be the multiset $\{c_{n-1}, c_{n-2}, \ldots, c_1\}$ determined by α and π. If



and if elements 1 and 2 do not both appear in α' or both in α'', it is easy to see that

$$\mu(\alpha, \pi) = (\mu(\alpha', \pi') + 1) \uplus (\mu(\alpha'', \pi'') + 1) \uplus \{0\} \tag{8}$$

for appropriate permutations π' and π'', where $(\mu + 1)$ denotes the multiset obtained by adding 1 to each element of μ. On the other hand, if elements 1 and 2 both appear in α', we have

$$\mu(\alpha, \pi) = (\mu(\alpha', \pi') + \epsilon) \uplus (\mu(\alpha'', \pi'') + 1) \uplus \{0\},$$

where $(\mu + \epsilon)$ denotes some multiset obtained by adding 1 to some elements of μ and 0 to the others. A similar formula holds when 1 and 2 both appear in α''. Let us say that multiset μ_1 *dominates* μ_2 if both μ_1 and μ_2 contain the same number of elements, and the kth largest element of μ_1 is greater than or equal to the kth largest element of μ_2 for all k; and let us define $\mu(\alpha)$ to be the "dominant" $\mu(\alpha, \pi)$, taken over all permutations π, in the sense that $\mu(\alpha)$ dominates $\mu(\alpha, \pi)$ for all π and $\mu(\alpha) = \mu(\alpha, \pi)$ for some π. The above formulas show that

$$\mu(\Box) = \emptyset, \qquad \mu\left(\begin{smallmatrix} & \bigcirc & \\ \alpha' & & \alpha'' \end{smallmatrix}\right) = (\mu(\alpha') + 1) \uplus (\mu(\alpha'') + 1) \uplus \{0\}; \tag{9}$$

hence $\mu(\alpha)$ *is the multiset of all distances from the root to the internal nodes of* α.

The reader who has followed the above train of thought will now see that we are ready to prove Kislitsyn's theorem (6); for $W_t(n)$ is less than or equal to $n - 1$ plus the $t - 1$ largest elements of $\mu(\alpha)$, where α is any tree being used in tree selection sorting. We may take α to be the complete binary tree with n external nodes (cf. Section 2.3.4.5), when

$$\begin{aligned} \mu(\alpha) &= \{\lfloor \log_2 1 \rfloor, \lfloor \log_2 2 \rfloor, \ldots, \lfloor \log_2 (n-1) \rfloor\} \\ &= \{\lceil \log_2 2 \rceil - 1, \lceil \log_2 3 \rceil - 1, \ldots, \lceil \log_2 n \rceil - 1\}. \end{aligned} \tag{10}$$

We obtain formula (6) when we consider the $t - 1$ largest elements of this multiset.

Kislitsyn's theorem gives a good upper bound for $W_t(n)$; he remarked that $V_3(5) = 6 < W_3(5) = 7$, but he was unable to find a better bound for $V_t(n)$, in general. A. Hadian and M. Sobel discovered a way to do this using *replacement selection* instead of tree selection (cf. Section 5.4.1). Their formula [Univ. of Minnesota, Dept. of Statistics, report 121 (May, 1969)],

$$V_t(n) \le n - t + (t-1)\lceil \log_2 (n + 2 - t) \rceil, \qquad n \ge t, \tag{11}$$

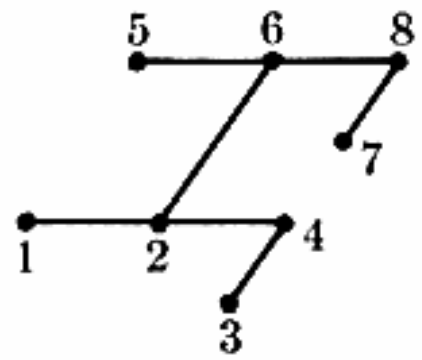
differs from (6) in that each element in the sum of (6) is replaced by the smallest element.

Hadian and Sobel's theorem (11) can be proved by using the following construction: First set up a binary tree for a knockout tournament on $n - t + 2$ items. (This takes $n - t + 1$ comparisons.) The largest item is greater than $n - t + 1$ others, so it can't be tth largest. Replace it, where it appears at an external node of the tree, by one of the $t - 2$ elements held in reserve, and find the largest element of the resulting $n - t + 2$; this requires at most $\lceil \log_2 (n + 2 - t) \rceil$ comparisons, because we need to recompute only one path in the tree. Repeat this operation $t - 2$ times in all, for each element held in reserve. Finally, replace the currently largest element by $-\infty$, and determine the largest of the remaining $n + 1 - t$; this requires at most $\lceil \log_2 (n + 2 - t) \rceil - 1$ comparisons, and it brings the tth largest element of the original set to the root of the tree. Summing the comparisons yields (11).

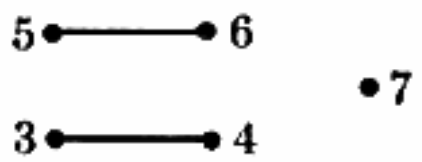
In relation (11) we should of course replace t by $n + 1 - t$ on the right-hand side whenever $n + 1 - t$ gives a better value (as when $n = 6$, $t = 3$).

Curiously, the formula gives a smaller bound for $V_7(13)$ than it does for $V_6(13)$. The upper bound in (11) is exact for $n \leq 6$, but as n and t get larger it is possible to obtain much better estimates of $V_t(n)$.

For example, the following elegant method (due to David G. Doren) can be used to show that $V_4(8) \leq 12$. Let the elements be $X_1, \ldots, X_8$; first compare $X_1{:}X_2$ and $X_3{:}X_4$ and the two winners, and do the same to $X_5{:}X_6$ and $X_7{:}X_8$ and their winners. Relabel elements so that $X_1 < X_2 < X_4 > X_3$, $X_5 < X_6 < X_8 > X_7$, then compare $X_2{:}X_6$; by symmetry assume that $X_2 < X_6$, so that we have the configuration



(Now X_1 and X_8 are out of contention and we must find the third largest of $\{X_2, \ldots, X_7\}$.) Compare $X_2{:}X_7$, and discard the smaller; in the worst case we have $X_2 < X_7$ and we must find the third largest of



This can be done in $V_3(5) - 2 = 4$ more steps, since the $V_3(5) = 6$ procedure of (11) begins by comparing two disjoint pairs of elements.

Other tricks of this kind can be used to produce the results shown in Table 1; no general method is evident as yet, and the values listed in the table for $n \geq 8$ may be subject to further improvement. Note that $V_3(10) \leq 14$, so (11) does not always give equality when $t = 3$. The fact that $V_4(7) = 10$ shows that (11) is already off by 2 when $n = 7$.

*Exercises 10–12 give constructions which improve on Eq. (11) in these cases.

A linear method. When n is odd and $t = \lceil n/2 \rceil$, the tth largest (and tth smallest) element is called the median. According to (11), we can find the median of n elements in $\approx \frac{1}{2} n \log_2 n$ comparisons; but this is only about twice as fast as sorting, even though we are asking for much less information. For several years, concerted efforts were made by a number of people to find an improvement over (11) when t and n are large; finally in 1971, Manuel Blum discovered a method which needed only $O(n \log \log n)$ steps. Blum's approach to the problem suggested a new class of techniques which led to the following construction due to R. Rivest and R. Tarjan:

Theorem L. $V_t(n) \leq 15n - 163$ *for* $1 \leq t \leq n$, *when* $n > 32$.

Proof. The theorem is trivial when n is small, since $V_t(n) \leq S(n) \leq 10n \leq 15n - 163$ for $32 < n \leq 2^{10}$. By adding at most 13 dummy "$-\infty$" elements, we may assume that $n = 7(2q + 1)$ for some integer $q \geq 73$. The following method may now be used to select the tth largest:

Step 1. Divide the elements into $2q + 1$ groups of seven elements each, and sort each of the groups. This takes at most $13(2q + 1)$ comparisons.

Step 2. Find the median of the $2q + 1$ median elements obtained in Step 1, and call it x. By induction on q, this takes at most $V_{q+1}(2q + 1) \leq 30q - 148$ comparisons.

Step 3. The $n - 1$ elements other than x have now been partitioned into three sets (see Fig. 41):

$4q + 3$ elements known to be greater than x (Region B);
$4q + 3$ elements known to be less than x (Region C);
$6q$ elements whose relation to x is unknown (Regions A, D).

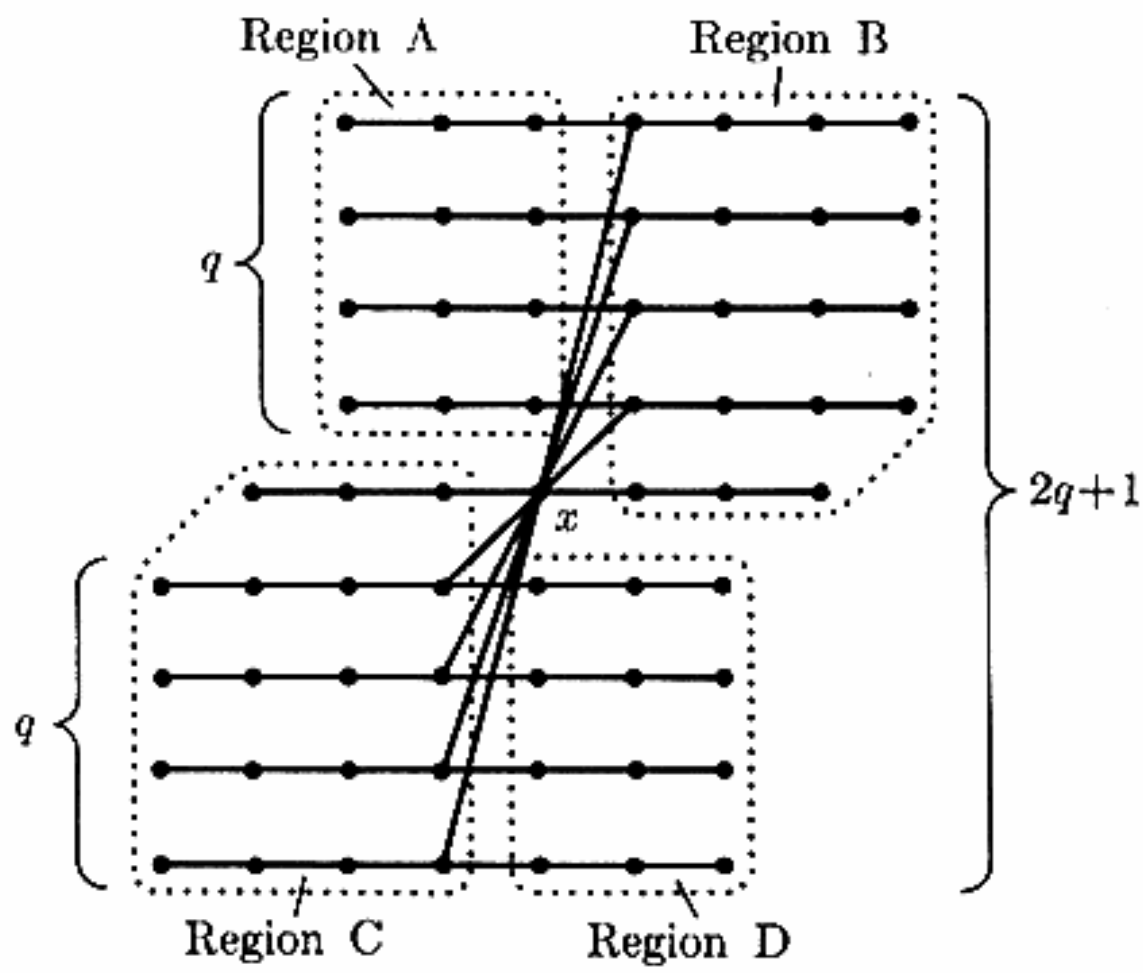

Fig. 41. The selection algorithm of Rivest and Tarjan ($q = 4$).

By making $4q$ additional comparisons, we can tell exactly which of the elements in regions A and D are less than x. (We first test x against the middle element of each triple.)

Step 4. We have now found r elements greater than x and $n - 1 - r$ elements less than x, for some r. If $t = r + 1$, x is the answer; if $t < r + 1$, we need to find the tth largest of the r large elements; and if $t > r + 1$, we need to find the $(t - 1 - r)$th largest of the $n - 1 - r$ small elements. The point is that r and $n - 1 - r$ are both less than or equal to $10q + 3$ (the size of regions A and D, plus either B or C). By induction on q this step therefore requires at most $15(10q + 3) - 163$ comparisons.

The total number of comparisons comes to at most

$$13(2q + 1) + 30q - 148 + 4q + 15(10q + 3) - 163 = 15(14q - 6) - 163.$$

Since we started with at least $14q - 6$ elements, the proof is complete. ∎

The method used in this proof is a little crude because it throws away good information in Step 4. Careful refinements by V. Pratt, R. Rivest, and R. Tarjan have shown that the constant 15 can be reduced to 5.43.

The average number. Instead of minimizing the *maximum* number of comparisons, we can ask instead for an algorithm which minimizes the *average* number of comparisons, assuming random order. As usual, this problem is considerably harder, and it is still unsolved even in the case $t = 2$. Claude Picard mentioned the problem in his book *Théorie des Questionnaires* (1965), and an extensive exploration was undertaken by Milton Sobel [*Univ. of Minnesota, Dept. of Statistics*, report 113 (November, 1968)].

Sobel constructed the procedure of Fig. 42, which finds the second largest of six elements using only $6\frac{1}{2}$ comparisons on the average. In the worst case, 8 comparisons are required, and this is worse than $V_2(6) = 7$; but all known procedures for this problem which require at most 7 comparisons use at least $6\frac{2}{3}$ comparisons on the average. Thus it is likely that no procedure which finds the second largest of six elements will be optimal in both the minimax and the minimean senses simultaneously.

Let $\overline{V}_t(n)$ denote the minimum average number of comparisons needed to find the tth largest of n elements. The following table shows the best upper bounds known for $\overline{V}_2(n)$, as computed by Sobel:

$$\begin{array}{rccccccccc} n = & 2 & 3 & 4 & 5 & 6 & 7 & 8 & 9 & 10 \\ \overline{V}_2(n) \le & 1 & 2\frac{2}{3} & 4 & 5\frac{4}{15} & 6\frac{1}{2} & 7\frac{17}{21} & 9 & 10\frac{1}{15} & 11\frac{4}{135} \end{array} \tag{12}$$

Sobel has conjectured that

$$\overline{V}_2(n) \ge n - 2 + \lfloor 2 \log_2 n \rfloor / 2. \tag{13}$$

R. W. Floyd discovered in 1970 that the median of n elements can be found

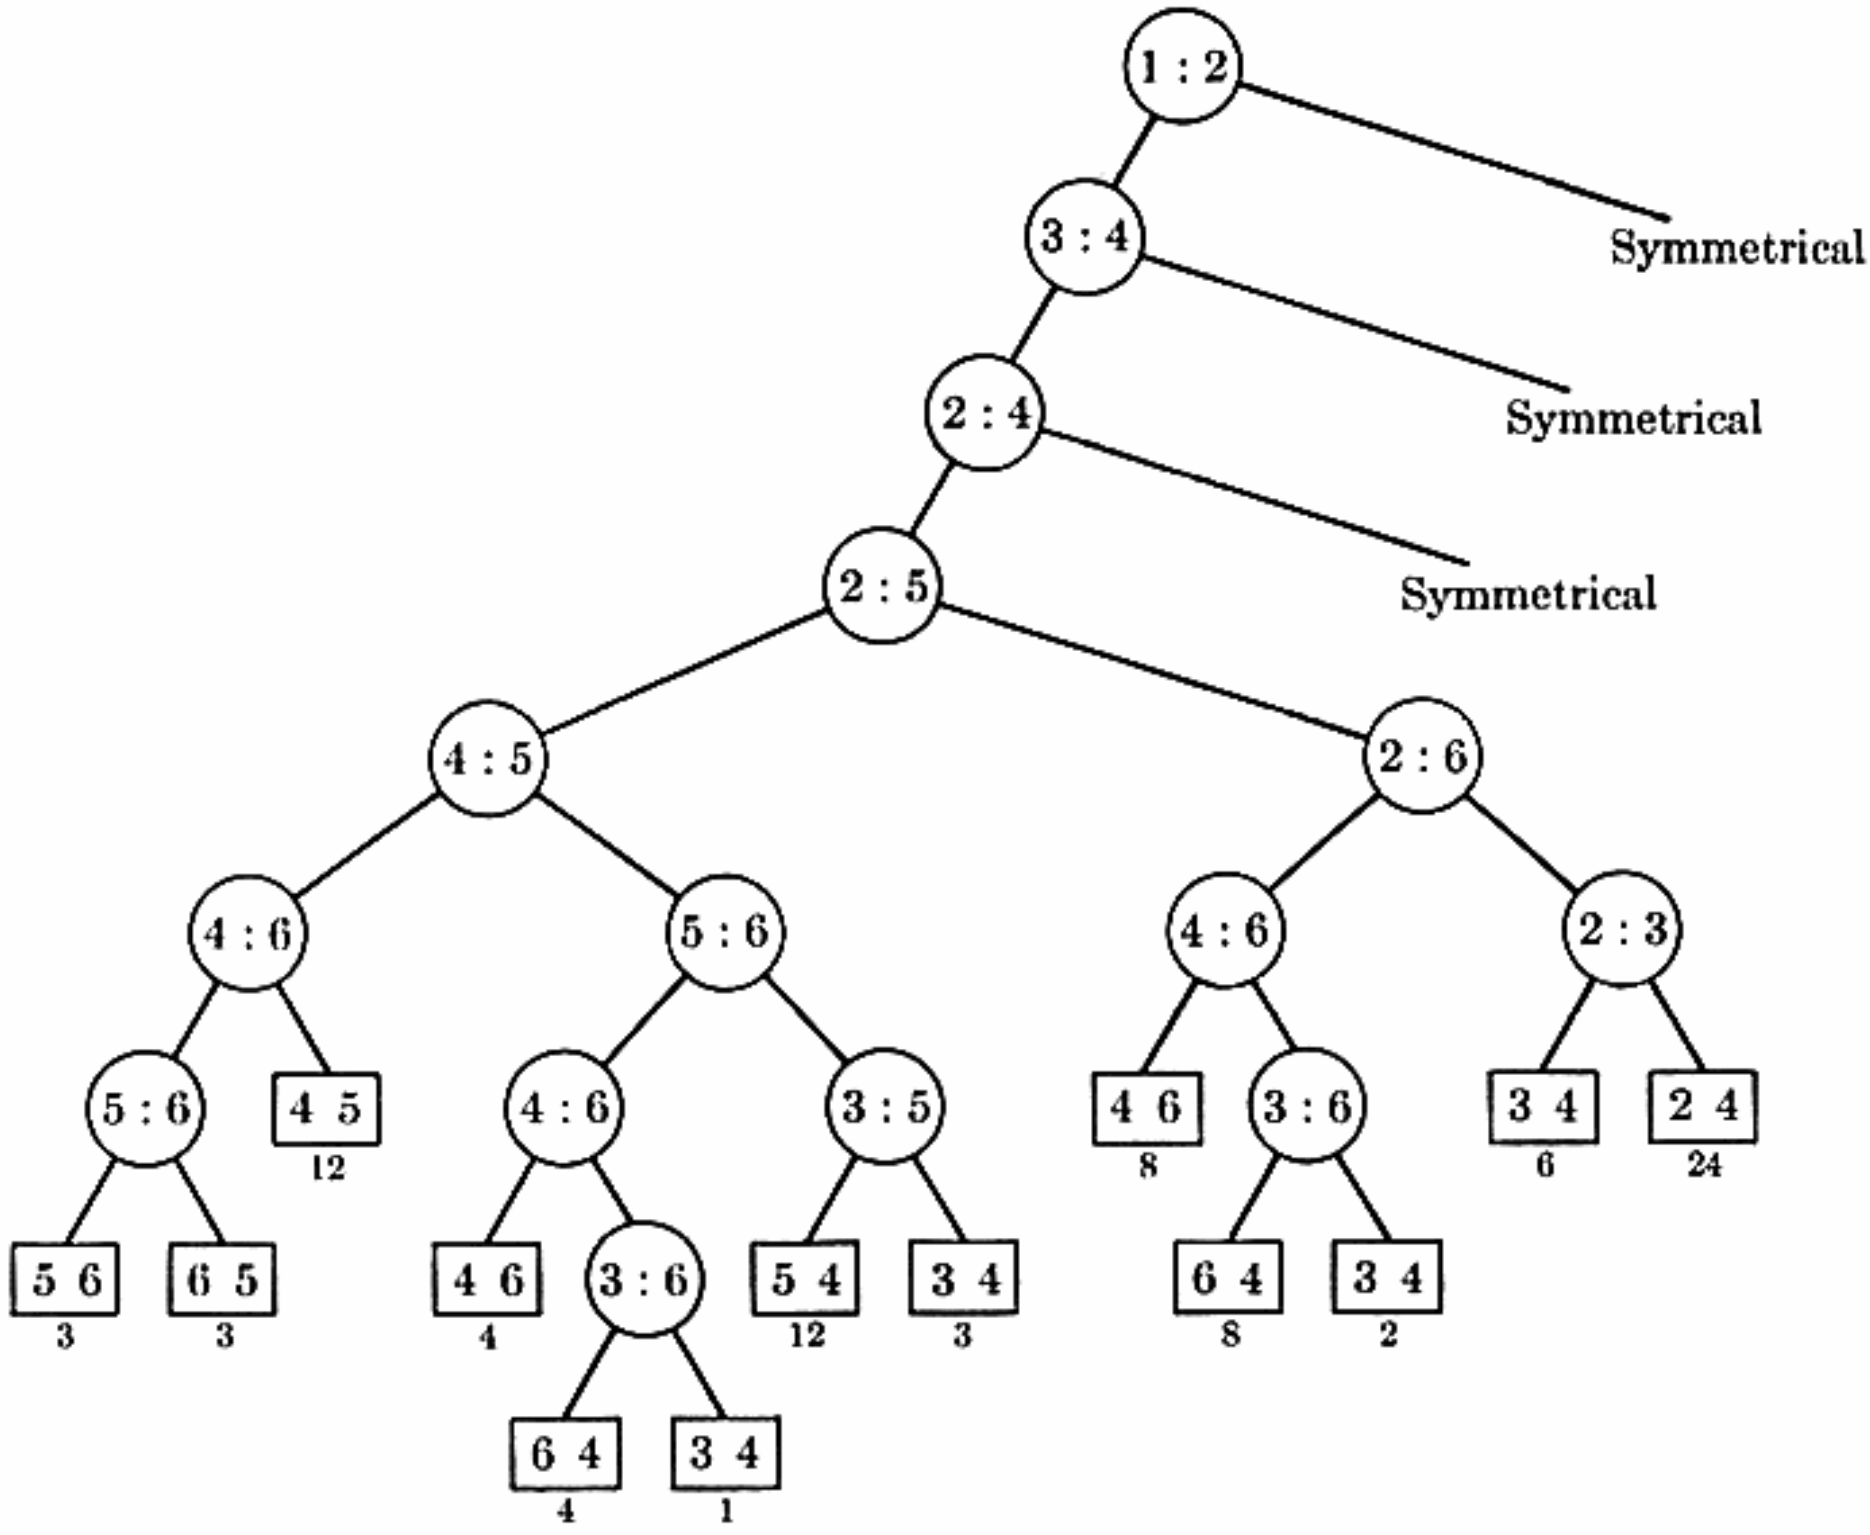

Fig. 42. A procedure which selects the second largest of $\{X_1, X_2, X_3, X_4, X_5, X_6\}$, using $6\frac{1}{2}$ comparisons on the average. Each "symmetrical" branch is identical to its brother, with names permuted in some appropriate manner. External nodes contain "j k" when X_j is known to be the second largest and X_k the largest; the number of permutations leading to this node appears immediately below it.

with only $\frac{3}{2}n + O(n^{2/3} \log n)$ comparisons, on the average. (See exercise 13.) He proved in fact that

$$\overline{V}_t(n) \leq n + t + f(n), \qquad \text{where} \qquad \lim_{n\to\infty} f(n)/n = 0. \tag{14}$$

This result is conjectured to be the best possible asymptotic formula, but no satisfactory lower bound has yet been obtained.

EXERCISES

1. [*15*] In Lewis Carroll's tournament (Figs. 39 and 40), why does player *13* get eliminated even though he has won his match in Round 3?

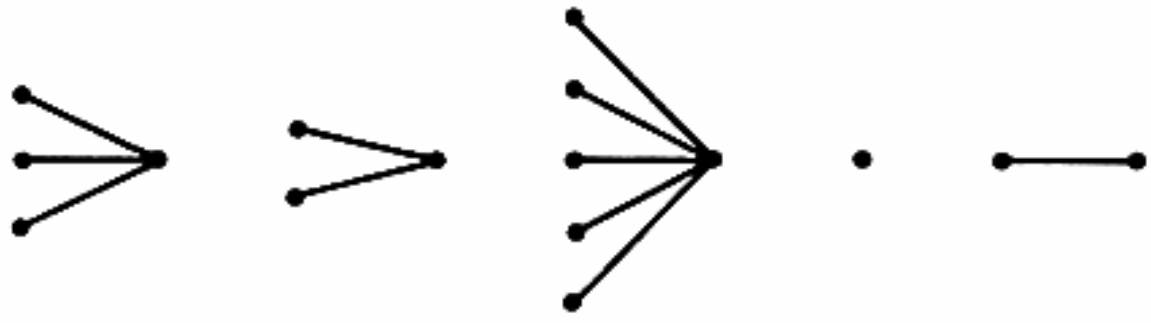
▶ **2.** [*M25*] Prove that after we have found the tth largest of n elements by a sequence of comparisons, we also know which $t - 1$ elements are greater than it, and which $n - t$ elements are less than it.

3. [*M21*] Prove that $V_t(n) \geq V_t(n-1) + 1$, for $1 \leq t \leq n$.

4. [*M20*] Prove that $W_t(n) \geq \lceil \log_2 n^{\underline{t}} \rceil$, where $n^{\underline{t}} = n(n-1)\ldots(n+1-t)$.

5. [*10*] Prove that $W_3(n) \leq V_3(n) + 1$.

▸ **6.** [*M26*] (R. W. Floyd.) Given n distinct elements $\{X_1, \ldots, X_n\}$ and relations $X_i < X_j$ for certain pairs (i, j), we wish to find the second largest element. If we know that $X_i < X_j$ and $X_i < X_k$ for $j \neq k$, X_i cannot possibly be the second largest, so it can be eliminated. The resulting relations now have a form such as



namely, m groups of elements which can be represented by a vector $(l_1, l_2, \ldots, l_m)$; the jth group contains $l_j + 1$ elements, one of which is known to be greater than the others. For example, the above configuration can be described by the vector (3, 2, 4, 0, 1); when no relations are known we have a vector of n zeros.

Let $f(l_1, l_2, \ldots, l_m)$ be the minimum number of comparisons needed to find the second largest element of such a partially ordered set. Prove that

$$f(l_1, l_2, \ldots, l_m) = m - 2 + \lceil \log_2 (2^{l_1} + 2^{l_2} + \cdots + 2^{l_m}) \rceil.$$

[*Hint:* Show that the best strategy is always to compare the largest elements of the two smallest groups, until reducing m to unity; use induction on $l_1 + l_2 + \cdots + l_m + 2m$.]

7. [*M20*] Prove (8).

8. [*M21*] Kislitsyn's formula (6) is based on tree selection sorting using the complete binary tree with n external nodes. Would a tree selection method based on some *other* tree give a better bound, for any t and n?

▸ **9.** [*20*] Draw a comparison tree for finding the median of five elements in at most six steps, using the replacement-selection method of Hadian and Sobel [cf. (11)].

10. [*35*] Show that the median of seven elements can be found in at most 10 steps.

11. [*28*] (Hadian and Sobel.) Show that the median of nine elements can be found in at most 15 steps, by extending the method of Doren stated in the text.

12. [*21*] (Hadian and Sobel.) Prove that $V_3(n) \leq V_3(n-1) + 2$. [*Hint:* Start by discarding the smallest of $\{X_1, X_2, X_3, X_4\}$.]

▸ **13.** [*HM28*] (R. W. Floyd.) Show that if we start by finding the median element of $\{X_1, \ldots, X_{n^{2/3}}\}$, using a recursively defined method, we can go on to find the median of $\{X_1, \ldots, X_n\}$ with an average of $\frac{3}{2}n + O(n^{2/3} \log n)$ comparisons.

▸ **14.** [*20*] (M. Sobel.) Show that it is possible to find the largest two elements of $\{X_1, X_2, X_3, X_4, X_5\}$, without necessarily knowing their relative order, using at most five comparisons.

15. [*22*] (I. Pohl.) Suppose that we are interested in minimizing space instead of time. What is the minimum number of data words needed in memory in order to compute the tth largest of n elements, if each element fills one word and if the elements are input one at a time into a single register?

▸**16.** [*25*] (I. Pohl.) Show that we can find both the maximum and the minimum of a set of n elements, using at most $\lceil \frac{3}{2}n \rceil - 2$ comparisons; and the latter number cannot be lowered. [*Hint:* Any stage in such an algorithm can be represented as a quadruple (a, b, c, d), where a elements have never been compared, b have won but never lost, c have lost but never won, d have both won and lost. Construct a suitable oracle.]

17. [*20*] (R. W. Floyd.) Show that it is possible to select, in order, both the k largest and the l smallest elements of a set of n elements, using at most $\lceil \frac{3}{2}n \rceil - k - l + \sum_{n+1-k<j\le n} \lceil \log_2 j \rceil + \sum_{n+1-l<j\le n} \lceil \log_2 j \rceil$ comparisons.

18. [*M20*] If groups of size 5, not 7, had been used in the proof of Theorem L, what theorem would have been obtained?

19. [*M44*] Find the exact value of $\overline{V}_2(6)$. Can this be achieved by a procedure which never makes more than seven comparisons?

20. [*M47*] Prove (or disprove) Sobel's conjecture (13).

21. [*25*] (S. Lin.) Prove that $W_3(2^k + 2) \le 2^k + 2k$, when $k \ge 3$.

22. [*M47*] Determine the values of $V_3(n)$ and $W_3(n)$ for all n.

23. [*M49*] What is the asymptotic value of $V_{\lceil n/2 \rceil}(n)$, as $n \to \infty$?

24. [*M48*] What is the asymptotic value of $\overline{V}_{\lceil n/2 \rceil}(n)$, as $n \to \infty$?

5.3.4. Networks for Sorting

In this section we shall study a "constrained" type of sorting which is especially interesting because of its applications and its rich underlying theory. The new constraint is to insist on a *homogeneous* sequence of comparisons, in the sense that whenever we compare K_i versus K_j the subsequent comparisons for the case $K_i < K_j$ are exactly the same as for the case $K_i > K_j$, but with i and j interchanged. Figure 43(a) shows a comparison tree in which this homogeneity condition is satisfied. (Note that the same number of comparisons is made on each level, so there are 2^m outcomes after m comparisons have been made; since $n!$ is not a power of 2, it follows that some of the comparisons will be redundant, in the sense that one of their subtrees can never arise in practice. In other words, some branches of the tree must make more comparisons than necessary in order to ensure that all of the corresponding branches of the tree will sort properly.)

Since each path from top to bottom of such a tree determines the entire tree, such a sorting scheme is most easily represented as a *network* as in Fig. 42(b). The boxes in such a network represent "comparator modules" which have two inputs (represented as lines coming into the module from above) and two outputs (represented as lines leading downward); the left-hand output is the smaller of the two inputs, and the right-hand output is the larger. At the bottom of the network, K_1' is the smallest of $\{K_1, K_2, K_3, K_4\}$, K_2' the second smallest, etc. It is not difficult to prove that any sorting network corresponds to a homogeneous comparison tree in the above sense, and any homogeneous tree corresponds to a network of comparator modules.

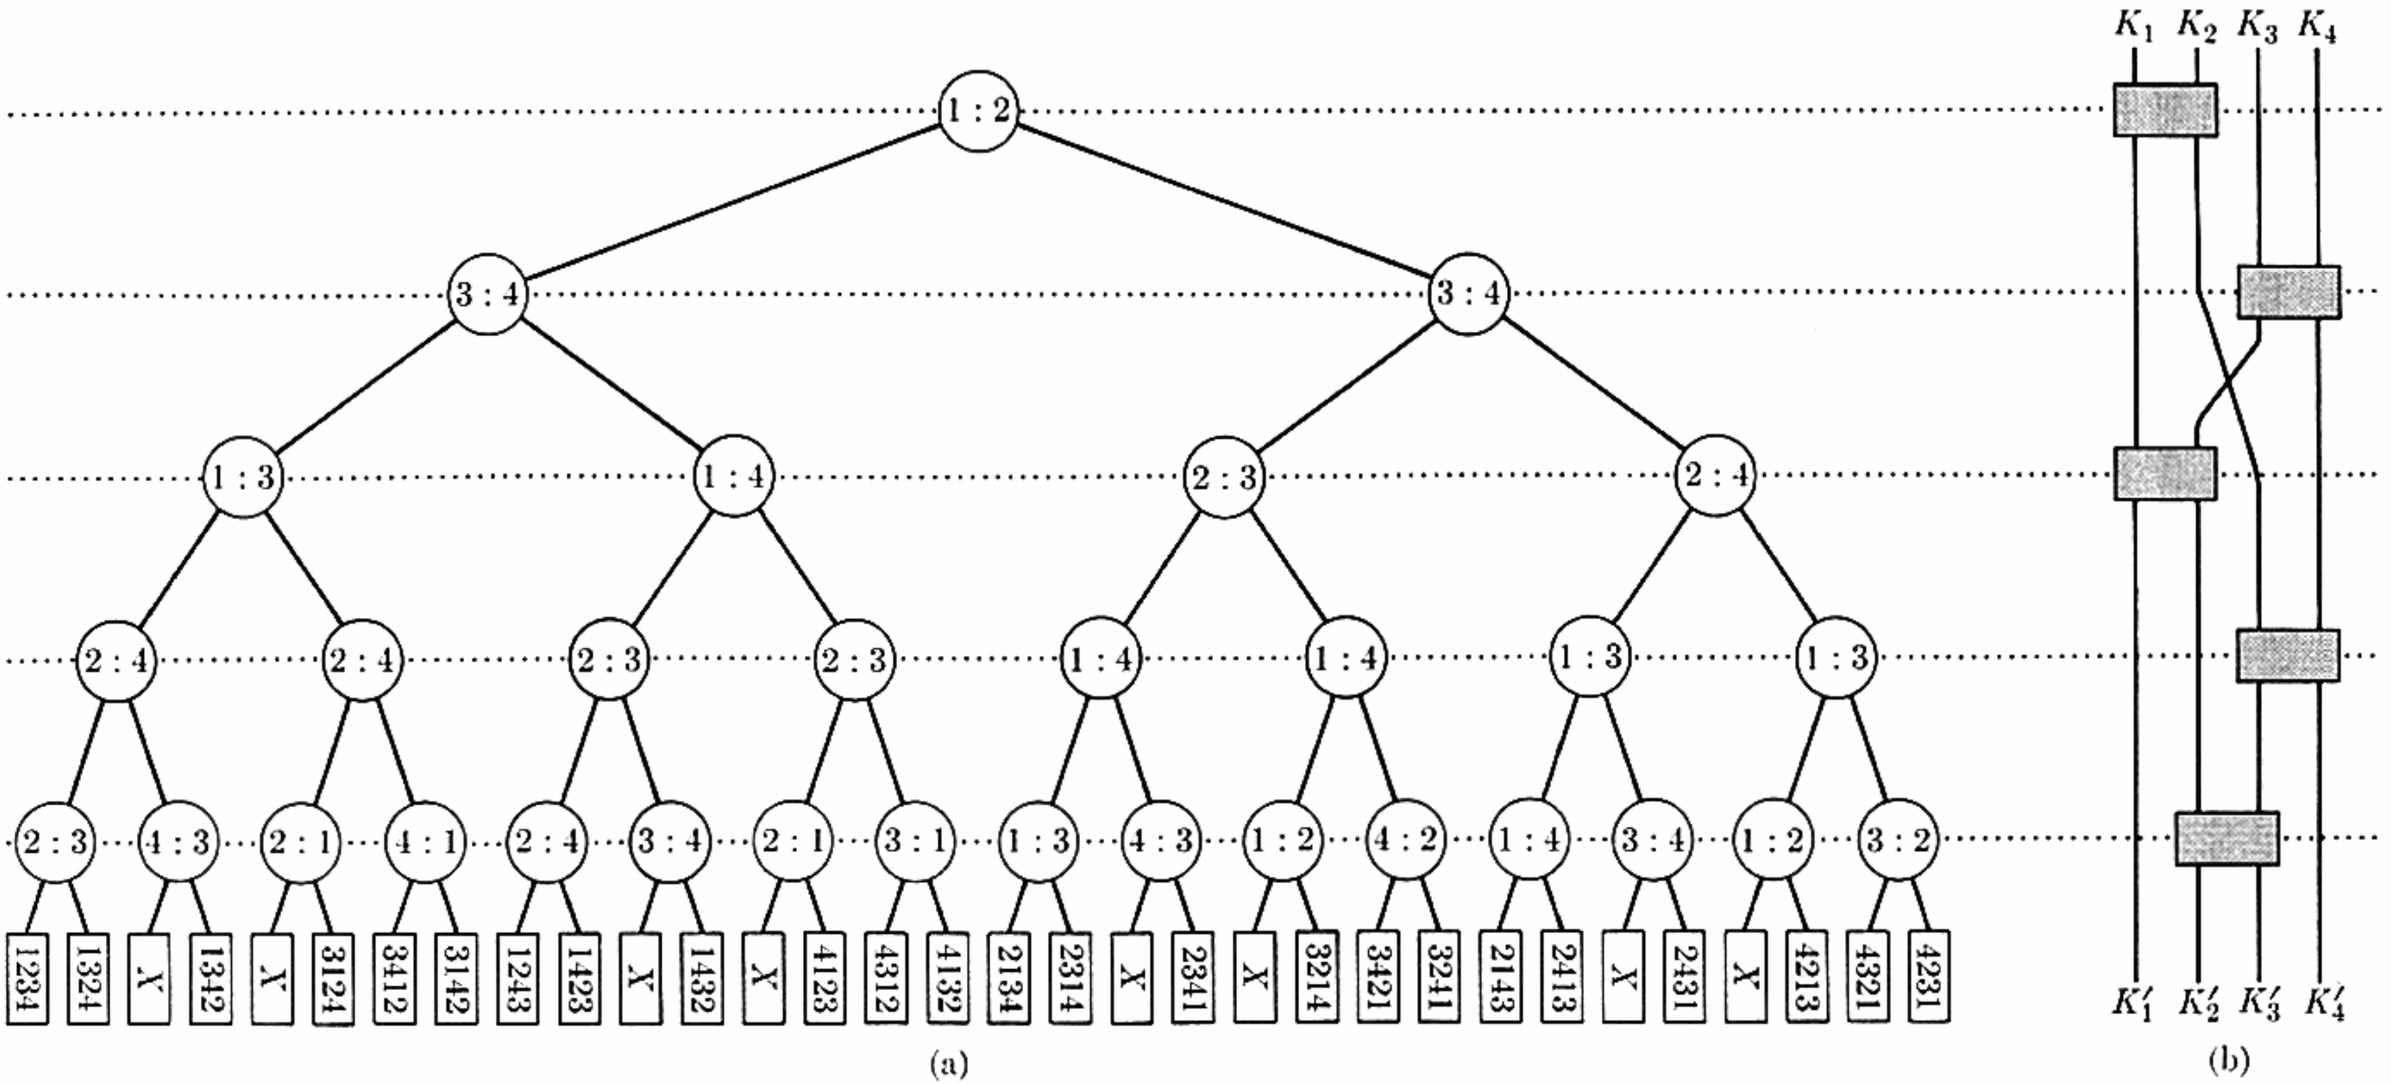


Fig. 43. (a) A homogeneous comparison tree. (b) The corresponding network.

Incidentally, we may note that comparator modules are fairly easy to manufacture, from an engineering point of view. For example, assume that the lines contain binary numbers, where one bit enters each module per unit time, most significant bit first. Each comparator module has three states, and behaves as follows:

Time t		Time $(t+1)$	
State	Inputs	State	Outputs
0	0 0	0	0 0
0	0 1	1	0 1
0	1 0	2	0 1
0	1 1	0	1 1
1	x y	1	x y
2	x y	2	y x

Initially all modules are in state 0 and are outputting 0 0. A module enters either state 1 or state 2 as soon as its inputs differ. Numbers which begin to be transmitted at the top of Fig. 43(b) at time t will begin to be output at the bottom, in sorted order, at time $t+3$, if a suitable delay element is attached to the K_1' and K_4' lines.

In order to develop the theory of sorting networks it is convenient to represent them in a slightly different way, illustrated in Fig. 44. Here numbers enter at the left, and comparator modules are represented by vertical connections between two lines; each comparator causes an interchange of its inputs, if necessary, so that the larger number appears on the lower line after passing the comparator. At the right of the diagram all the numbers are in order from top to bottom.

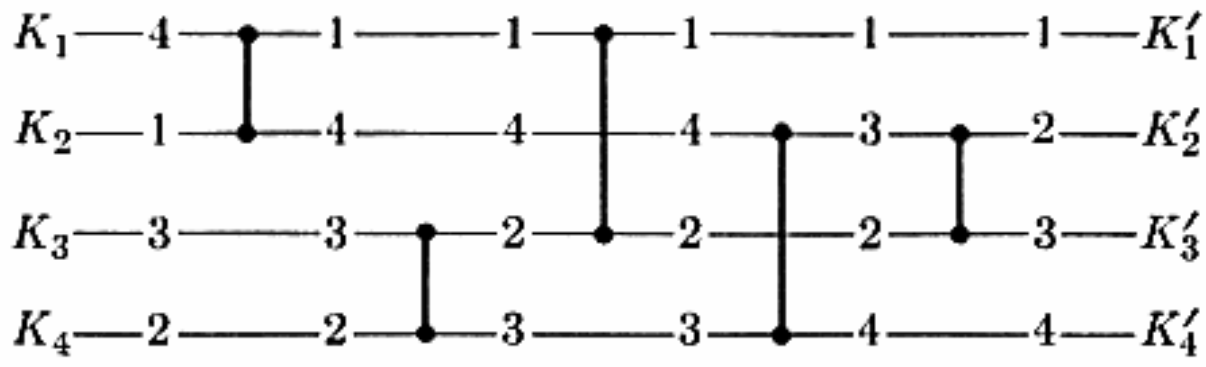

Fig. 44. Another way to represent the network of Fig. 43, as it sorts the sequence $\langle 4, 1, 3, 2\rangle$.

Our previous studies of optimal sorting have concentrated on minimizing the number of comparisons with little or no regard for any underlying data movement or for the complexity of the decision structure that may be necessary. In this respect sorting networks have some advantages, since the data can be maintained in n locations and the decision structure is "straight line"; there is no need to remember the results of previous comparisons—the plan is immutably fixed in advance. Another important advantage of sorting networks is that it may be possible to overlap several of the operations, performing them

simultaneously (on a suitable machine). For example, the five steps in Figs. 43 and 44 can be collapsed into three when simultaneous nonoverlapping comparisons are allowed, since the first two and the second two can be combined; we shall exploit this property of sorting networks later in this section. Thus sorting networks can be very useful, although it is not at all obvious that efficient n-element sorting networks can be constructed for large n; we may find that many additional comparisons are needed in order to keep the decision structure homogeneous.

There are two simple ways to construct a sorting network for $n + 1$ elements when an n-element network is given, using either the principle of *insertion* or the principle of *selection*. Figure 45(a) shows how the $(n + 1)$st element can be inserted into its proper place after the first n elements have been sorted; and part (b) of the figure shows how the largest element can be selected before we proceed to sort the remaining ones. Repeated application of Fig. 45(a) gives the network analog of straight insertion sorting (Algorithm 5.2.1S), and repeated application of Fig. 45(b) yields the network analog of the bubble sort (Algorithm 5.2.2B). Figure 46 shows the corresponding six-element networks. It is interesting to note that when we collapse either network together to allow simultaneous operations, both methods reduce to the same "triangular" $(2n - 3)$-stage procedure (Fig. 47).

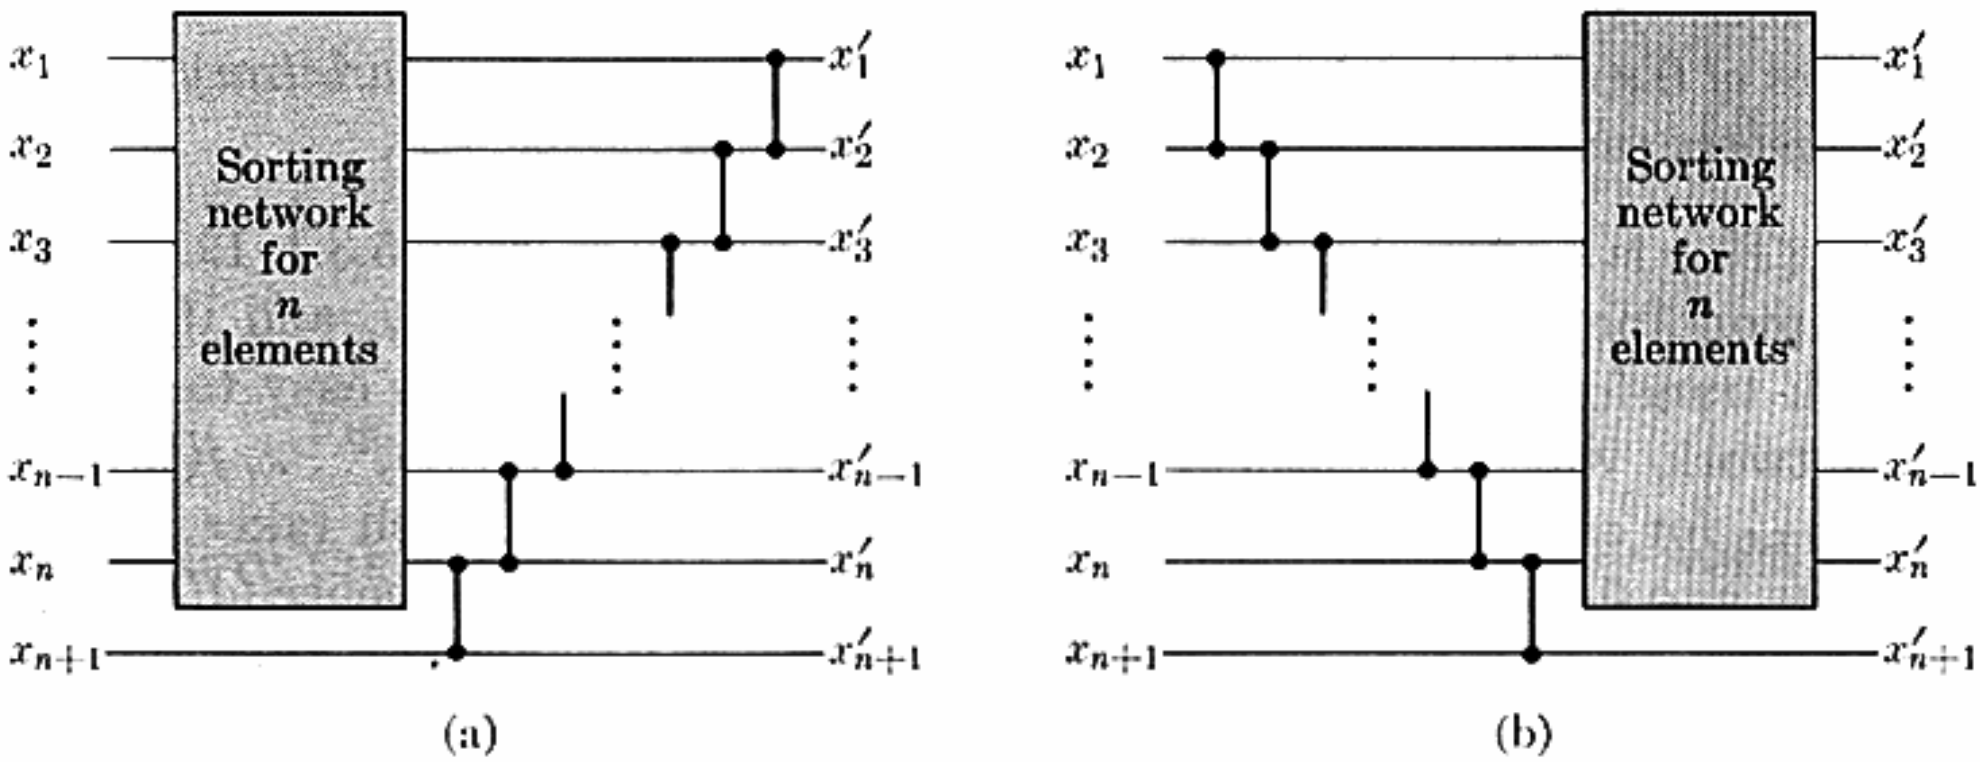

Fig. 45. Making $(n + 1)$-sorters from n-sorters: (a) insertion, (b) selection.

Fig. 46. Network analogs of elementary internal sorting schemes, obtained by applying Fig. 45 repeatedly: (a) straight insertion, (b) bubble sort.

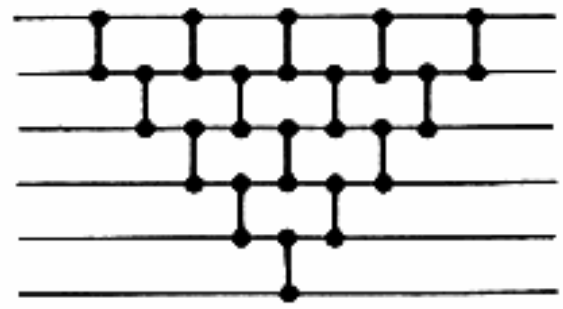

Fig. 47. With parallelism, straight insertion = bubble sort!

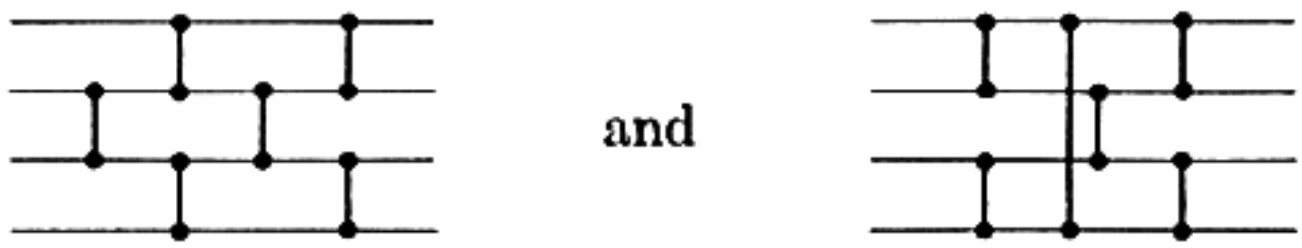
It is easy to prove that the network of Figs. 43 and 44 will sort any set of four numbers into order, since the first four comparators route the smallest and the largest elements to the correct places, and the last comparator puts the remaining two elements in order. But it is not always so easy to tell whether or not a given network will sort all possible input sequences; for example, both



are valid 4-element sorting networks, but the proofs of their validity are not trivial. It would be sufficient to test each n-element network on all $n!$ permutations of n distinct numbers, but in fact we can get by with far fewer tests:

Theorem Z (*Zero-one principle*). *If a network with n input lines sorts all 2^n sequences of 0's and 1's into nondecreasing order, it will sort any arbitrary sequence of n numbers into nondecreasing order.*

Proof. (This is a special case of Bouricius's theorem, exercise 5.3.1–12.) If $f(x)$ is any monotonic function, with $f(x) \le f(y)$ whenever $x \le y$, and if a given network transforms $\langle x_1, \ldots, x_n \rangle$ into $\langle y_1, \ldots, y_n \rangle$, then it is easy to see that the network will transform $\langle f(x_1), \ldots, f(x_n) \rangle$ into $\langle f(y_1), \ldots, f(y_n) \rangle$. If $y_i > y_{i+1}$ for some i, consider the monotonic function f which takes all numbers $< y_i$ into 0 and all numbers $\ge y_i$ into 1; this defines a sequence $\langle f(x_1), \ldots, f(x_n) \rangle$ of 0's and 1's which is not sorted by the network. Hence if all $0 - 1$ sequences are sorted, we have $y_i \le y_{i+1}$ for $1 \le i < n$. ∎

The zero-one principle is quite helpful in the construction of sorting networks. As a nontrivial example, we can derive a generalized version of Batcher's "merge exchange" sort (Algorithm 5.2.2M). The idea is to sort $m + n$ elements by sorting the first m and the last n independently, then applying an (m, n)-*merging network* to the result. An (m, n)-merging network can be constructed inductively as follows:

a) If $m = 0$ or $n = 0$, the network is empty. If $m = n = 1$, the network is a single comparator module.
b) If $mn > 1$, let the sequences to be merged be $\langle x_1, \ldots, x_m \rangle$ and $\langle y_1, \ldots, y_n \rangle$. Merge the "odd sequences" $\langle x_1, x_3, \ldots, x_{2\lceil m/2 \rceil - 1} \rangle$ and $\langle y_1, y_3, \ldots, y_{2\lceil n/2 \rceil - 1} \rangle$, obtaining the sorted result $\langle v_1, v_2, \ldots, v_{\lceil m/2 \rceil + \lceil n/2 \rceil} \rangle$; and merge

the "even sequences" $\langle x_2, x_4, \ldots, x_{\lfloor m/2 \rfloor}\rangle$ and $\langle y_2, y_4, \ldots, y_{\lfloor n/2 \rfloor}\rangle$, obtaining the sorted result $\langle w_1, w_2, \ldots, w_{\lfloor m/2 \rfloor+\lfloor n/2 \rfloor}\rangle$. Finally, apply the comparison-interchange operations

$$w_1{:}v_2, \quad w_2{:}v_3, \quad w_3{:}v_4, \quad \ldots, \quad w_{\lfloor m/2 \rfloor+\lfloor n/2 \rfloor}{:}v^* \tag{1}$$

to the sequence

$$\langle v_1, w_1, v_2, w_2, v_3, w_3, \ldots, v_{\lfloor m/2 \rfloor+\lfloor n/2 \rfloor}, w_{\lfloor m/2 \rfloor+\lfloor n/2 \rfloor}, v^*, v^{**}\rangle; \tag{2}$$

the result will be sorted. (!) (Here $v^* = v_{\lfloor m/2 \rfloor+\lfloor n/2 \rfloor+1}$ does not exist if both m and n are even, and $v^{**} = v_{\lfloor m/2 \rfloor+\lfloor n/2 \rfloor+2}$ does not exist unless both m and n are odd; the total number of comparator modules indicated in (1) is $\lfloor (m + n - 1)/2. \rfloor$)

Batcher's (m, n)-merging network is called the *odd-even merge*. A (4, 7)-merge constructed according to these principles is illustrated in Fig. 48.

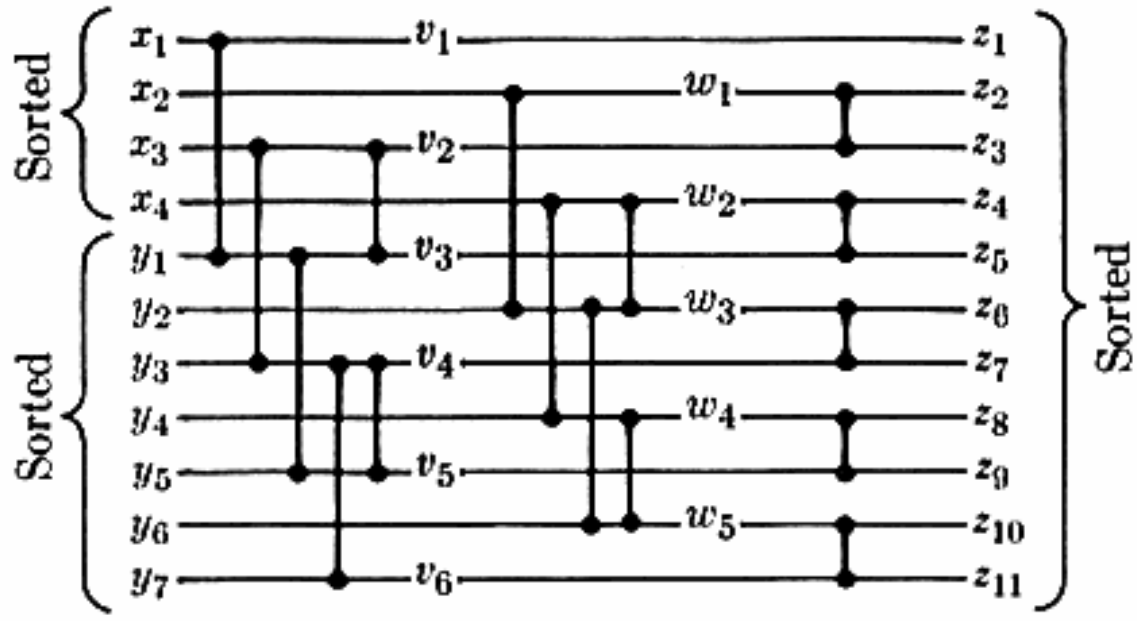


Fig. 48. The odd-even merge, when $m = 4$ and $n = 7$.

To prove that this rather strange merging procedure actually works, when $mn > 1$, we use the zero-one principle, testing it on all sequences of 0's and 1's. After the initial m-sort and n-sort, the sequence $\langle x_1, \ldots, x_m\rangle$ will consist of k 0's followed by $m - k$ 1's, and the sequence $\langle y_1, \ldots, y_n\rangle$ will be l 0's followed by $n - l$ 1's, for some k and l. Hence the sequence $\langle v_1, v_2, \ldots\rangle$ will consist of exactly $\lceil k/2 \rceil + \lceil l/2 \rceil$ 0's, followed by 1's; and $\langle w_1, w_2, \ldots\rangle$ will consist of $\lfloor k/2 \rfloor + \lfloor l/2 \rfloor$ 0's, followed by 1's. Now here's the point:

$$(\lceil k/2 \rceil + \lceil l/2 \rceil) - (\lfloor k/2 \rfloor + \lfloor l/2 \rfloor) = 0, \quad 1, \quad \text{or} \quad 2. \tag{3}$$

If this difference is 0 or 1, the sequence (2) is already in order, and if the difference is 2 one of the comparison-interchanges in (1) will fix everything up. This completes the proof. (Note that the zero-one principle reduces the merging problem from a consideration of $\binom{m+n}{m}$ cases to only $(m + 1)(n + 1)$, represented by the two parameters k and l.)

Let $C(m, n)$ be the number of comparator modules used in the odd-even merge for m and n, not counting the initial m-sort and n-sort; we have

$$C(m, n) = \begin{cases} mn, & \text{if} \quad mn \le 1; \\ C(\lceil m/2 \rceil, \lceil n/2 \rceil) + C(\lfloor m/2 \rfloor, \lfloor n/2 \rfloor) & \\ \quad + \lfloor (m + n - 1)/2 \rfloor, & \text{if} \quad mn > 1. \end{cases} \tag{4}$$

This is not an especially simple function of m and n, in general, but by noting that $C(1, n) = n$ and that

$$\begin{aligned} &C(m + 1, n + 1) - C(m, n) \\ &\qquad = 1 + C(\lfloor m/2 \rfloor + 1, \lfloor n/2 \rfloor + 1) - C(\lfloor m/2 \rfloor, \lfloor n/2 \rfloor), \qquad \text{if} \quad mn \ge 1, \end{aligned}$$

we can derive the relation

$$C(m + 1, n + 1) - C(m, n) = t + 2 + \lfloor n/2^{t+1} \rfloor,$$
$$\text{if} \quad n \ge m \ge 1 \quad \text{and} \quad t = \lfloor \log_2 m \rfloor. \tag{5}$$

Consequently,

$$C(m, m + r) = B(m) + m + R_m(r), \qquad \text{for} \quad m \ge 0, r \ge 0, \tag{6}$$

where $B(m)$ is the "binary insertion" function $\sum_{1 \le k \le m} \lceil \log_2 k \rceil$ of Eq. 5.3.1–3, and where $R_m(r)$ denotes the sum of the first m terms of the series

$$\left\lfloor \frac{r+0}{1} \right\rfloor + \left\lfloor \frac{r+1}{2} \right\rfloor + \left\lfloor \frac{r+2}{4} \right\rfloor + \left\lfloor \frac{r+3}{4} \right\rfloor + \left\lfloor \frac{r+4}{8} \right\rfloor + \cdots + \left\lfloor \frac{r+j}{2^{\lfloor \log_2 j \rfloor + 1}} \right\rfloor + \cdots. \tag{7}$$

In particular, when $r = 0$, we have the important special case

$$C(m, m) = B(m) + m. \tag{8}$$

Furthermore if $t = \lceil \log_2 m \rceil$,

$$\begin{aligned} R_m(r + 2^t) &= R_m(r) + 1 \cdot 2^{t-1} + 2 \cdot 2^{t-2} + \cdots + 2^{t-1} \cdot 2^0 + m \\ &= R_m(r) + m + t \cdot 2^{t-1}. \end{aligned}$$

Hence $C(m, n + 2^t) - C(m, n)$ has a simple form, and

$$C(m, n) = \left(\frac{t}{2} + \frac{m}{2^t} \right) n + O(1), \qquad \text{for } m \text{ fixed}, \quad n \to \infty, \quad t = \lceil \log_2 m \rceil; \tag{9}$$

the $O(1)$ term is an eventually periodic function of n, with period length 2^t. The asymptotic value of $C(n, n)$ as $n \to \infty$ is $n \log_2 n$, by Eq. (8) and exercise 5.3.1–15.

Minimum-comparison networks. Let $\hat{S}(n)$ be the minimum number of comparators needed in a sorting network for n elements; clearly $\hat{S}(n) \ge S(n)$,

where $S(n)$ is the minimum number of comparisons needed in an unrestricted sorting procedure (cf. Section 5.3.1). We have $\hat{S}(4) = 5 = S(4)$, so the new constraint causes no loss of efficiency when $n = 4$; but already when $n = 5$ it turns out that $\hat{S}(5) = 9$ while $S(5) = 7$. The problem of determining $\hat{S}(n)$ seems to be even harder than the problem of determining $S(n)$; even the asymptotic behavior of $\hat{S}(n)$ is still unknown.

It is interesting to trace the history of this problem, since each step was forged with some difficulty. Sorting networks were first explored by P. N. Armstrong, R. J. Nelson, and D. J. O'Connor, about 1954 [see *U.S. Patent 3029413*]; they showed that $\hat{S}(n+1) \leq \hat{S}(n) + n$. In the words of their patent attorney, "By the use of skill, it is possible to design economical n-line sorting switches using a reduced number of two-line sorting switches"; they gave special constructions for $4 \leq n \leq 8$, using 5, 9, 12, 18, and 19 comparators, respectively. In Nelson's subsequent work on the problem together with R. C. Bose, a general procedure for constructing sorting networks was devised prior to 1960, showing that $\hat{S}(2^n) \leq 3^n - 2^n$ for all n; hence $\hat{S}(n) = O(n^{\log_2 3}) = O(n^{1.585})$. Bose and Nelson published their interesting method in *JACM* **9** (1962), 282–296, where they conjectured that it was best possible; T. N. Hibbard [*JACM* **10** (1963), 142–150] found a similar but slightly simpler method which used the same number of comparisons, thereby reinforcing the conjecture.

In 1964, R. W. Floyd and D. E. Knuth found a new way to approach the problem, leading to an asymptotic bound of the form $\hat{S}(n) = O(n^{1+c/\sqrt{\log n}})$. Working independently, K. E. Batcher discovered the general merging strategy outlined above; using a number of comparators defined by

$$c(1) = 0, \quad c(n) = c(\lceil n/2 \rceil) + c(\lfloor n/2 \rfloor) + C(\lceil n/2 \rceil, \lfloor n/2 \rfloor) \quad \text{for} \quad n \geq 2, \tag{10}$$

he proved that (see exercise 5.2.2–14)

$$c(2^t) = (t^2 - t + 4)2^{t-2} - 1;$$

and it follows that $\hat{S}(n) = O(n(\log n)^2)$. Neither Batcher nor Floyd and Knuth published their constructions until some time later [*Notices of the Amer. Math. Soc.* **14** (1967), 283; *Proc. AFIPS Spring Joint Computer Conference* **32** (1968), 307–314].

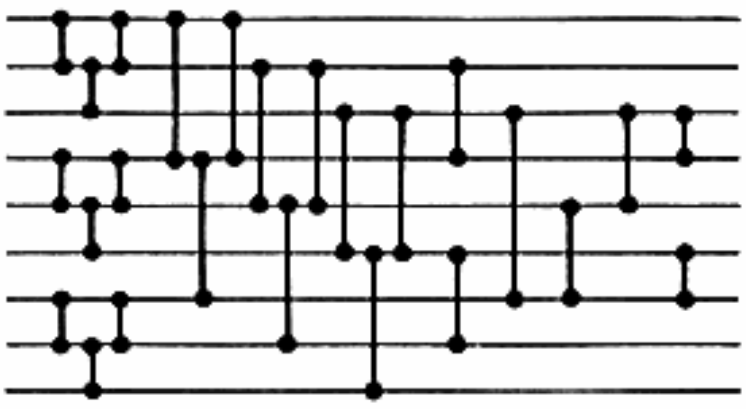
Several people have found ways to improve on the number of comparators used by Batcher's merge-exchange construction; the following table shows the best upper bounds currently known for $\hat{S}(n)$:

$n =$	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	
$c(n) =$	0	1	3	5	9	12	16	19	26	31	37	41	48	53	59	63	(11)
$\hat{S}(n) \leq$	0	1	3	5	9	12	16	19	25	29	35	39	46	51	56	60	

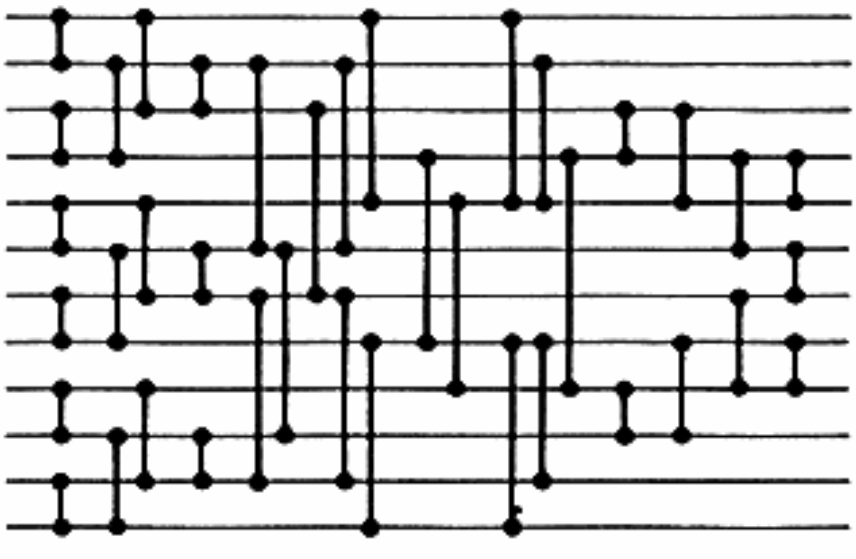
Since $\hat{S}(n) < c(n)$ for $8 < n \leq 16$, merge exchange is nonoptimal for all $n > 8$. When $n \leq 8$, merge exchange is equivalent in the number of comparators to

the construction of Bose and Nelson. Floyd and Knuth proved in 1964–1966 that the above values of $\hat{S}(n)$ are *exact* for $n \leq 8$ [see *A Survey of Combinatorial Theory* (North-Holland, 1972), Chapter 15]; the values of $\hat{S}(n)$ for $n > 8$ are still not known.

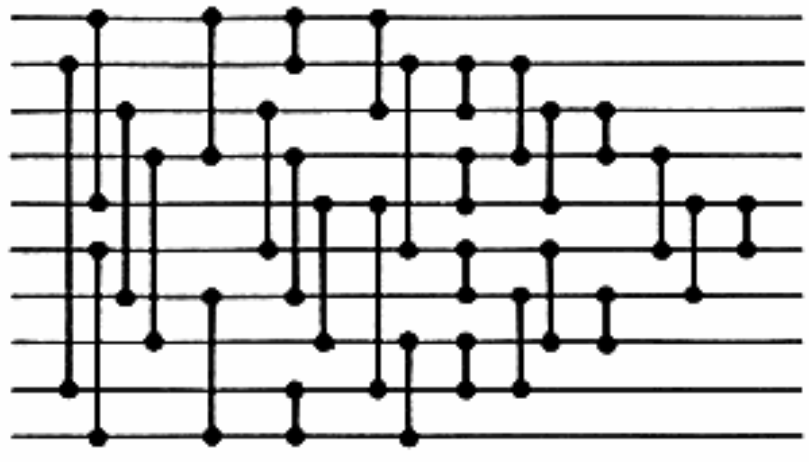
Constructions which lead to the above values for $\hat{S}(n)$ are shown in Fig. 49. The network for $n = 9$, based on an interesting three-way merge, was found by R. W. Floyd in 1964; its validity can be established by using the general principle described in exercise 27. The network for $n = 10$ was discovered by A. Waksman in 1969, by regarding the inputs as permutations of $\{1, 2, \ldots, 10\}$ and trying to reduce as much as possible the number of possible values that can appear on each line at a given stage, while maintaining some symmetry.



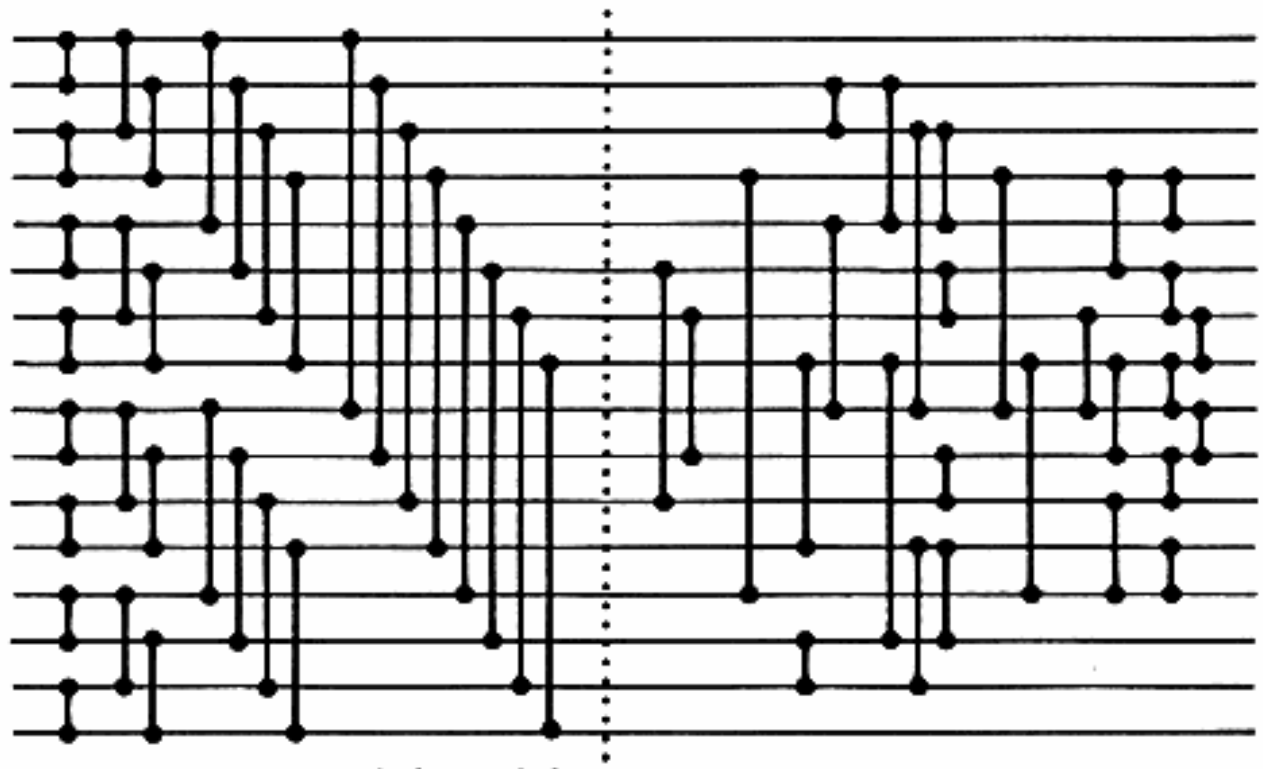
$n = 9$ 25 modules, delay 10



$n = 12$ 39 modules, delay 9



$n = 10$ 29 modules, delay 9



$n = 16$ 60 modules, delay 10

Fig. 49. Efficient sorting networks.

A 62-comparator sorting network for 16 elements was found by G. Shapiro in 1969, and this was rather surprising since Batcher's method (63 comparisons) would appear to be at its best when n is a power of 2. Soon after hearing of Shapiro's construction, M. W. Green tripled the amount of surprise by finding the 60-comparison sorter in Fig. 49. The first portion of Green's construction is fairly easy to understand; after the 32 comparison/interchanges to the left of the dotted line have been made, the lines can be labeled with the 16 subsets of $\{a, b, c, d\}$, in such a way that the line labeled s is known to contain a number less than or equal to the contents of the line labeled t whenever s is a subset of t. The state of the sort at this point is discussed further in exercise 32. Comparisons made on subsequent levels of Green's network become increasingly mysterious, however, and as yet nobody has seen how to generalize the construction in order to obtain correspondingly efficient networks for higher values of n.

Shapiro and Green also discovered the network shown for $n = 12$. When $n = 11$, 13, 14, or 15, good networks can be found by removing the bottom line of the network for $n + 1$, together with all comparators touching that line.

For the best networks currently known as $n \to \infty$, see the Ph.D. thesis of D. Van Voorhis (Stanford University, 1971); his networks require asymptotically $\frac{1}{4}n(\log_2 n)^2 - \alpha n \log_2 n$ comparators, where $\alpha = \frac{1}{4} + \frac{1}{6}\sum_{k\geq 0} 2^{-2^k-k} \approx 0.356852$.

Minimum-time networks. In physical realizations of sorting networks, and on parallel computers, it is possible to do nonoverlapping comparison-exchanges at the same time; therefore it is natural to try to minimize the delay time. A moment's reflection shows that the delay time of a sorting network is equal to the maximum number of comparators in contact with any "path" through the network, if we define a path to consist of any left-to-right route which possibly switches lines at the comparators. We can put a sequence number on each comparator indicating the earliest time it can be executed; this is one higher than the maximum of the sequence numbers of the comparators which precede it. (See Fig. 50(a); part (b) of the figure shows the same network redrawn so that each comparison is done at the earliest possible moment.)

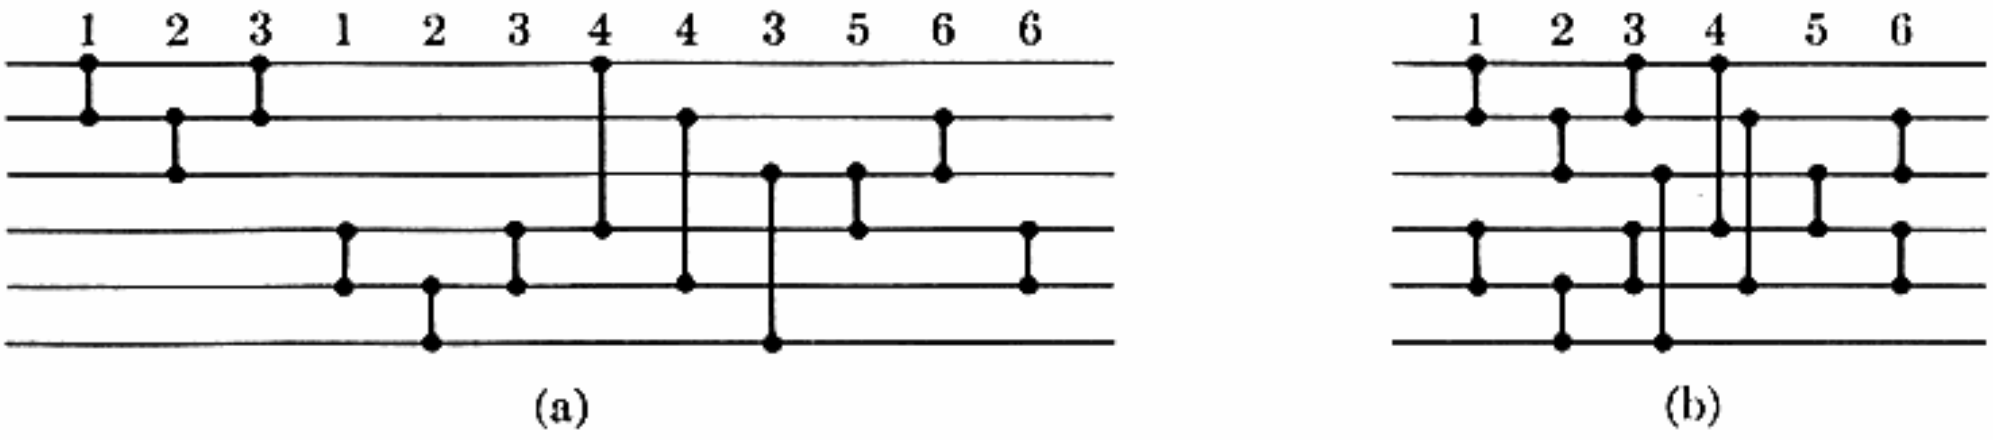


Fig. 50. Doing each comparison at the earliest possible time.

Batcher's odd-even merging network described above takes $T_B(m, n)$ units of time, where $T_B(m, 0) = T_B(0, n) = 0$, $T_B(1, 1) = 1$, and

$$T_B(m, n) = 1 + \max\,(T_B(\lfloor m/2 \rfloor, \lfloor n/2 \rfloor), \quad T_B(\lceil m/2 \rceil, \lceil n/2 \rceil)) \quad \text{for} \quad mn \geq 2.$$

We can use these relations to prove that $T_B(m, n + 1) \geq T_B(m, n)$, by induction; hence $T_B(m, n) = 1 + T_B(\lceil m/2 \rceil, \lceil n/2 \rceil)$ for $mn \geq 2$, and it follows that

$$T_B(m, n) = 1 + \lceil \log_2 \max\,(m, n) \rceil, \quad \text{for} \quad mn \geq 1. \tag{12}$$

Exercise 5 shows that Batcher's sorting method therefore has a delay time of

$$\binom{1 + \lceil \log_2 n \rceil}{2}. \tag{13}$$

Let $\hat{T}(n)$ be the minimum achievable delay time in any sorting network for n elements. It is possible to improve some of the networks described above so that they have less delay time but use no more comparators, as shown for $n = 6$ and $n = 9$ in Fig. 51, and for $n = 10$ in exercise 7. Still smaller delay time can be achieved if we add one or two extra modules, as shown in the remarkable networks for $n = 10$, 12, and 16 in Fig. 51. These constructions yield the following upper bounds on $\hat{T}(n)$ for small n:

$n =$	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16
$\hat{T}(n) \leq$	0	1	3	3	5	5	6	6	7	7	8	8	9	9	9	9

(14)

For $n \leq 8$ the values given here are known to be exact (see exercise 4). The networks in Fig. 51 merit careful study, because it is by no means obvious that they sort; they were discovered in 1969–1971 by G. Shapiro ($n = 6$, 9, 12) and D. Van Voorhis ($n = 10$, 16).

Merging networks. Let $\hat{M}(m, n)$ denote the minimum number of comparator modules needed in a network that merges m elements $x_1 \leq \cdots \leq x_m$ with n elements $y_1 \leq \cdots \leq y_n$ to form the sorted sequence $z_1 \leq \cdots \leq z_{m+n}$. At present no merging networks have been discovered which are superior to the odd-even merge described above; hence the function $C(m, n)$ in (6) represents the best upper bound known for $\hat{M}(m, n)$.

R. W. Floyd has discovered an interesting way to find *lower* bounds for this merging problem.

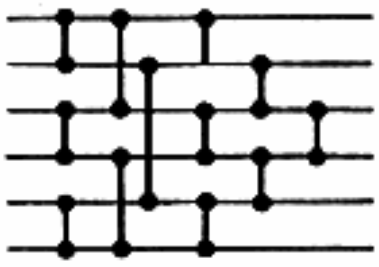
Theorem F. *$\hat{M}(2n, 2n) \geq 2\hat{M}(n, n) + n$, for all $n \geq 1$.*

Proof. Consider a network with $\hat{M}(2n, 2n)$ comparator modules, capable of sorting all input sequences $\langle z_1, \ldots, z_{4n} \rangle$ such that $z_1 \leq z_3 \leq \cdots \leq z_{4n-1}$ and $z_2 \leq z_4 \leq \cdots \leq z_{4n}$. We may assume that each module replaces (z_i, z_j) by $(\min\,(z_i, z_j), \max\,(z_i, z_j))$, for some $i < j$ (see exercise 16). The comparators can therefore be divided into three classes:

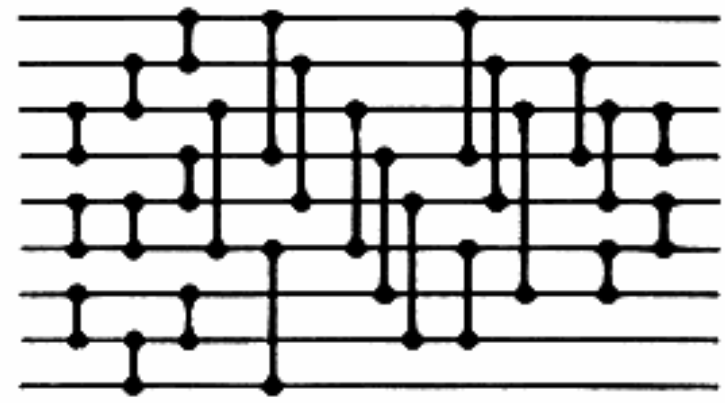
a) $i \leq 2n$ and $j \leq 2n$.

b) $i > 2n$ and $j > 2n$.

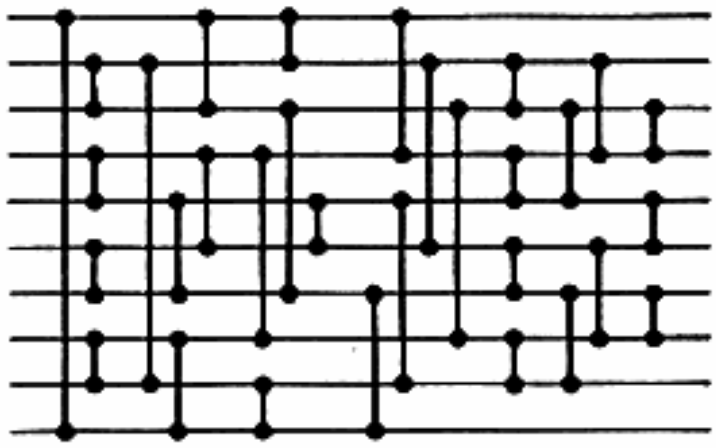
c) $i \leq 2n$ and $j > 2n$.



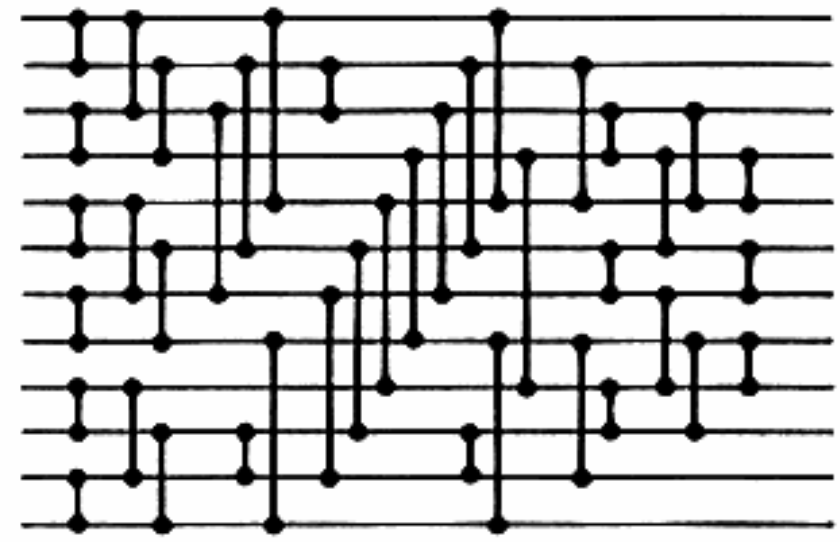
$n = 6$ 12 modules, delay 5



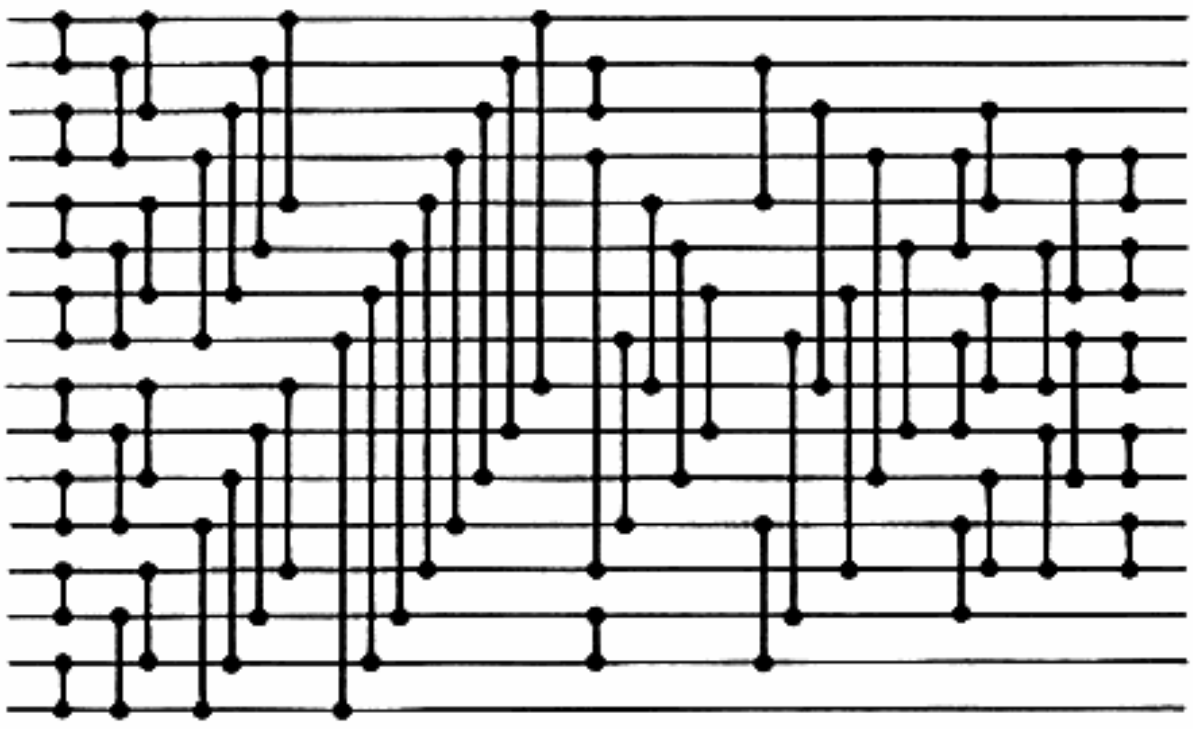
$n = 9$ 25 modules, delay 8



$n = 10$ 31 modules, delay 7



$n = 12$ 40 modules, delay 8



$n = 16$ 61 modules, delay 9

Fig. 51. Sorting networks which are unusually fast, when comparisons are performed in parallel.

Class (a) must contain at least $\hat{M}(n, n)$ comparators, since $z_{2n+1}, z_{2n+2}, \ldots, z_{4n}$ may be already in their final position when the merge starts; similarly, there are at least $\hat{M}(n, n)$ comparators in class (b). Furthermore the input sequence $\langle 0, 1, 0, 1, \ldots, 0, 1\rangle$ shows that class (c) contains at least n comparators, since n zeros must move from $\{z_{2n+1}, \ldots, z_{4n}\}$ to $\{z_1, \ldots, z_{2n}\}$. ∎

Repeated use of Theorem F proves that $\hat{M}(2^m, 2^m) \geq \frac{1}{2}(m + 2)2^m$; hence $\hat{M}(n, n) \geq \frac{1}{2}n \log_2 n + O(n)$. Merging *without* the network restriction requires only $M(n, n) = 2n - 1$ comparisons; hence we have proved that merging with networks is intrinsically harder than merging in general. The odd-even merge

shows that $\hat{M}(n, n) \leq C(n, n) = n \log_2 n + O(n)$, so the asymptotic behavior of $\hat{M}(n, n)$ is known within a factor of 2. (The exact value of $\hat{M}(n, n)$ is known for $n \leq 5$, see exercise 9.)

Bitonic sorting. When simultaneous comparisons are allowed, we have seen in Eq. (12) that the odd-even merge uses $\lceil \log_2 (2n) \rceil$ units of delay time, when $1 \leq m \leq n$. Batcher has devised another type of network for merging, called a *bitonic sorter*, which lowers the delay time to $\lceil \log_2 (m + n) \rceil$ although it requires more comparator modules.

Let us say that a sequence $\langle z_1, \ldots, z_p \rangle$ of p numbers is *bitonic* if $z_1 \geq \cdots \geq z_k \leq \cdots \leq z_p$ for some k, $1 \leq k \leq p$. (Compare this with the ordinary definition of "monotonic" sequences.) A bitonic sorter of order p is a comparator network capable of sorting any bitonic sequence of length p into nondecreasing order. The problem of merging $x_1 \leq \cdots \leq x_m$ with $y_1 \leq \cdots \leq y_n$ is a special case of the bitonic sorting problem, since merging can be done by applying a bitonic sorter of order $m + n$ to the sequence $\langle x_m, \ldots, x_1, y_1, \ldots, y_n \rangle$.

Note that when the sequence $\langle z_1, \ldots, z_p \rangle$ is bitonic, so are all of its subsequences. Shortly after Batcher discovered the odd-even merging networks, he observed that we can construct a bitonic sorter of order p in an analogous way, by first sorting the bitonic subsequences $\langle z_1, z_3, z_5, \ldots \rangle$ and $\langle z_2, z_4, z_6, \ldots \rangle$ independently, then comparing and interchanging $z_1 : z_2$, $z_3 : z_4$, ... (See exercise 10 for a proof.) If $C'(p)$ is the corresponding number of comparator modules, we have

$$C'(p) = C'(\lceil p/2 \rceil) + C'(\lfloor p/2 \rfloor) + \lfloor p/2 \rfloor, \qquad \text{for} \qquad p \geq 2; \tag{15}$$

and the delay time is clearly $\lceil \log_2 p \rceil$. Figure 52 shows the bitonic sorter of order 7 constructed in this way: it can be used as a (3, 4)- as well as a (2, 5)-merging network, with three units of delay; the odd-even merge for $m = 2$ and $n = 5$ has one less comparator but one more level of delay.

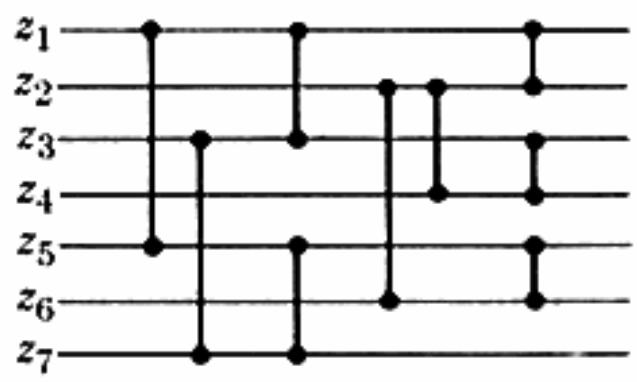


Fig. 52. Batcher's bitonic sorter of order 7.

Batcher's bitonic sorter of order 2^k is particularly interesting; it consists of k levels of 2^{k-1} comparators each. If we number the input lines $z_0, z_1, \ldots, z_{2^k-1}$, element z_i is compared to z_j on level l if and only if i and j differ only in the lth most significant bit of their binary representations. This simple structure leads to parallel sorting networks which are as fast as merge exchange (Algorithm 5.2.2M) but considerably easier to implement. (See exercises 11 and 13.)

When $m = n$, it is not difficult to show that both the odd-even merge and Batcher's bitonic sorter provide the absolute minimum delay time achievable in any merging network. The nth smallest output of an (n, n) merging network must depend upon all $2n$ of the inputs, and if it can be computed in l steps, it involves at most 2^l of the inputs; hence $2^l \geq 2n$, $l \geq \lceil \log_2 (2n) \rceil$.

When $m < n$, the nth output of an (m, n) merging network depends on $2m + 1$ of the inputs (cf. exercise 29), so the same argument gives a minimum delay time of $\lceil \log_2 (2m + 1) \rceil$ for merging in this case. Batcher has shown [Report GER-14122 (Akron, Ohio: Goodyear Aerospace Corporation, 1968)] that this minimum delay time is achievable if we allow "multiple fanout" in the network, i.e., the splitting of lines so that the same number is fed to many modules at the same time. For example, his network which is capable of merging one item with n others in only two levels of delay is illustrated for $n = 6$ in Fig. 53. Of course, networks with multiple fanout do not conform to our conventions, and it is fairly easy to see that any $(1, n)$ merging network without multiple fanout must have a delay time of $\log_2 (n + 1)$ or more. (See exercise 14.)

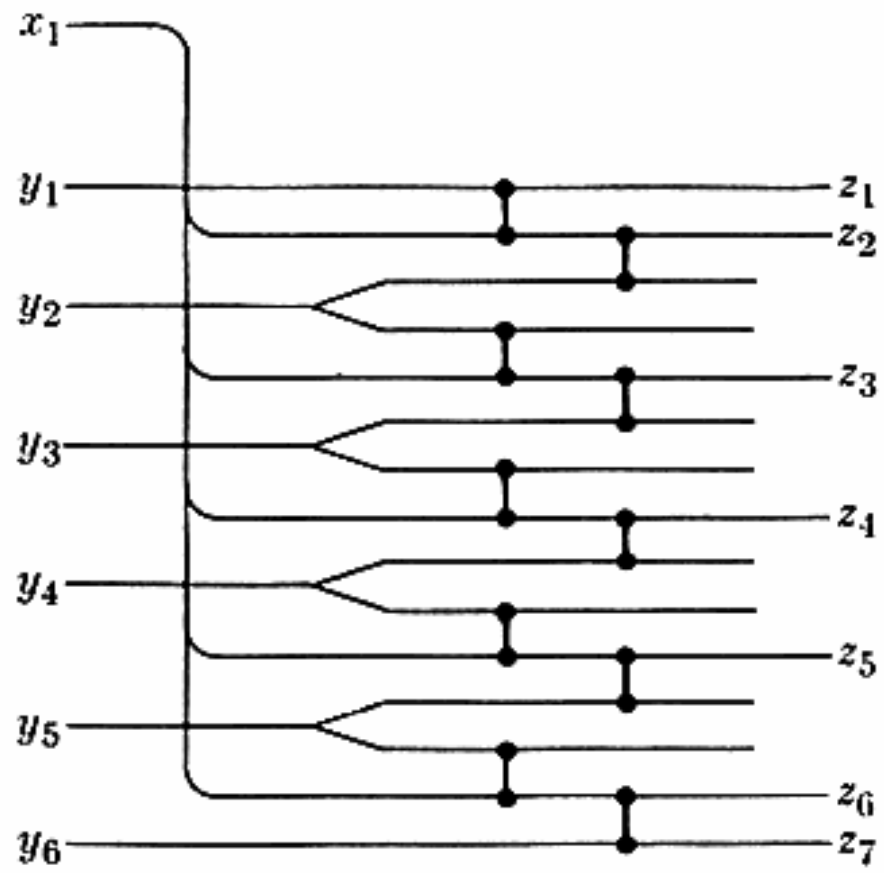

Fig. 53. Merging one item with six others, with multiple fanout, in order to achieve the minimum possible delay time.

Selection networks. We can also use networks to approach the problem of Section 5.3.3. Let $\hat{U}_t(n)$ denote the minimum number of comparators required in a network which moves the t largest of n distinct inputs into t specified output lines; they are allowed to appear in any order on these output lines. Let $\hat{V}_t(n)$ denote the minimum number of comparators required to move the tth largest of n distinct inputs into a specified output line; and let $\hat{W}_t(n)$ denote the minimum number of comparators required to move the t largest of n distinct inputs into t specified output lines in nondecreasing order. It is not difficult to see (cf. exercise 17) that

$$\hat{U}_t(n) \leq \hat{V}_t(n) \leq \hat{W}_t(n). \tag{16}$$

Suppose first that we have $2t$ elements $\langle x_1, \ldots, x_{2t}\rangle$ and we wish to select the largest t; V. E. Alekseyev [*Kibernetika* **5**, 5 (1969), 99–103] has observed that we can do the job by first sorting $\langle x_1, \ldots, x_t\rangle$ and $\langle x_{t+1}, \ldots, x_{2t}\rangle$, then comparing and interchanging

$$x_1 : x_{2t}, \qquad x_2 : x_{2t-1}, \qquad \ldots, \qquad x_t : x_{t+1}. \tag{17}$$

Since none of these pairs can contain more than one of the largest t elements (why?), Alekseyev's procedure must select the largest t elements.

If we want to select the t largest of nt elements, we can apply the procedure $n - 1$ times (eliminating t elements each time); hence

$$\hat{O}_t(nt) \le (n-1)(2\hat{S}(t) + t). \tag{18}$$

Alekseyev has also derived an interesting *lower* bound for the selection problem.

Theorem A. $\hat{O}_t(n) \ge (n-t)\lceil \log_2(t+1)\rceil$.

Proof. It is most convenient to consider the equivalent problem of selecting the *smallest* t elements. We can attach numbers (l, u) to each line of a comparator network, as shown in Fig. 54, where l and u denote respectively the minimum and maximum values that can appear at that position when the input is a permutation of $\{1, 2, \ldots, n\}$. Let l_i and l_j be the lower bounds on lines i and j before a comparison of $x_i : x_j$, and let l_i' and l_j' be the corresponding lower bounds after the comparison. It is obvious that $l_i' = \min(l_i, l_j)$, and exercise 24 proves the (nonobvious) relation

$$l_j' \le l_i + l_j. \tag{19}$$

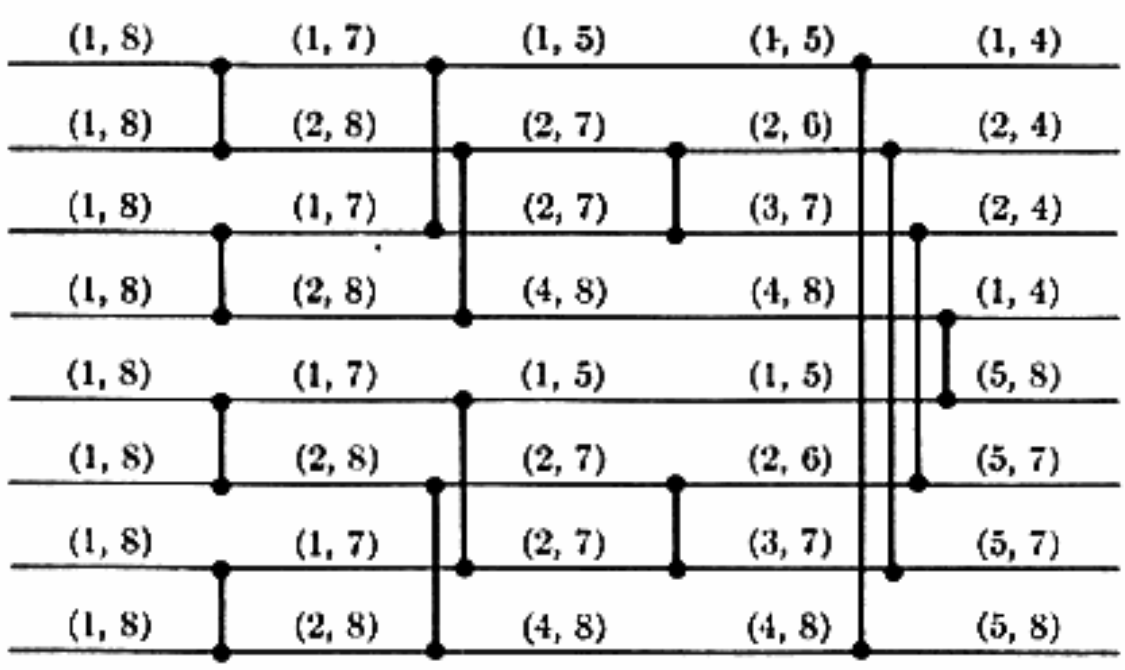

Fig. 54. Separating the largest four from the smallest four. (Numbers on these lines are used in the proof of Theorem A.)

Now let us reinterpret the network operations in another way (see Fig. 55): All input lines are assumed to contain zero, and each "comparator" now places the smaller of its inputs on the upper line and the larger *plus one* on the lower line. The resulting numbers $\langle m_1, m_2, \ldots, m_n \rangle$ have the property that

$$2^{m_i} \geq l_i \tag{20}$$

throughout the network, since this holds initially and it is preserved by each comparator because of (19). Furthermore, the final value of

$$m_1 + m_2 + \cdots + m_n$$

is the total number of comparators in the network, since each comparator adds unity to this sum.

If the network selects the smallest t numbers, $n - t$ of the l_i are $\geq t + 1$; hence $n - t$ of the m_i must be $\geq \lceil \log_2 (t + 1) \rceil$. ∎

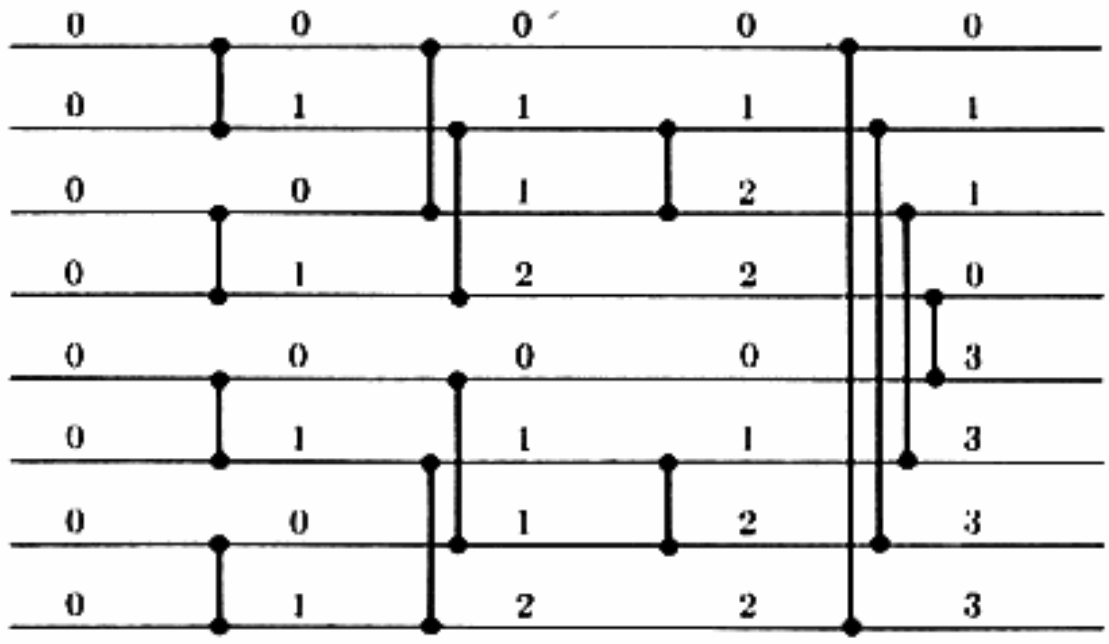

Fig. 55. Another interpretation for the network of Fig. 54.

The lower bound in Theorem A turns out to be exact when $t = 1$ and when $t = 2$ (see exercise 19). Table 1 gives some values of $\hat{U}_t(n)$, $\hat{V}_t(n)$, and $\hat{W}_t(n)$ for small t and n.

Table 1

COMPARISONS NEEDED IN SELECTION NETWORKS $(\hat{U}_t(n), \hat{V}_t(n), \hat{W}_t(n))$

	$t = 1$	$t = 2$	$t = 3$	$t = 4$	$t = 5$	$t = 6$
$n = 1$	(0, 0, 0)					
$n = 2$	(1, 1, 1)	(0, 1, 1)				
$n = 3$	(2, 2, 2)	(2, 3, 3)	(0, 2, 3)			
$n = 4$	(3, 3, 3)	(4, 5, 5)	(3, 5, 5)	(0, 3, 5)		
$n = 5$	(4, 4, 4)	(6, 7, 7)	(6, 7, 8)	(4, 7, 9)	(0, 4, 9)	
$n = 6$	(5, 5, 5)	(8, 9, 9)	(8, 10, 10)	(8, 10, 12)	(5, 9, 12)	(0, 5, 12)

EXERCISES—First Set

Several of the following exercises develop the theory of sorting networks in detail, and it is convenient to introduce some notation. We let $[i:j]$ stand for a comparison/interchange module. A network with n inputs and r comparator modules is written $[i_1:j_1][i_2:j_2]\ldots[i_r:j_r]$, where each of the i's and j's is $\leq n$; we shall call it an *n-network* for short. A network is called *standard* if $i_q < j_q$ for $1 \leq q \leq r$. Thus, for example, Fig. 44 on page 222 depicts a standard 4-network which is denoted by the comparator sequence [1:2][3:4][1:3][2:4][2:3].

The text's convention for drawing network diagrams represents only standard networks; all comparators $[i:j]$ are represented by a line from i to j, where $i < j$. When nonstandard networks must be drawn, we can use an *arrow* from i to j, indicating that the larger number goes to the point of the arrow. For example, Fig. 56 illustrates a nonstandard network for 16 elements, whose comparators are [1:2][4:3][5:6][8:7] etc. Exercise 11 proves that Fig. 56 is a sorting network.

If $x = \langle x_1, \ldots, x_n\rangle$ is an n-vector and α is an n-network, we write $x\alpha$ for the vector of numbers $\langle (x\alpha)_1, \ldots, (x\alpha)_n\rangle$ produced by the network. For brevity, we also let $a \vee b = \max(a, b)$, $a \wedge b = \min(a, b)$, $\bar{a} = 1 - a$. Thus $(x[i:j])_i = x_i \wedge x_j$, $(x[i:j])_j = x_i \vee x_j$, and $(x[i:j])_k = x_k$ when $i \neq k \neq j$. We say α is a *sorting network* iff $(x\alpha)_i \leq (x\alpha)_{i+1}$ for all x and for $1 \leq i < n$.

The symbol $e^{(i)}$ stands for a vector which is 1 in position i, 0 elsewhere; thus $(e^{(i)})_j = \delta_{ij}$. The symbol D_n stands for the set of all 2^n n-place vectors of 0's and 1's, and P_n stands for the set of all $n!$ vectors which are permutations of $\{1, 2, \ldots, n\}$. We write $x \wedge y$ and $x \vee y$ for the vectors $\langle x_1 \wedge y_1, \ldots, x_n \wedge y_n\rangle$ and $\langle x_1 \vee y_1, \ldots, x_n \vee y_n\rangle$, and we write $x \leq y$ if $x_i \leq y_i$ for all i. Thus $x \leq y$ iff $x \vee y = y$ iff $x \wedge y = x$. If x and y are in D_n, we say that x *covers* y if $x = y \vee e^{(i)} \neq y$ for some i. Finally for all x in D_n we let $\nu(x)$ be the number of 1's in x, and $\zeta(x)$ the number of 0's; thus $\nu(x) + \zeta(x) = n$.

1. [*20*] Draw a network diagram for the odd-even merge when $m = 3$ and $n = 5$.

2. [*22*] Show that V. Pratt's sorting algorithm (exercise 5.2.1–30) leads to a sorting network for n elements which has approximately $(\log_2 n)(\log_3 n)$ levels of delay. Draw the corresponding network for $n = 12$.

3. [*M20*] (K. E. Batcher.) Find a simple relation between $C(m, m-1)$ and $C(m, m)$.

▸ **4.** [*M23*] Prove that $\hat{T}(6) = 5$.

5. [*M21*] Prove that (13) is the delay time associated with the sorting network outlined in (10).

6. [*28*] Let $T(n)$ be the minimum number of stages needed to sort by making *simultaneous disjoint comparisons* (without the network constraint); each such set of comparisons can be represented as a node containing a set of pairs $i_1:j_1$, $i_2:j_2$, $\ldots$, $i_r:j_r$ where $i_1, j_1, i_2, j_2, \ldots, i_r, j_r$ are distinct, with 2^r branches below this node for the respective cases

$$\langle K_{i_1} < K_{j_1}, K_{i_2} < K_{j_2}, \ldots, K_{i_r} < K_{j_r}\rangle,$$
$$\langle K_{i_1} > K_{j_1}, K_{i_2} < K_{j_2}, \ldots, K_{i_r} < K_{j_r}\rangle, \qquad \text{etc.}$$

Prove that $T(5) = T(6) = 5$.

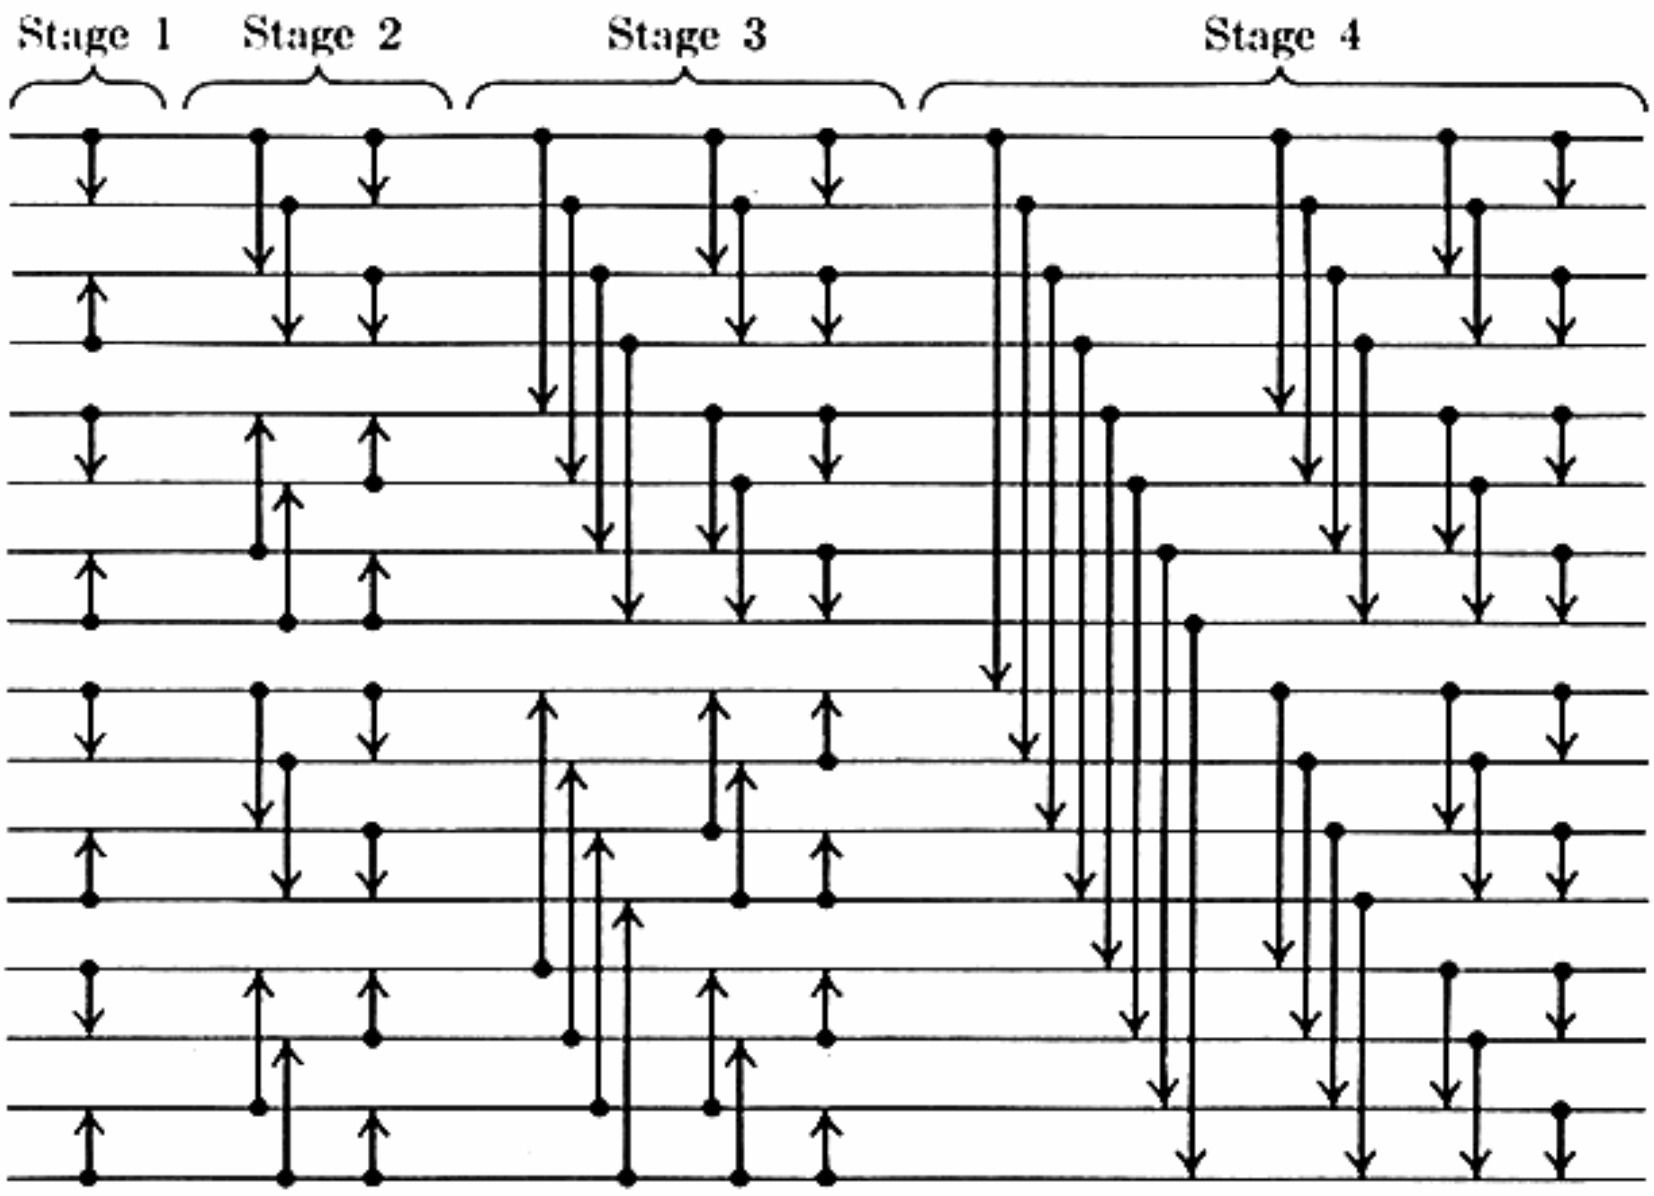

Fig. 56. A nonstandard sorting network based on bitonic sorting.

7. [*25*] Show that if the final comparator of the network for $n = 10$ in Fig. 49 is moved just ahead of the second- and third-last comparators, the network will still sort.

8. [*M20*] Prove that $\hat{M}(m_1 + m_2, n_1 + n_2) \geq \hat{M}(m_1, n_1) + \hat{M}(m_2, n_2) + \min(m_1, n_2)$, for $m_1, m_2, n_1, n_2 \geq 0$.

9. [*M25*] (R. W. Floyd.) Prove that $\hat{M}(3, 3) = 6$, $\hat{M}(4, 4) = 9$, $\hat{M}(5, 5) = 13$.

10. [*M22*] Prove that Batcher's bitonic sorter, as defined in the remarks preceding (15), is valid. [*Hint:* It is only necessary to prove that all sequences consisting of k 1's followed by l 0's followed by $n - k - l$ 1's will be sorted.]

11. [*M23*] Prove that Batcher's bitonic sorter of order 2^p will not only sort sequences $\langle z_0, z_1, \ldots, z_{2^p-1}\rangle$ for which $z_0 \geq \cdots \geq z_k \leq \cdots \leq z_{2^p-1}$, it also will sort any sequence for which $z_0 \leq \cdots \leq z_k \geq \cdots \geq z_{2^p-1}$. [As a consequence, the network in Fig. 56 will sort 16 elements, since each stage separated by dotted lines consists of bitonic sorters or reverse-order bitonic sorters, applied to sequences that have been sorted in opposite directions.]

12. [*M20*] Prove or disprove: If x and y are bitonic sequences of the same length, so are $x \vee y$ and $x \wedge y$.

▸**13.** [*24*] (H. S. Stone.) Show that a sorting network for 2^t elements can be constructed by following the pattern illustrated for $t = 4$ in Fig. 57. Each of the t^2 steps in this scheme consists of a "perfect shuffle" of the first 2^{t-1} elements with the last 2^{t-1}, followed by simultaneous operations performed on 2^{t-1} pairs of adjacent elements. Each of the latter operations is either "0" (no operation), "+" (a standard comparator module), or "−" (a reverse comparator module). The sorting proceeds in t stages of t steps each; during the last stage all operations are "+". During stage s, for $s < t$, we do $t - s$ steps in which all operations are "0", followed by s steps in which the operations within step 8 consist alternately of 2^q "+" followed by 2^q "−", for $q = 1, 2, \ldots, s$.

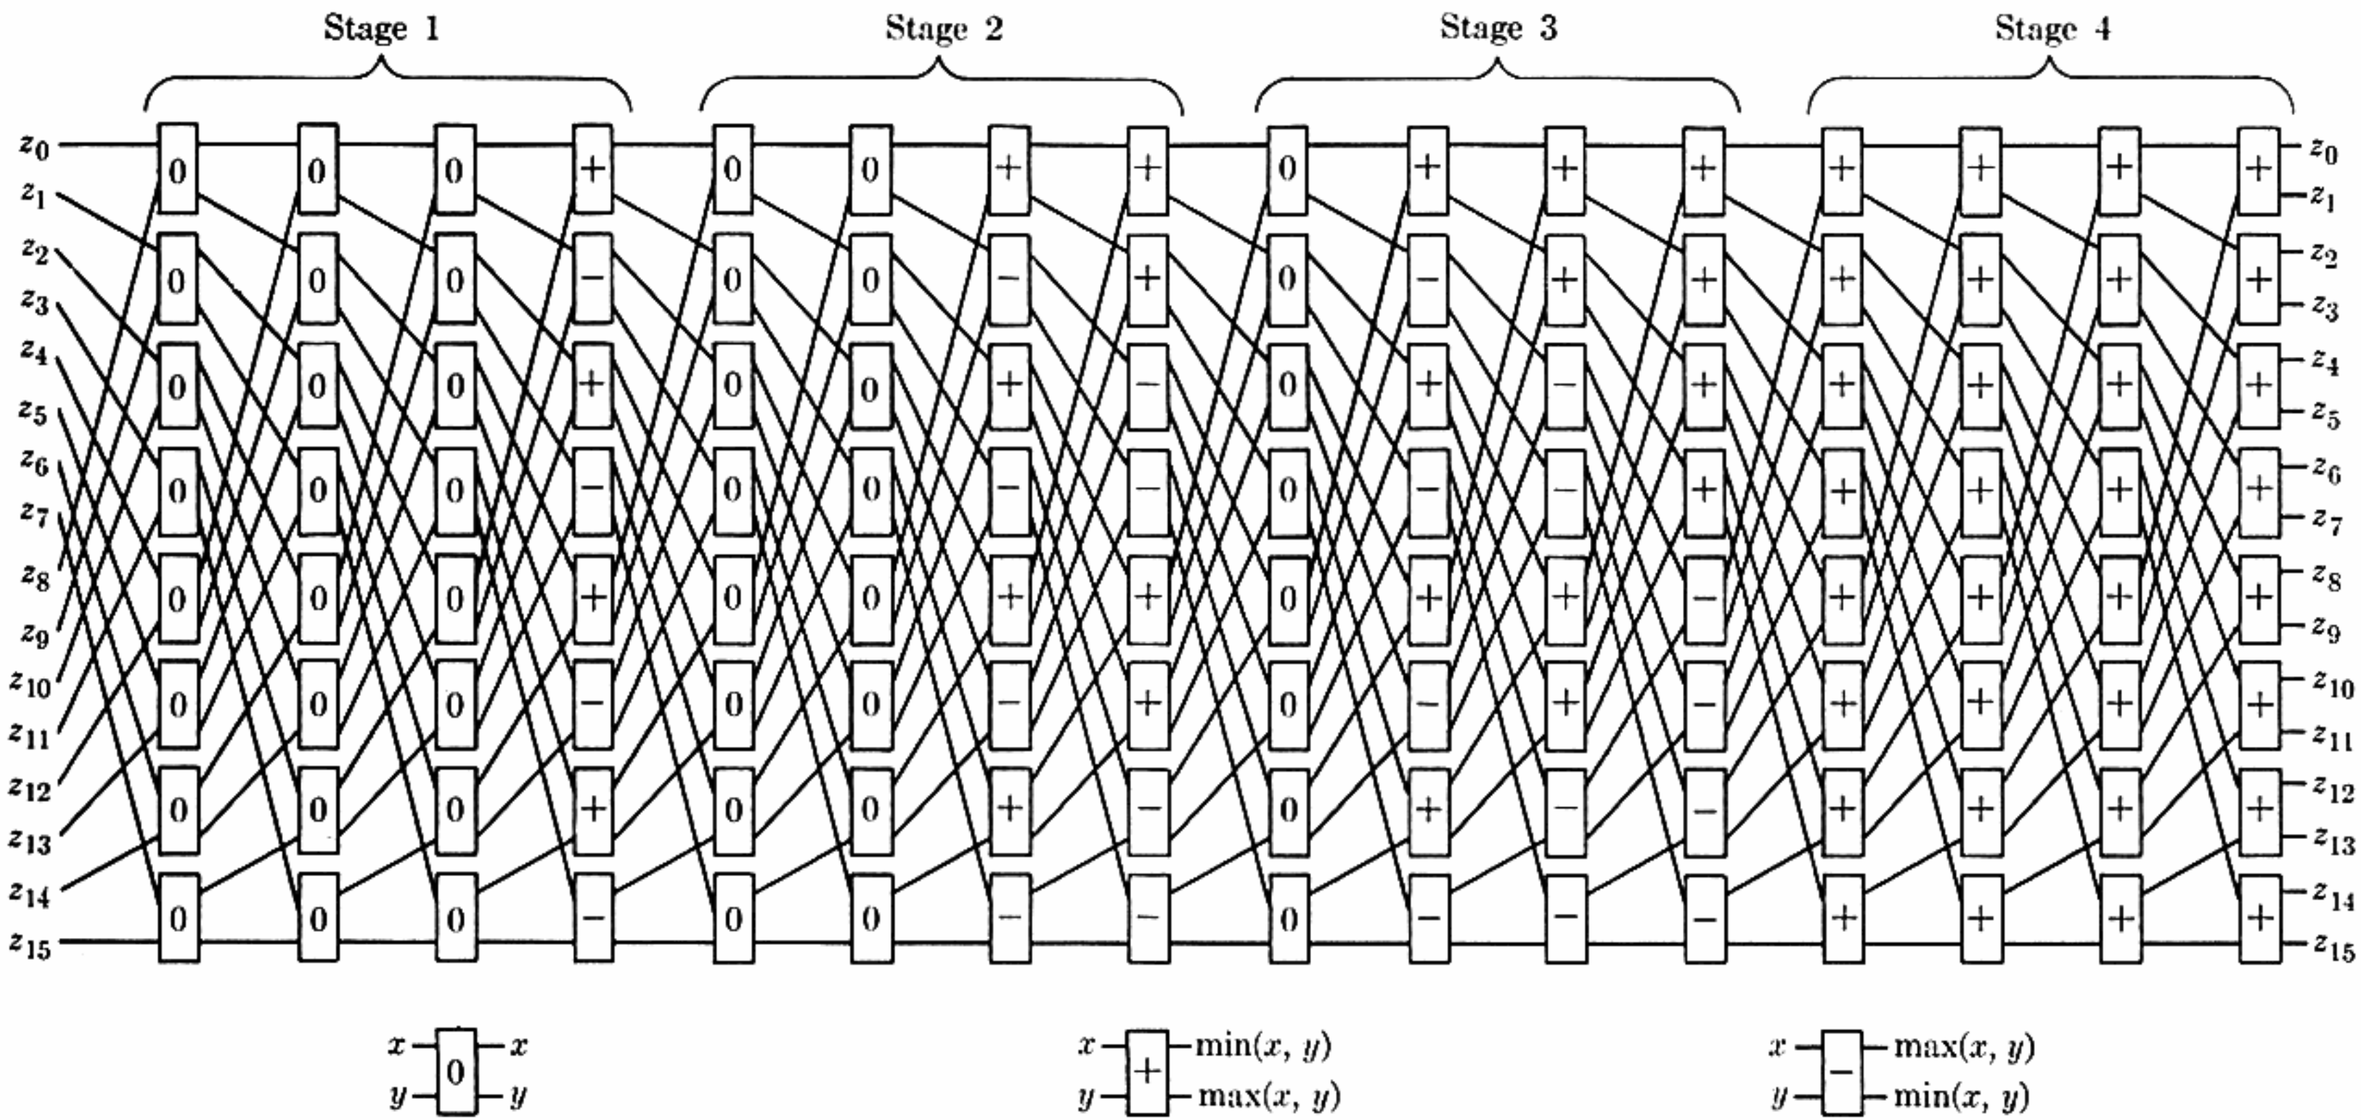

Fig. 57. Sorting 16 elements with "perfect shuffles."

[Note that this sorting scheme could be performed by a fairly simple device whose circuitry performs one "shuffle-and-operate" step and feeds the output lines back into the input. The first three steps in Fig. 57 could of course be eliminated; they have been retained only to make the pattern clear. Stone notes that the same pattern "shuffle/operate" occurs in several other algorithms, such as the fast Fourier transform (cf. Section 4.6.4).]

14. [*M20*] Prove that any $(1, n)$-merging network without multiple fanout must have at least $\lceil \log_2 (n+1) \rceil$ levels of delay.

15. [*20*] Find a nonstandard sorting network for four elements which has only five comparator modules.

16. [*M22*] Prove that the following algorithm transforms any sorting network $[i_1{:}j_1] \ldots [i_r{:}j_r]$ into a standard sorting network:

T1. Let q be the smallest index such that $i_q > j_q$. If no such index exists, stop.

T2. Change all occurrences of i_q to j_q, and all occurrences of j_q to i_q, in all comparators $[i_s{:}j_s]$ for $q \le s \le r$. Return to T1. ∎

For example, the network [4:1][3:2][1:3][2:4][1:2][3:4] is first transformed into [1:4][3:2][4:3][2:1][4:2][3:1], then [1:4][2:3][4:2][3:1][4:3][2:1], then [1:4][2:3][2:4][3:1][2:3][4:1], etc., until the standard network [1:4][2:3][2:4][1:3][1:2][3:4] is obtained.

17. [*M25*] Let D_{tn} be the set of all $\binom{n}{t}$ sequences $\langle x_1, \ldots, x_n \rangle$ of 0's and 1's having exactly t 1's. Show that $\hat{U}_t(n)$ is the minimum number of comparators needed in a network which sorts all the elements of D_{tn}; $\hat{V}_t(n)$ is the minimum number needed to sort $D_{tn} \cup D_{(t-1)n}$; and $\hat{W}_t(n)$ is the minimum number needed to sort $\bigcup_{0 \le k \le t} D_{kn}$.

▸ **18.** [*M20*] Prove that a network which finds the median of $2t - 1$ elements requires at least $(t-1)\lceil \log_2 (t+1) \rceil + \lceil \log_2 t \rceil$ comparator modules. [*Hint:* See the proof of Theorem A.]

19. [*M22*] Prove that $\hat{U}_2(n) = 2n - 4$ and $\hat{V}_2(n) = 2n - 3$, for all $n \ge 2$.

20. [*24*] Prove that $\hat{V}_3(5) = 7$.

21. [*M15*] Let α be any n-network, and let x and y be n-vectors. Prove that $x \le y$ implies that $x\alpha \le y\alpha$.

22. [*M15*] Prove that if x and y are n-vectors of real numbers, then $x \cdot y \le (x\alpha) \cdot (y\alpha)$. (Here $x \cdot y$ is the dot product, $x_1y_1 + \cdots + x_ny_n$.)

23. [*M17*] Let α be an n-network. Prove that there is a permutation $p \in P_n$ such that $(p\alpha)_i = j$ if and only if there are vectors x, y in D_n such that x covers y, $(x\alpha)_i = 1$, $(y\alpha)_i = 0$, and $\zeta(y) = j$.

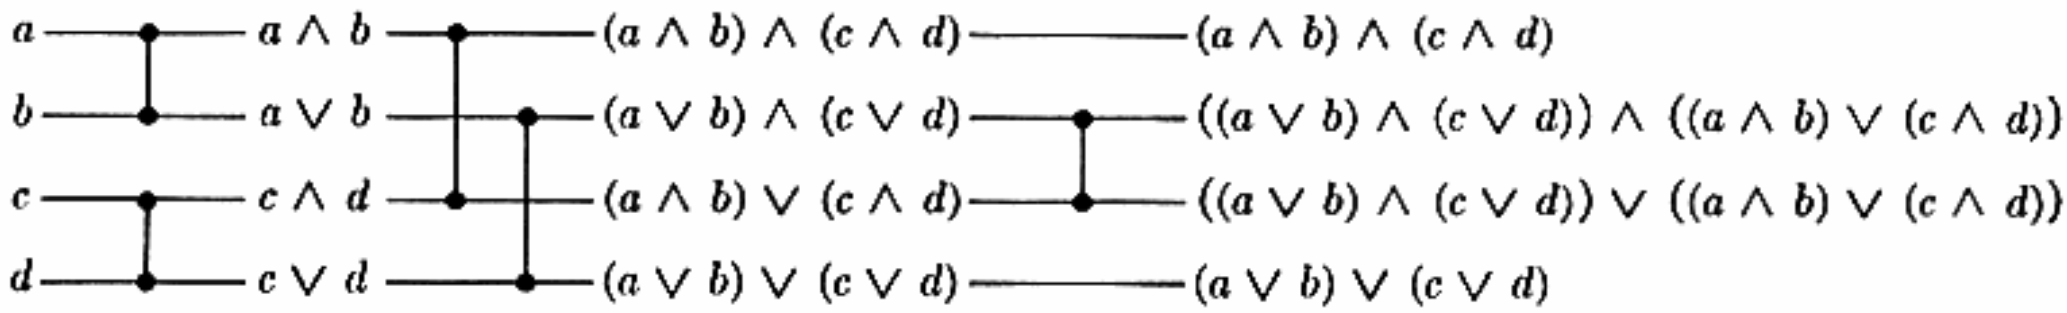
▸ **24.** [*M21*] (V. E. Alekseyev.) Let α be an n-network, and for $1 \le k \le n$ let $l_k = \min \{(p\alpha)_k \mid p \text{ in } P_n\}$, $u_k = \max \{(p\alpha)_k \mid p \text{ in } P_n\}$ denote the lower and upper bounds on the range of values which may appear in line k of the output. Let l'_k and u'_k be defined similarly for the network $\alpha' = \alpha[i{:}j]$. Prove that $l'_i = l_i \wedge l_j$, $l'_j \le l_i + l_j$, $u'_i \ge u_i + u_j - (n+1)$, $u'_j = u_i \vee u_j$. [*Hint:* Given vectors x and y in D_n with $(x\alpha)_i = (y\alpha)_j = 0$, $\zeta(x) = l_i$, $\zeta(y) = l_j$, find a vector z in D_n with $(z\alpha')_j = 0$, $\zeta(z) \le l_i + l_j$.]

25. [*M30*] Let l_k and u_k be as defined in exercise 24. Prove that the set $\{(p\alpha)_k \mid p \text{ in } P_n\}$ includes all integers between l_k and u_k inclusive.

26. [*M24*] (R. W. Floyd.) Let α be an n-network. Prove that the set $D_n\alpha = \{x\alpha \mid x \text{ in } D_n\}$ can be determined from the set $P_n\alpha = \{p\alpha \mid p \text{ in } P_n\}$; and conversely, $P_n\alpha$ can be determined from $D_n\alpha$.

▶**27.** [*M20*] Let x and y be vectors, and let $x\alpha$ and $y\alpha$ be sorted. Prove that $(x\alpha)_i \le (y\alpha)_j$ if and only if, for every choice of j elements from y we can choose i elements from x, such that every chosen x element is $\le$ some chosen y element. Use this principle to prove that *if we sort the rows of any matrix, then sort the columns, the rows will remain in order.*

▶**28.** [*M20*] The following diagram shows that it is possible to write down formulas for the contents of all lines in a sorting network in terms of the inputs:



Using the commutative laws $x \wedge y = y \wedge x$, $x \vee y = y \vee x$, the associative laws $x \wedge (y \wedge z) = (x \wedge y) \wedge z$, $x \vee (y \vee z) = (x \vee y) \vee z$, the distributive laws $x \wedge (y \vee z) = (x \wedge y) \vee (x \wedge z)$, $x \vee (y \wedge z) = (x \vee y) \wedge (x \vee z)$, the absorption laws $x \wedge (x \vee y) = x \vee (x \wedge y) = x$, and the idempotent laws $x \wedge x = x \vee x = x$, we can reduce the formulas at the right of this network to $(a \wedge b \wedge c \wedge d)$, $(a \wedge b \wedge c) \vee (a \wedge b \wedge d) \vee (a \wedge c \wedge d) \vee (b \wedge c \wedge d)$, $(a \wedge b) \vee (a \wedge c) \vee (a \wedge d) \vee (b \wedge c) \vee (b \wedge d) \vee (c \wedge d)$, $a \vee b \vee c \vee d$, respectively.

Prove that, in general, the tth largest element of $\{x_1, \ldots, x_n\}$ is given by the "elementary symmetric function"

$$\sigma_t(x_1, \ldots, x_n) = \vee\{x_{i_1} \wedge x_{i_2} \wedge \ldots \wedge x_{i_t} \mid 1 \le i_1 < i_2 < \cdots < i_t \le n\}.$$

[There are $\binom{n}{t}$ terms being $\vee$'d together. Thus the problem of finding minimum-cost sorting networks is equivalent to the problem of computing the elementary symmetric functions with a minimum number of "and/or" circuits, where at every stage we replace two quantities ϕ and ψ by $\phi \wedge \psi$ and $\phi \vee \psi$.]

29. [*M20*] Given that $x_1 \le x_2 \le x_3$ and $y_1 \le y_2 \le y_3 \le y_4 \le y_5$, and that $z_1 \le z_2 \le \cdots \le z_8$ is the result of merging the x's with the y's, find formulas for each of the z's in terms of the x's and the y's, using the operators $\wedge$ and $\vee$.

30. [*HM24*] Prove that any formula involving $\wedge$ and $\vee$ and the independent variables $\{x_1, \ldots, x_n\}$ can be reduced using the identities in exercise 28 to a "canonical" form $\tau_1 \vee \tau_2 \vee \cdots \vee \tau_k$, where $k \ge 1$, each τ_i has the form $\wedge\{x_j \mid j \text{ in } S_i\}$ where S_i is a subset of $\{1, 2, \ldots, n\}$, and no set S_i is included in S_j for $i \ne j$. Prove also that two such canonical forms are equal for all $x_1, \ldots, x_n$ if and only if they are identical (up to order).

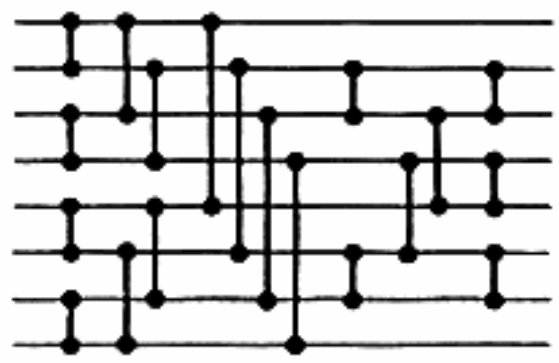
31. [*M24*] (R. Dedekind, 1897.) Let δ_n be the number of distinct canonical forms on $x_1, \ldots, x_n$ in the sense of exercise 30. Thus $\delta_1 = 1$, $\delta_2 = 4$, and $\delta_3 = 18$. What is δ_4?

32. [*M28*] (M. W. Green.) Let $G_1 = \{00, 01, 11\}$, and let G_{n+1} be the set of all strings $\theta\phi\psi\omega$ such that θ, ϕ, ψ, ω have length 2^{n-1} and $\theta\phi$, $\psi\omega$, $\theta\psi$, and $\phi\omega$ are in G_n.

Let α be the network consisting of the first four levels of the 16-sorter shown in Fig. 48. Show that $D_{16}\alpha = G_4$, and prove that it has exactly $\delta_4 + 2$ elements. (Cf. exercise 31.)

▸ **33.** [*M22*] Not all δ_n of the functions of $\langle x_1, \ldots, x_n \rangle$ in exercise 31 can appear in comparator networks. In fact, prove that the function $(x_1 \wedge x_2) \vee (x_2 \wedge x_3) \vee (x_3 \wedge x_4)$ cannot appear as an output of any comparator network on $\langle x_1, \ldots, x_n \rangle$.

34. [*23*] Is the following a sorting network?



35. [*20*] Prove that any *standard* sorting network must contain each of the "adjacent" comparators $[i:i+1]$, for $1 \leq i < n$, at least once.

▸ **36.** [*22*] The network of Fig. 47 involves only *adjacent* comparisons $[i:i+1]$; let us call such a network *primitive*. (a) Prove that a primitive sorting network for n elements must have at least $\binom{n}{2}$ comparators. [*Hint:* Consider the inversions of a permutation.] (b) (R. W. Floyd, 1964.) Let α be a primitive network for n elements, and let x be a vector such that $(x\alpha)_i > (x\alpha)_j$ for some $i < j$. Prove that $(y\alpha)_i > (y\alpha)_j$, where y is the vector $\langle n, n-1, \ldots, 1 \rangle$. (c) As a consequence of (b), a primitive network is a sorting network if and only if it sorts the single vector $\langle n, n-1, \ldots, 1 \rangle$!

37. [*M22*] The *odd-even transposition sort* for n numbers, $n \geq 3$, is a network n levels deep with $\frac{1}{2}n(n-1)$ comparators, arranged in a brick-like pattern as shown in Fig. 58. (When n is even, there are two possibilities.) Such a sort is especially easy to implement in hardware, since only two kinds of actions are performed alternately. Prove that such a network is, in fact, a valid sorting network. [*Hint:* See exercise 36.]

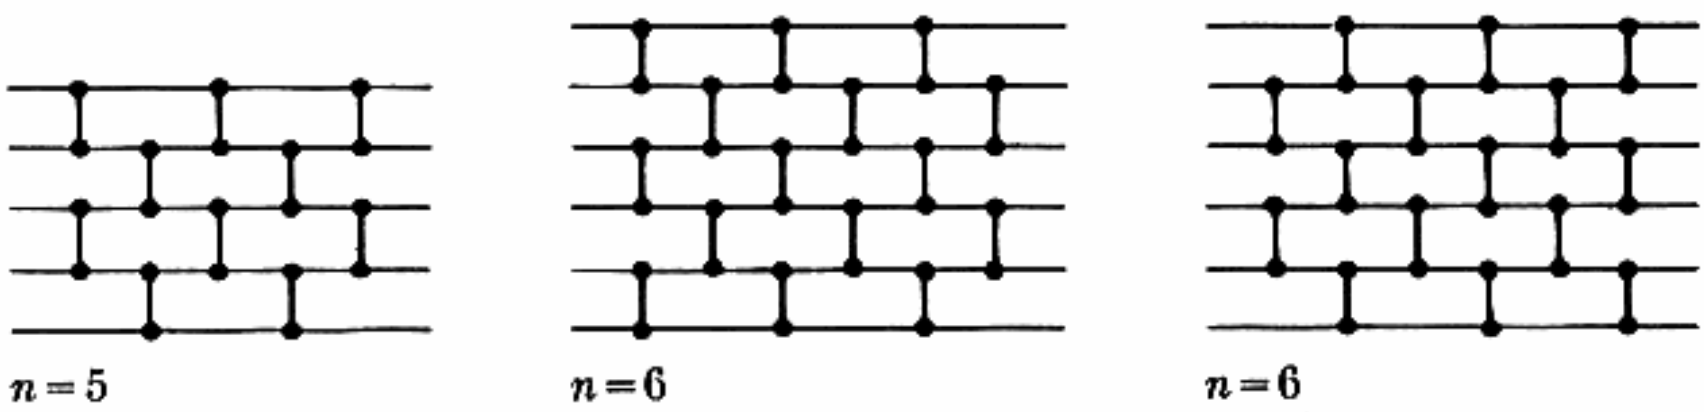


Fig. 58. The odd-even transposition sort.

38. [*29*] We may interpret sorting networks in another way, letting each line carry a multiset of m numbers, instead of a single number; under this interpretation, the operation $[i:j]$ replaces x_i and x_j, respectively, by $x_i \Cap x_j$ and $x_i \Cup x_j$, the least m and the greatest m of the $2m$ numbers $x_i \uplus x_j$. (See Fig. 59 for an illustration of this interpretation when $m = 2$.) If a and b are multisets of m numbers each, we say that $a \ll b$ iff $a \Cap b = a$ (equivalently, $a \Cup b = b$; the largest element of a is less than or equal to the smallest of b). Thus $a \Cap b \ll a \Cup b$.

Let α be an n-network, and let $x = \langle x_1, \ldots, x_n \rangle$ be a vector in which each x_i is a multiset of m elements. Prove that if $(x\alpha)_i$ is not $\ll (x\alpha)_j$ in the above interpretation, there is a vector y in D_n such that $(y\alpha)_i = 1$ and $(y\alpha)_j = 0$. [Consequently, a sorting

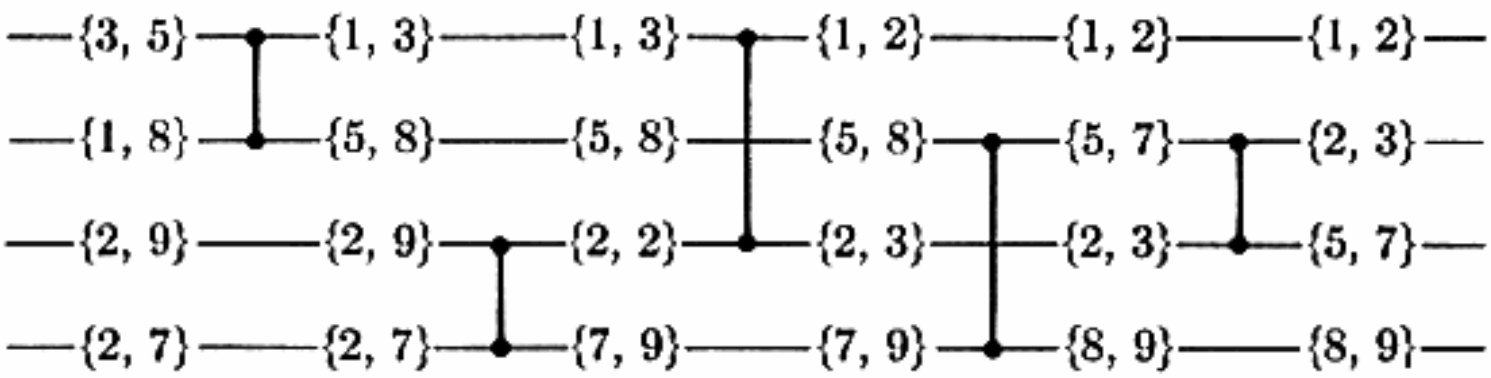

Fig. 59. Another interpretation of the sorting network in Fig. 44: each comparator module performs a merge operation.

network for n elements becomes a sorting network for mn elements if we replace comparisons by m-way merges. Figure 60 shows an 8-element sorter constructed from a 4-element sorter by using this observation.]

▸**39.** [*M23*] Show that, in the notation of exercise 38, $(x \curlywedge y) \curlywedge z = x \curlywedge (y \curlywedge z)$ and $(x \curlyvee y) \curlyvee z = x \curlyvee (y \curlyvee z)$; however $(x \curlyvee y) \curlywedge z$ is *not* always equal to $(x \curlywedge z) \curlyvee (y \curlywedge z)$, and $(x \curlywedge y) \curlyvee (x \curlywedge z) \curlyvee (y \curlywedge z)$ does *not* always equal the middle m elements of $x \uplus y \uplus z$. Find a correct formula, in terms of x, y, z and the $\curlywedge$ and $\curlyvee$ operations, for those middle elements.

▸**40.** [*M25*] (R. L. Graham.) The comparator $[i:j]$ is called *redundant* in the network $\alpha_1[i:j]\alpha_2$ if either $(x\alpha_1)_i \leq (x\alpha_1)_j$ for all vectors x, or $(x\alpha_1)_i \geq (x\alpha_1)_j$ for all vectors x. Prove that if α is a network with r irredundant comparators, there are at least r distinct ordered pairs (i, j) of distinct indices such that $(x\alpha)_i \leq (x\alpha)_j$ for all vectors x. (Consequently, a network with no redundant comparators contains at most $\binom{n}{2}$ modules.)

▸**41.** [*M27*] (V. E. Alekseyev.) Let $\alpha = [i_1:j_1] \ldots [i_r:j_r]$ be an n-network; for $1 \leq s \leq r$ we define $\alpha^s = [i'_1:j'_1] \ldots [i'_{s-1}:j'_{s-1}][i_s:j_s] \ldots [i_r:j_r]$, where the i'_k and j'_k are obtained from i_k and j_k by changing i_s to j_s and changing j_s to i_s wherever they appear. For example, if $\alpha = [1:2][3:4][1:3][2:4][2:3]$, then $\alpha^4 = [1:4][3:2][1:3][2:4][2:3]$.

a) Prove that $D_n\alpha = D_n(\alpha^s)$.

b) Prove that $(\alpha^s)^t = (\alpha^t)^s$.

c) A *conjugate* of α is any network of the form $(\ldots((\alpha^{s_1})^{s_2}) \ldots)^{s_k}$. Prove that α has at most 2^{r-1} conjugates.

d) Let $g_\alpha(x) = 1$ if $x \in D_n\alpha$, 0 if $x \notin D_n\alpha$; and let

$$f_\alpha(x) = (\bar{x}_{i_1} \vee x_{j_1}) \wedge \cdots \wedge (\bar{x}_{i_r} \vee x_{j_r}).$$

Prove that $g_\alpha(x) = \bigvee \{f_{\alpha'}(x) \mid \alpha' \text{ is a conjugate of } \alpha\}$.

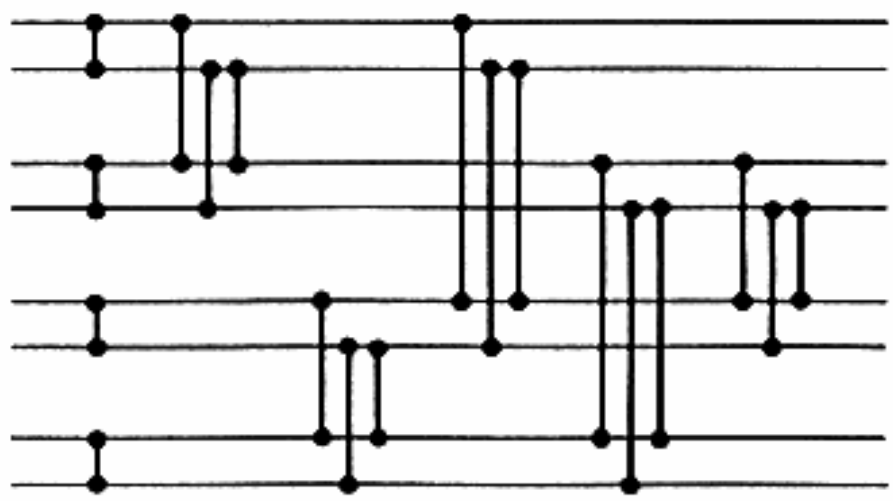

Fig. 60. An 8-sorter constructed from a 4-sorter, by using the merging interpretation.

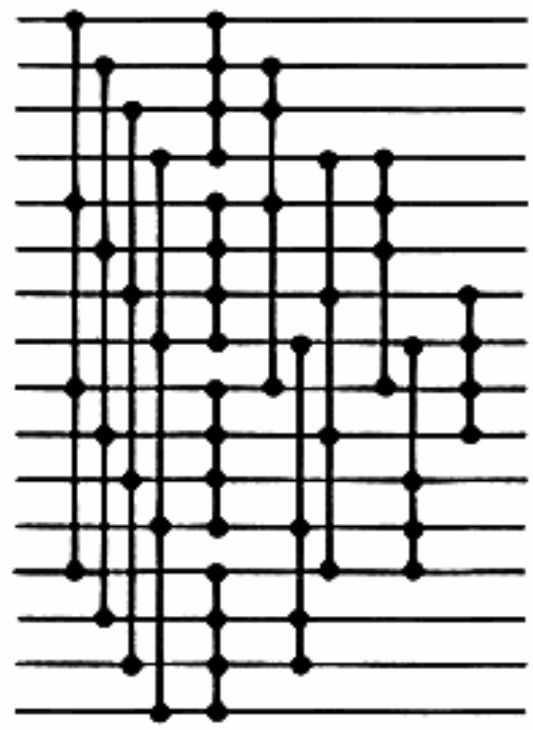
c) Let G_α be the directed graph with vertices $\{1, \ldots, n\}$, and arcs $i_s \rightarrow j_s$ for $1 \leq s \leq r$. Prove that α is a sorting network if and only if $G_{\alpha'}$ has an oriented path from i to $i+1$ for $1 \leq i < n$ and for all α' conjugate to α. [This condition is somewhat remarkable, since G_α does not depend on the order of the comparators in α.]

▶ **42.** [*25*] (D. Van Voorhis.) Prove that $\hat{S}(n) \geq \hat{S}(n-1) + \lceil \log_2 n \rceil$.

43. [*23*] A *permutation network* is a sequence of modules $[i_1:j_1] \ldots [i_r:j_r]$ where each module $[i:j]$ can be set by external controls to pass its inputs unchanged or to switch x_i and x_j (irrespective of the values of x_i and x_j), and such that each permutation of the inputs is achievable on the output lines by some setting of the modules. Every sorting network is clearly a permutation network, but the converse is not true: Find a permutation network for five elements which has only eight modules.

44. [*46*] Study the properties of sorting networks which are made from m-sorter modules instead of 2-sorters. (For example, G. Shapiro has constructed the network



which sorts 16 elements using fourteen 4-sorters. Is this best possible? Are there efficient ways to sort m^2 elements with m-sorter modules, for all m?)

45. [*48*] Find an (m, n) merging network with less than $C(m, n)$ comparators, or prove that none exists.

46. [*48*] Find an (m, n) merging network with less than $\lceil \log_2 (m+n) \rceil$ levels of delay, or prove that none exists.

47. [*48*] Study the class of sorting schemes that can be implemented with perfect shuffle networks as in Fig. 57, with other patterns of "0", "+", and "−" operations.

48. [*HM49*] Explore the properties of the $\hat{\wedge}$ and $\hat{\vee}$ operations defined in exercise 38. Is it possible to characterize all of the identities in this algebra in some nice way, or to derive them all from a finite set of identities? In this regard, identities such as $x \mathbin{\hat{\wedge}} x \mathbin{\hat{\wedge}} x = x \mathbin{\hat{\wedge}} x$, or $x \mathbin{\hat{\wedge}} (x \mathbin{\hat{\vee}} (x \mathbin{\hat{\wedge}} (x \mathbin{\hat{\vee}} y))) = x \mathbin{\hat{\wedge}} (x \mathbin{\hat{\vee}} y)$, which hold only for $m \leq 2$, are of comparatively little interest; consider only the identities which are true for *all* m.

49. [*M49*] What is the asymptotic behavior of the function $T(n)$ defined in exercise 6? Is $T(n) < \hat{T}(n)$ for some n?

50. [*50*] Find the exact value of $\hat{S}(n)$ for some $n > 8$.

51. [*M50*] Prove that the asymptotic value of $\hat{S}(n)$ is not $O(n \log n)$.

EXERCISES—Second Set

The following exercises deal with several different types of optimality questions related to sorting. The first few problems are based on an interesting "multi-head" generalization of the bubble sort, investigated by P. N. Armstrong and R. J. Nelson as early as 1954. [See *U.S. Patents 3029413, 3034102.*] Let $1 = h_1 < h_2 < \cdots < h_m = n$ be an increasing sequence of integers; we shall call it a "head sequence" of length m and span n, and we shall use it to define a special kind of sorting method. The sorting of records $R_1 \ldots R_N$ proceeds in several passes, and each pass consists of $N + n - 1$ steps. On step j, for $j = 1 - n, 2 - n, \ldots, N - 1$, the records $R_{j+h[1]}, R_{j+h[2]}, \ldots, R_{j+h[m]}$ are examined and rearranged if necessary so that their keys are in order. (We say that $R_{j+h[1]}, \ldots, R_{j+h[m]}$ are "under the read-write heads." When $j + h[k]$ is < 1 or $> N$, record $R_{j+h[k]}$ is left out of consideration; in effect, the keys $K_0, K_{-1}, K_{-2}, \ldots$ are treated as $-\infty$ and $K_{N+1}, K_{N+2}, \ldots$ are treated as $+\infty$. Therefore step j is actually trivial when $j \le -h[m-1]$ or $j > N - h[2]$.)

For example, the following table shows one pass of a sort when $m = 3$, $N = 9$, and $h_1 = 1$, $h_2 = 2$, $h_3 = 4$:

	K_{-2}	K_{-1}	K_0	K_1	K_2	K_3	K_4	K_5	K_6	K_7	K_8	K_9	K_{10}	K_{11}	K_{12}
$j = -3$	—	—		3	1	4	5	9	2	6	8	7			
$j = -2$		—	—	3	1	4	5	9	2	6	8	7			
$j = -1$			—	3	1	4	5	9	2	6	8	7			
$j = 0$				1	3	4	5	9	2	6	8	7			
$j = 1$				1	3	4	5	9	2	6	8	7			
$j = 2$				1	3	2	4	9	5	6	8	7			
$j = 3$				1	3	2	4	6	5	9	8	7			
$j = 4$				1	3	2	4	5	6	9	8	7			
$j = 5$				1	3	2	4	5	6	7	8	9			
$j = 6$				1	3	2	4	5	6	7	8	9	—		
$j = 7$				1	3	2	4	5	6	7	8	9		—	
$j = 8$				1	3	2	4	5	6	7	8	9	—		—

Note that when $m = 2$, $h_1 = 1$, and $h_2 = 2$, this "multi-head" method reduces to the bubble sort (Algorithm 5.2.2B).

52. [*21*] (James Dugundji.) Prove that if $h[k+1] = h[k] + 1$ for some k, $1 \le k < m$, the multihead sorter defined above will eventually sort any input file in a finite number of passes. But if $h[k+1] \ge h[k] + 2$ for $1 \le k < m$, the input might *never* become sorted.

▸**53.** [*30*] (Armstrong and Nelson.) Given that $h[k+1] \le h[k] + k$ for $1 \le k < m$, and $N \ge n - 1$, prove that the largest $n - 1$ elements always move to their final destination on the first pass. [*Hint:* Use the zero-one principle; when sorting 0's and 1's, with less than n 1's, prove that it is impossible to have all heads sensing a 1 unless all 0's lie to the left of the heads.]

Prove that sorting will be complete in at most $\lceil (N-1)/(n-1) \rceil$ passes when the heads satisfy the given conditions. Is there an input file which requires this many passes?

54. [*26*] If $n = N$, prove that the first pass can be guaranteed to place the smallest key into position R_1 if and only if $h[k+1] \leq 2h[k]$ for $1 \leq k < m$.

55. [*34*] (J. Hopcroft.) A "perfect sorter" for N elements is a multi-head sorter with $N = n$ which always finishes in one pass. Exercise 53 proves that the sequence $\langle h_1, h_2, h_3, h_4, \ldots, h_m\rangle = \langle 1, 2, 4, 7, \ldots, 1 + \binom{m}{2}\rangle$ gives a perfect sorter for $N = \binom{m}{2} + 1$ elements, using $m = (\sqrt{8N-7}+1)/2$ heads. For example, the head sequence $\langle 1, 2, 4, 7, 11, 16, 22\rangle$ is a perfect sorter for 22 elements.

Prove that, in fact, the head sequence $\langle 1, 2, 4, 7, 11, 16, 23\rangle$ is a perfect sorter for 23 elements.

56. [*49*] Study the largest N for which m-head perfect sorters exist, given m. Is $N = O(m^2)$?

57. [*23*] (V. Pratt.) When each head h_k is in position 2^{k-1} for $1 \leq k \leq m$, how many passes are necessary to sort the sequence $z_1\, z_2 \ldots z_{2^m-1}$ of 0's and 1's where $z_j = 0$ iff j is a power of 2?

58. [*24*] (*Uniform sorting.*) The tree of Fig. 34 in Section 5.3.1 makes the comparison 2:3 in both branches on level 1, and on level 2 it compares 1:3 in each branch unless that comparison would be redundant. In general, we can consider the class of all sorting algorithms which are uniform in that way; assuming that the $M = \binom{N}{2}$ pairs $\{(a, b) \mid 1 \leq a < b \leq N\}$ have been arranged into a sequence

$$(a_1, b_1)\ (a_2, b_2), \ldots, (a_M, b_M),$$

we can successively make each of the comparisons $K_{a_1}{:}K_{b_1}$, $K_{a_2}{:}K_{b_2}$, ... whose outcome is not already known. Each of the $M!$ arrangements of the (a, b) pairs defines a uniform sorting algorithm. The concept of uniform sorting is due to H. L. Beus [*JACM* **17** (1970), 482–495], whose work has suggested the next few exercises.

It is convenient to define uniform sorting formally by means of graph theory. Let G be the directed graph on the vertices $\{1, 2, \ldots, N\}$, having no arcs. For $i = 1, 2, \ldots, M$ we add arcs to G as follows:

Case 1. G contains a path from a_i to b_i. Add the arc $a_i \rightarrow b_i$ to G.

Case 2. G contains a path from b_i to a_i. Add the arc $b_i \rightarrow a_i$ to G.

Case 3. G contains no path from a_i to b_i or b_i to a_i. Compare $K_{a_i}{:}K_{b_i}$; then add the arc $a_i \rightarrow b_i$ to G if $K_{a_i} \leq K_{b_i}$, the arc $b_i \rightarrow a_i$ if $K_{a_i} > K_{b_i}$.

We are concerned primarily with the number of key comparisons made by a uniform sorting algorithm, not with the mechanism by which redundant comparisons are actually avoided; the graph G need not be constructed explicitly, it is used here merely to help define the concept of uniform sorting.

We shall also consider *restricted uniform sorting*, in which only paths of length 2 are counted in cases 1, 2, and 3 above. (A restricted uniform sorting algorithm may make some redundant comparisons, but exercise 59 shows that the analysis is somewhat simpler in the restricted case.)

Prove that the restricted uniform algorithm is the same as the uniform algorithm when the sequence of pairs is taken in lexicographic order

$$(1, 2)(1, 3)(1, 4) \ldots (1, N)(2, 3)(2, 4) \ldots (2, N) \ldots (N-1, N).$$

Show in fact that both algorithms are equivalent to "quicksort" (Algorithm 5.2.2Q) when the keys are distinct and when quicksort's redundant comparisons are removed as in exercise 5.2.2–24. (Disregard the order in which the comparisons are actually made in quicksort, consider only which pairs of keys are compared.)

59. [*M38*] Given a pair sequence $(a_1, b_1) \ldots (a_M, b_M)$ as in exercise 58, let c_i be the number of pairs (j, k) such that $j < k < i$ and (a_i, b_i), (a_j, b_j), (a_k, b_k) forms a triangle. (a) Prove that the average number of comparisons made by the restricted uniform sorting algorithm is $\sum_{1 \le i \le M} 2/(c_i + 2)$. (b) Use the results of (a) and exercise 58 to determine the average number of irredundant comparisons performed by quicksort. (c) The following pair sequence is inspired by (but not equivalent to) merge sorting:

$$(1, 2)(3, 4)(5, 6) \ldots (1, 3)(1, 4)(2, 3)(2, 4)(5, 7) \ldots (1, 5)(1, 6)(1, 7)(1, 8)(2, 5) \ldots$$

Does the uniform method based on this sequence do more or less comparisons than quicksort, on the average?

60. [*M29*] In the worst case, quicksort does $\binom{N}{2}$ comparisons. Do all restricted uniform sorting algorithms (in the sense of exercise 57) perform $\binom{N}{2}$ comparisons in their worst case?

61. [*M48*] (H. L. Beus.) Does quicksort have the minimum average number of comparisons, over all (restricted) uniform sorting algorithms?

62. [*25*] The Ph.D. thesis "Electronic Data Sorting" by Howard B. Demuth (Stanford University: October, 1956) was perhaps the first paper to deal in any detail with questions of computational complexity. Demuth considered several abstract models for sorting devices, and established lower and upper bounds on the mean and maximum execution times achievable with each model. His simplest model, the "circular non-reversible memory" (Fig. 61), is the subject of this exercise.

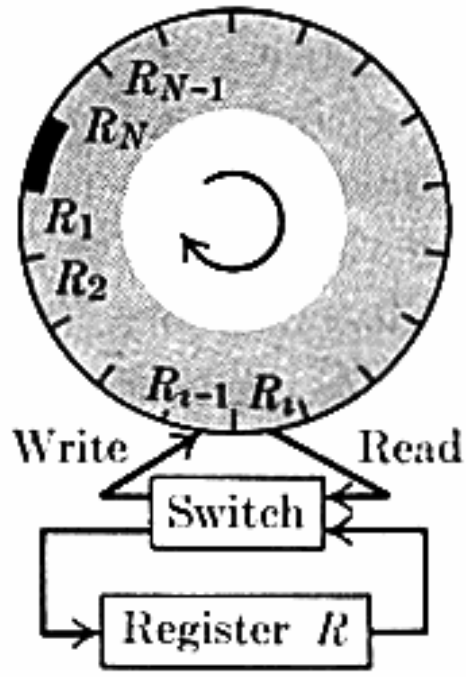


Fig. 61. A device for which the bubble-sort strategy is optimum.

Consider a machine which sorts $R_1\ R_2 \ldots R_N$ in a number of passes, where each pass contains the following $N + 1$ steps:

Step 1. Set $R \leftarrow R_1$. (R is an internal machine register.)

Step i, for $1 < i \le N$.

Either (a) Set $R_{i-1} \leftarrow R$, $R \leftarrow R_i$;
or (b) Set $R_{i-1} \leftarrow R_i$, leaving R unchanged.

Step $N + 1$. Set $R_N \leftarrow R$.

The problem is to find a way to choose between alternatives (a) and (b) each time, in order to minimize the number of passes required to sort.

Prove that the "bubble sort" technique is optimum for this model. In other words, show that the strategy which selects alternative (a) whenever $R \le R_i$ and alternative (b) whenever $R > R_i$ will achieve the minimum number of passes.

5.4. EXTERNAL SORTING

Now it is time for us to study the interesting problems which arise when the number of records to be sorted is larger than our computer can hold in its high-speed internal memory. External sorting is quite different from internal sorting, even though the problem in both cases is to sort a given file into nondecreasing order, since efficient storage accessing on external files is rather severely limited. The data structures must be arranged so that comparatively slow peripheral memory devices (tapes, disks, drums, etc.) can quickly cope with the requirements of the sorting algorithm. Consequently most of the internal sorting techniques we have studied (insertion, exchange, selection) are virtually useless for external sorting, and it is necessary to reconsider the whole question.

Suppose, for example, that we have a file of 5000 records $R_1 R_2 \ldots R_{5000}$ to sort, and that each record R_i is 20 words long (although the keys K_i are not necessarily this long). If only 1000 of these records will fit in the internal memory of a particular computer at one time, what shall we do?

One fairly obvious solution is to start by sorting each of the five subfiles $R_1 \ldots R_{1000}$, $R_{1001} \ldots R_{2000}$, $\ldots$, $R_{4001} \ldots R_{5000}$, independently, then to merge the resulting subfiles together. Fortunately the process of merging uses only very simple data structures, namely linear lists which are traversed in a sequential manner as stacks or as queues; hence merging can be done without difficulty on the least expensive external memory devices.

The process just described—internal sorting followed by "external merging"—is very commonly used, and we shall devote most of our study of external sorting to variations on this theme.

The ascending sequences of records, which are produced by the initial internal sorting phase, are often called *strings* in the published literature about sorting; this terminology is fairly widespread, but it unfortunately conflicts with even more widespread usage in other branches of computer science, where "strings" are *arbitrary* sequences of symbols. Our study of permutations has already given us a perfectly good name for the sorted segments of a file, which are conventionally called ascending runs or simply *runs*. Therefore we shall consistently use the word "runs" to describe sorted portions of a file. In this way it is possible to distinguish between "strings of runs" and "runs of strings" without ambiguity. (Of course, "runs of a program" means something else again; we can't have everything.)

Let us first consider the process of external sorting when *magnetic tapes* are used for auxiliary storage. Perhaps the simplest and most appealing way to merge with tapes is the *balanced 2-way merge*, following the central idea which was used in Algorithms 5.2.4N, S, and L. We use four "working tapes" in this process. During the first phase, ascending runs produced by internal sorting are placed alternately on Tapes 1 and 2, until the input is exhausted. Then Tapes 1 and 2 are rewound to their beginnings, and we merge the runs from these tapes, obtaining new runs which are twice as long as the original ones; the new runs are written alternately on Tapes 3 and 4 as they are being formed.

(If Tape 1 contains one more run than Tape 2, an extra "dummy" run of length 0 is assumed to be present on Tape 2.) Then all tapes are rewound, and the contents of Tapes 3 and 4 are merged into quadruple-length runs recorded alternately on Tapes 1 and 2. The process continues, doubling the length of runs each time, until only one run is left (namely the entire sorted file). If S runs were produced during the internal sorting phase, and if $2^{k-1} < S \le 2^k$, this balanced 2-way merge procedure makes exactly $k = \lceil \log_2 S \rceil$ merging passes over all the data.

For example, in the above situation where 5000 records are to be sorted with an internal memory capacity of 1000, we have $S = 5$. The initial distribution phase of the sorting process places five runs on tape as follows:

$$\begin{array}{ll} \text{Tape 1} & R_1 \ldots R_{1000};\ R_{2001} \ldots R_{3000};\ R_{4001} \ldots R_{5000}. \\ \text{Tape 2} & R_{1001} \ldots R_{2000};\ R_{3001} \ldots R_{4000}. \\ \text{Tape 3} & \text{(empty)} \\ \text{Tape 4} & \text{(empty)} \end{array} \tag{1}$$

The first pass of merging then produces longer runs on Tapes 3 and 4, as it reads Tapes 1 and 2, as follows:

$$\begin{array}{ll} \text{Tape 3} & R_1 \ldots R_{2000};\ R_{4001} \ldots R_{5000}. \\ \text{Tape 4} & R_{2001} \ldots R_{4000}. \end{array} \tag{2}$$

(A dummy run has implicitly been added at the end of Tape 2, so that the last run $R_{4001} \ldots R_{5000}$ on Tape 1 is merely copied onto Tape 3.) After all tapes are rewound, the next pass over the data produces

$$\begin{array}{ll} \text{Tape 1} & R_1 \ldots R_{4000}. \\ \text{Tape 2} & R_{4001} \ldots R_{5000}. \end{array} \tag{3}$$

(Again that run $R_{4001} \ldots R_{5000}$ was simply copied; but if we had started with 8000 records, Tape 2 would have contained $R_{4001} \ldots R_{8000}$ at this point.) Finally, after another spell of rewinding, $R_1 \ldots R_{5000}$ is produced on Tape 3, and the sorting is complete.

Balanced merging can easily be generalized to the case of T tapes, for any $T \ge 3$. Choose any number P with $1 \le P < T$, and divide the T tapes into two "banks," with P tapes on the left bank and $T - P$ on the right. Distribute the initial runs as evenly as possible onto the P tapes in the left bank; then do a P-way merge from the left to the right, followed by a $(T - P)$-way merge from the right to the left, etc., until sorting is complete. The best choice of P usually turns out to be $\lceil T/2 \rceil$ (see exercises 3, 4).

Balanced two-way merging is the special case $T = 4$, $P = 2$. Let us reconsider the example above using more tapes, taking $T = 6$ and $P = 3$.

The initial distribution now gives us

$$\begin{array}{ll} \text{Tape 1} & R_1 \ldots R_{1000};\ R_{3001} \ldots R_{4000}. \\ \text{Tape 2} & R_{1001} \ldots R_{2000};\ R_{4001} \ldots R_{5000}. \\ \text{Tape 3} & R_{2001} \ldots R_{3000}. \end{array} \tag{4}$$

And the first merging pass produces

$$\begin{array}{ll} \text{Tape 4} & R_1 \ldots R_{3000}. \\ \text{Tape 5} & R_{3001} \ldots R_{5000}. \\ \text{Tape 6} & \text{(Empty)} \end{array} \tag{5}$$

(A dummy run has been assumed on Tape 3.) The second merging pass completes the job, placing $R_1 \ldots R_{5000}$ on Tape 1. In this special case $T = 6$ is essentially the same as $T = 5$, since the sixth tape is used only when $S \geq 7$.

Three-way merging actually requires somewhat more computer processing time than two-way merging, but this is generally negligible compared to the time needed to read, write, and rewind the tapes; we can get a fairly good estimate of the running time by considering only the amount of tape motion. The example in (4) and (5) required only two passes over the data, compared to three passes when $T = 4$, so the merging takes only about two-thirds as long when $T = 6$.

Balanced merging is quite simple, but if we look more closely, we find immediately that it isn't the *best* way to handle the particular cases treated above! Instead of going from (1) to (2) and rewinding all of the tapes, we should have stopped the first merging pass after Tapes 3 and 4 contained $R_1 \ldots R_{2000}$ and $R_{2001} \ldots R_{4000}$, respectively, with Tape 1 poised ready to read $R_{4001} \ldots R_{5000}$. Then Tapes 2, 3, 4 could be rewound and we could complete the sort by doing a three-way merge onto Tape 2. The total number of records read from tape during this procedure would be only $4000 + 5000 = 9000$, compared to $5000 + 5000 + 5000 = 15{,}000$ in the balanced scheme. A smart computer would be able to figure this out!

Indeed, when we have five runs and four tapes we can do even better by distributing them as follows:

$$\begin{array}{ll} \text{Tape 1} & R_1 \ldots R_{1000};\ R_{3001} \ldots R_{4000}. \\ \text{Tape 2} & R_{1001} \ldots R_{2000};\ R_{4001} \ldots R_{5000}. \\ \text{Tape 3} & R_{2001} \ldots R_{3000}. \\ \text{Tape 4} & \text{(Empty)} \end{array}$$

Then a three-way merge to Tape 4, followed by a rewind of Tapes 3 and 4, followed by a three-way merge to Tape 3, would complete the sort with only $3000 + 5000 = 8000$ records read.

And, of course, if we had six tapes we could put the initial runs on Tapes 1 through 5 and complete the sort in one pass by doing a five-way merge to

Tape 6. These considerations indicate that simple balanced merging isn't the best, and it is interesting to look for improved merging patterns.

Subsequent portions of this chapter investigate external sorting more deeply. In Section 5.4.1, we consider the "internal sorting" phase which produces the initial runs; of particular interest is the technique of "replacement selection," which takes advantage of the order present in most data to produce long initial runs that actually exceed the internal memory capacity by a significant amount. Section 5.4.1 also discusses a suitable data structure for multiway merging.

The most important merging patterns are discussed in Sections 5.4.2 through 5.4.5. It is convenient to have a rather naive conception of tape sorting as we learn the characteristics of these patterns, before we come to grips with the harsh realities of real tape drives and real data that is to be sorted. For example, we may blithely assume (as we did above) that the original input records appear magically during the initial distribution phase; in fact, these input records probably will occupy one of our tapes, and they may even fill several tape reels since tapes aren't of infinite length! It is best to ignore such mundane considerations until after an academic understanding of the classical merging patterns has been gained. Then Section 5.4.6 brings the discussion down to earth by discussing real-life constraints which strongly influence the choice of a merging pattern. Section 5.4.6 compares the basic merging patterns of Sections 5.4.2 through 5.4.5, using a variety of assumptions which arise in practice.

Some other approaches to external sorting, *not* based on merging, are discussed in Sections 5.4.7 and 5.4.8. Finally Section 5.4.9 completes our survey of external sorting by treating the important problem of sorting on bulk memories such as disks and drums.

EXERCISES

1. [*15*] The text suggests internal sorting first, followed by external merging. Why don't we do away with the internal sorting phase, simply merging the records into longer and longer runs right from the start?

2. [*10*] What will the sequence of tape contents be, analogous to (1) through (3), when the example records $R_1\ R_2 \ldots R_{5000}$ are sorted using a 3-tape balanced method with $P = 2$? Compare this to the 4-tape merge; how many passes are made over all the data, after the initial distribution of runs?

3. [*20*] Show that the balanced $(P, T - P)$-way merge applied to S initial runs takes $2k$ passes, when $P^k(T - P)^{k-1} < S \leq P^k(T - P)^k$; and it takes $2k + 1$ passes, when $P^k(T - P)^k < S \leq P^{k+1}(T - P)^k$.

Give simple formulas for (a) the exact number of passes, as a function of S, when $T = 2P$; and (b) the approximate number of passes, as $S \to \infty$, for general P and T.

4. [*HM15*] What value of P, for $1 \leq P < T$, makes $P(T - P)$ a maximum?

In Section 5.2.4, we studied internal sorting methods based on two-way merging, the process of combining two ordered sequences into a single ordered sequence. It is not difficult to extend this to the notion of P-way merging, where P input runs are combined into a single output run.

Let's assume that we have been given P ascending runs, i.e., sequences of records whose keys are in nondecreasing order. The obvious way to merge them is to look at the first record of each run and to select the record whose key is smallest; this record is transferred to the output and removed from the input, and the process is repeated. At any given time we need to look at only P keys (one from each input run) and select the smallest. If two or more keys are smallest, an arbitrary one is selected.

When P isn't too large, it is convenient to make this selection by simply doing $P - 1$ comparisons to find the smallest of the current keys. But when P is, say, 8 or more, we can save work by using a *selection tree* as described in Section 5.2.3; then only about $\log_2 P$ comparisons are needed each time, once the tree has been set up.

Consider, for example, the case of four-way merging, with a two-level selection tree:

Step 1.
$$087\begin{cases}087\begin{cases}087 & 503 & \infty\\ 170 & 908 & \infty\end{cases}\\ 154\begin{cases}154 & 426 & 653 & \infty\\ 612 & \infty\end{cases}\end{cases}$$

Step 2.
$$087\ \ 154\begin{cases}170\begin{cases}503 & \infty\\ 170 & 908 & \infty\end{cases}\\ 154\begin{cases}154 & 426 & 653 & \infty\\ 612 & \infty\end{cases}\end{cases}$$

Step 3.
$$087\ \ 154\ \ 170\begin{cases}170\begin{cases}503 & \infty\\ 170 & 908 & \infty\end{cases}\\ 426\begin{cases}426 & 653 & \infty\\ 612 & \infty\end{cases}\end{cases}$$

$\vdots$

Step 9.
$$087\ \ 154\ \ 170\ \ 426\ \ 503\ \ 612\ \ 653\ \ 908\ \ \infty\ \begin{cases}\infty\ \begin{cases}\infty\\ \infty\end{cases}\\ \infty\ \begin{cases}\infty\\ \infty\end{cases}\end{cases}$$

An additional key "∞" has been placed at the end of each run in this example, so that the merging terminates gracefully. Since external merging generally deals with very long runs, the addition of records with ∞ keys does not add

substantially to the length of the data or to the amount of work involved in merging, and such "sentinel" records frequently serve as a useful way to delimit the runs on a file.

Each step after the first in the above process consists of replacing the smallest element by the succeeding element in its run, and changing the corresponding path in the selection tree. Thus the three positions of the tree which contain 087 in Step 1 are changed in Step 2; the three positions containing 154 in Step 2 are changed in Step 3; and so on. The process of replacing one key by another in the selection tree is called *replacement selection*.

We can look at this four-way merge in several ways. From one standpoint it is equivalent to three two-way merges performed concurrently as coroutines; each node in the selection tree represents one of the sequences involved in concurrent merging processes. The selection tree is also essentially operating as a priority queue, with a "smallest in, first out" discipline.

As in Section 5.2.3 we could use a heap instead of a selection tree, to implement the priority queue. (The heap would, of course, be arranged so that the *smallest* element appears at the top, instead of the largest, reversing the order of Eq. 5.2.3–3.) Since a heap does not have a fixed size, we could therefore avoid the use of "∞" keys; merging would be complete when the heap becomes empty. On the other hand, external sorting applications usually deal with comparatively long records and keys, so that the heap is filled with pointers to keys instead of the keys themselves; we shall see below that selection trees can be represented by pointers in such a convenient manner that they are probably superior to heaps in this situation.

A tree of "losers." Figure 62 shows the complete binary tree with 12 external (square) nodes and 11 internal (circular) nodes; the external nodes have been

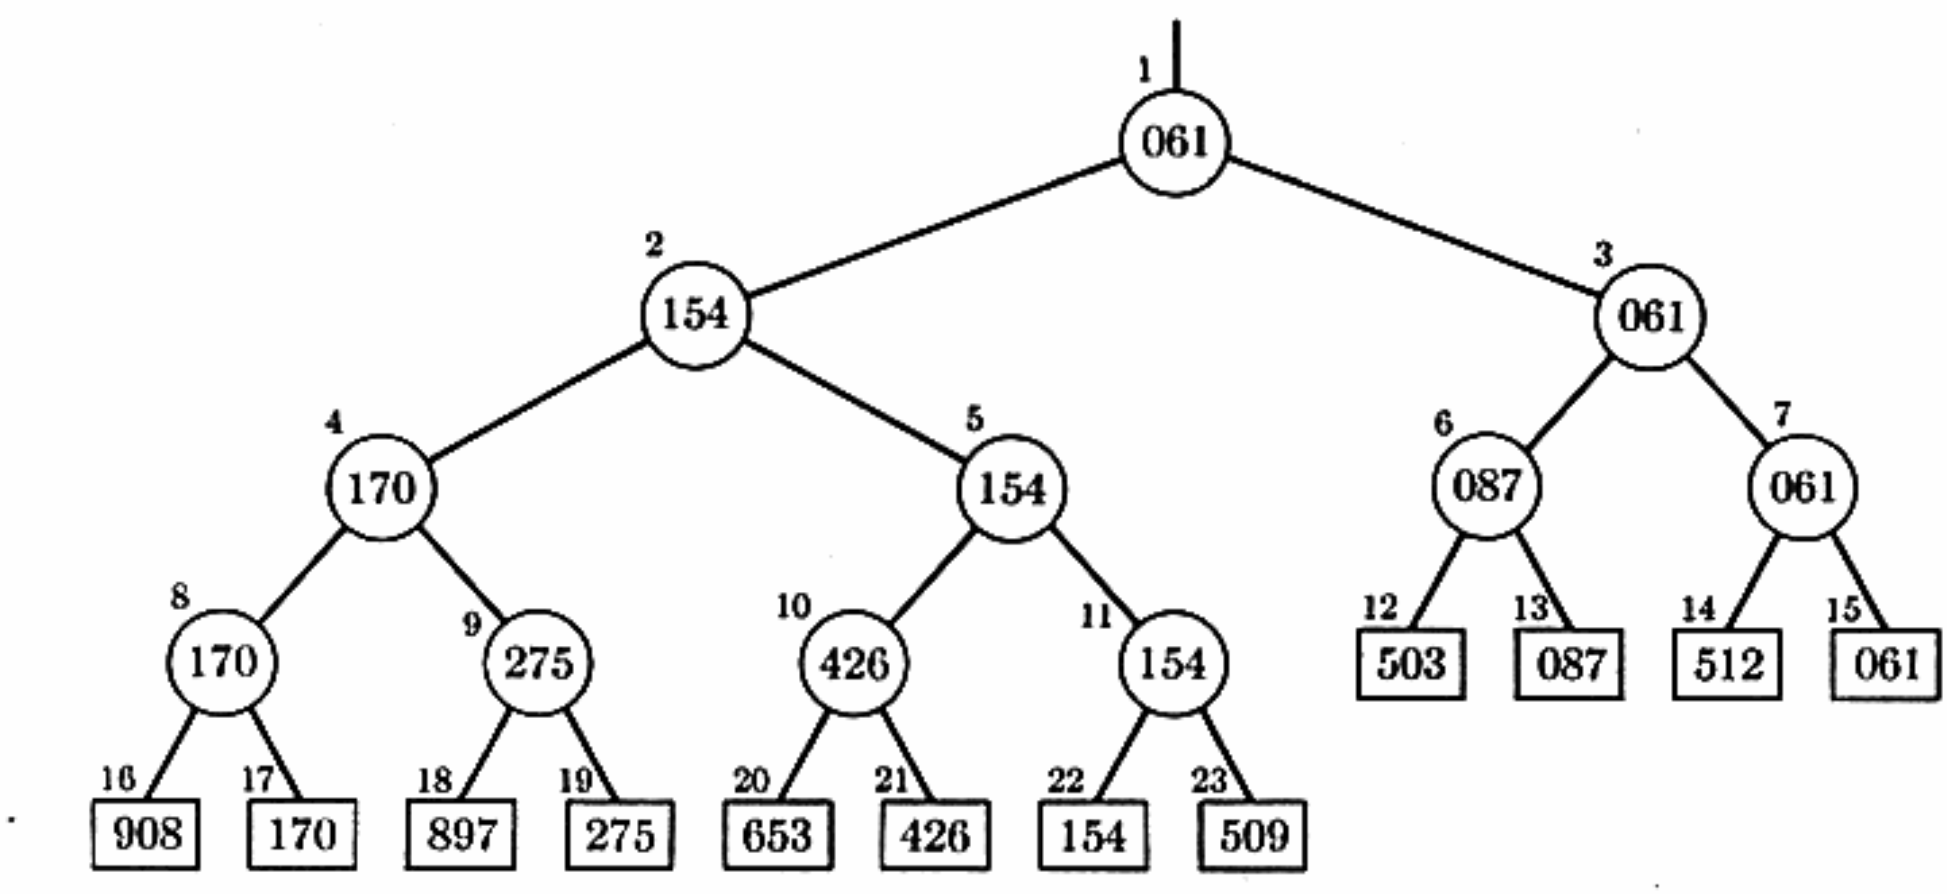

Fig. 62. A tournament to select the smallest key, using a complete binary tree whose nodes are numbered from 1 to 23.

filled with keys, and the internal nodes have been filled with the "winners" if the tree is regarded as a tournament to select the smallest key. The smaller numbers above each node show the traditional way to allocate consecutive storage positions for complete binary trees.

When the smallest key, 061, is to be replaced by another key in the selection tree of Fig. 62, we will have to look at the keys 512, 087, and 154, and no other existing keys, in order to determine the new state of the selection tree. Considering the tree as a tournament, these three keys are the losers in the matches played by 061. This suggests that what we really ought to store in the internal nodes of the tree is the *loser* of each match, instead of the winner; then the information required for updating the tree is readily available.

Figure 63 shows the same tree as Fig. 62, but with the losers represented instead of the winners. An extra node number 0 has been appended at the top of the tree, to indicate the champion of the tournament. Note that each key except the champion is a loser exactly once (cf. Section 5.3.3), so each key appears once in an external node and once in an internal node.

In practice, the external nodes at the bottom of Fig. 63 will represent fairly long records stored in computer memory, and the internal nodes will represent pointers to those records. Note that P-way merging calls for exactly P external nodes and P internal nodes, each in adjacent groups, so that several efficient methods of storage allocation suggest themselves. It is not difficult to see how to use a "loser-oriented" tree for replacement selection; we shall discuss the algorithm in some detail later in this section.

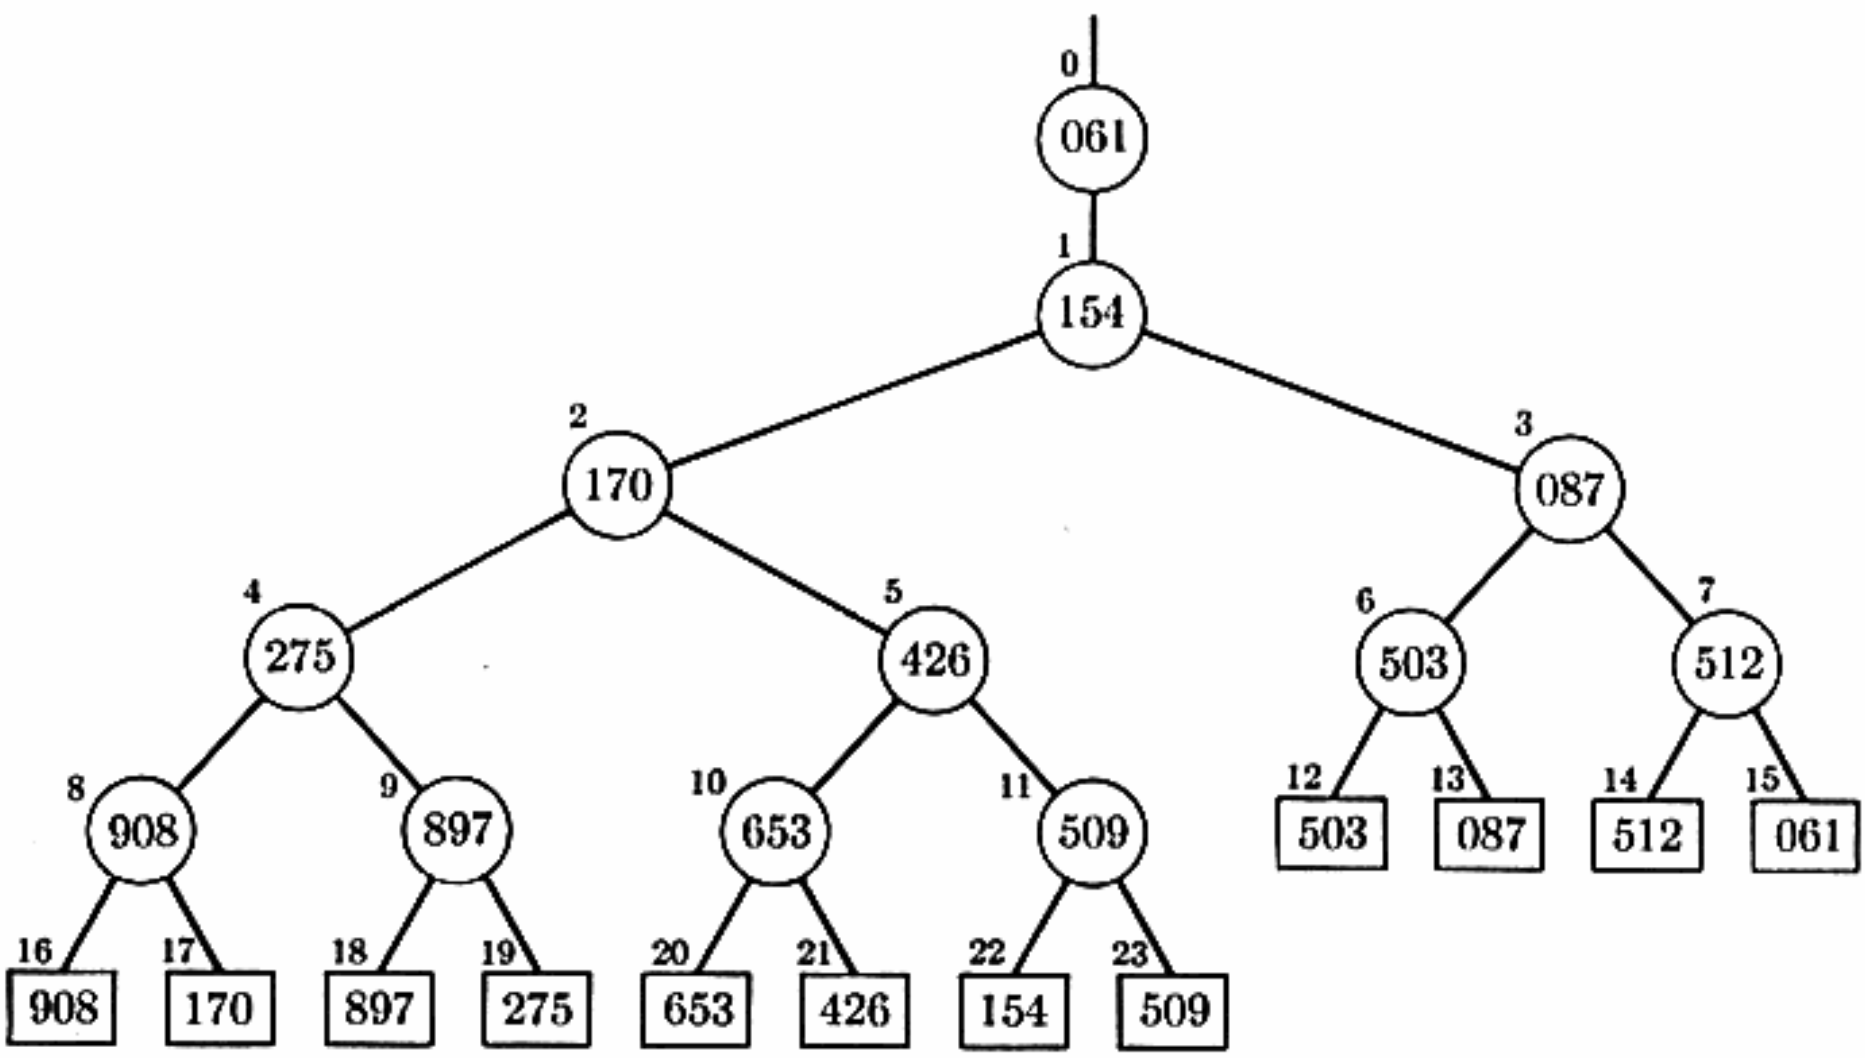

Fig. 63. The same tournament as Fig. 62, but showing the losers instead of the winners; the champion appears at the very top.

Initial runs by replacement selection. The technique of replacement selection can be used also in the first phase of external sorting, if we essentially do a P-way merge of the input data with itself! In this case we take P to be fairly large, so that the internal memory is essentially filled. When a record is output, it is replaced by the next record from the input. If the new record has a smaller key than the one just output, we cannot include it in the current run; but otherwise we can enter it into the selection tree in the usual way and it will form part of the run currently being produced. Thus the runs can contain more than P records each, even though we never have more than P in the selection tree at any time. Table 1 illustrates this process for $P = 4$; parenthesized numbers are waiting for inclusion in the following run.

Table 1

EXAMPLE OF FOUR-WAY REPLACEMENT SELECTION

Memory contents				Output
503	087	512	061	061
503	087	512	908	087
503	170	512	908	170
503	897	512	908	503
(275)	897	512	908	512
(275)	897	653	908	653
(275)	897	(426)	908	897
(275)	(154)	(426)	908	908
(275)	(154)	(426)	(509)	(end run)
275	154	426	509	154
275	612	426	509	275
		etc.		

This important method of forming initial runs was first described by Harold H. Seward [Master's Thesis, Digital Computer Laboratory Report R-232 (Mass. Inst. of Technology, 1954), 29–30], who gave reason to believe that the runs would contain more than $1.5P$ records when applied to random data. A. I. Dumey had also suggested the idea about 1950 in connection with a special sorting device planned by Engineering Research Associates, but he did not publish it. The name "replacement selecting" was coined by E. H. Friend [*JACM* **3** (1956), 154], who remarked that "the expected length of the sequences produced eludes formulation but experiment suggests that $2P$ is a reasonable expectation."

A clever way to show that $2P$ is indeed the expected run length was discovered by E. F. Moore, who compared the situation to a snowplow on a circular track [*U.S. Patent 2983904* (1961), cols. 3–4]. Consider the situation shown in Fig. 64; flakes of snow are falling uniformly on a circular road, and a lone snowplow is continually clearing the snow. Once the snow has been plowed

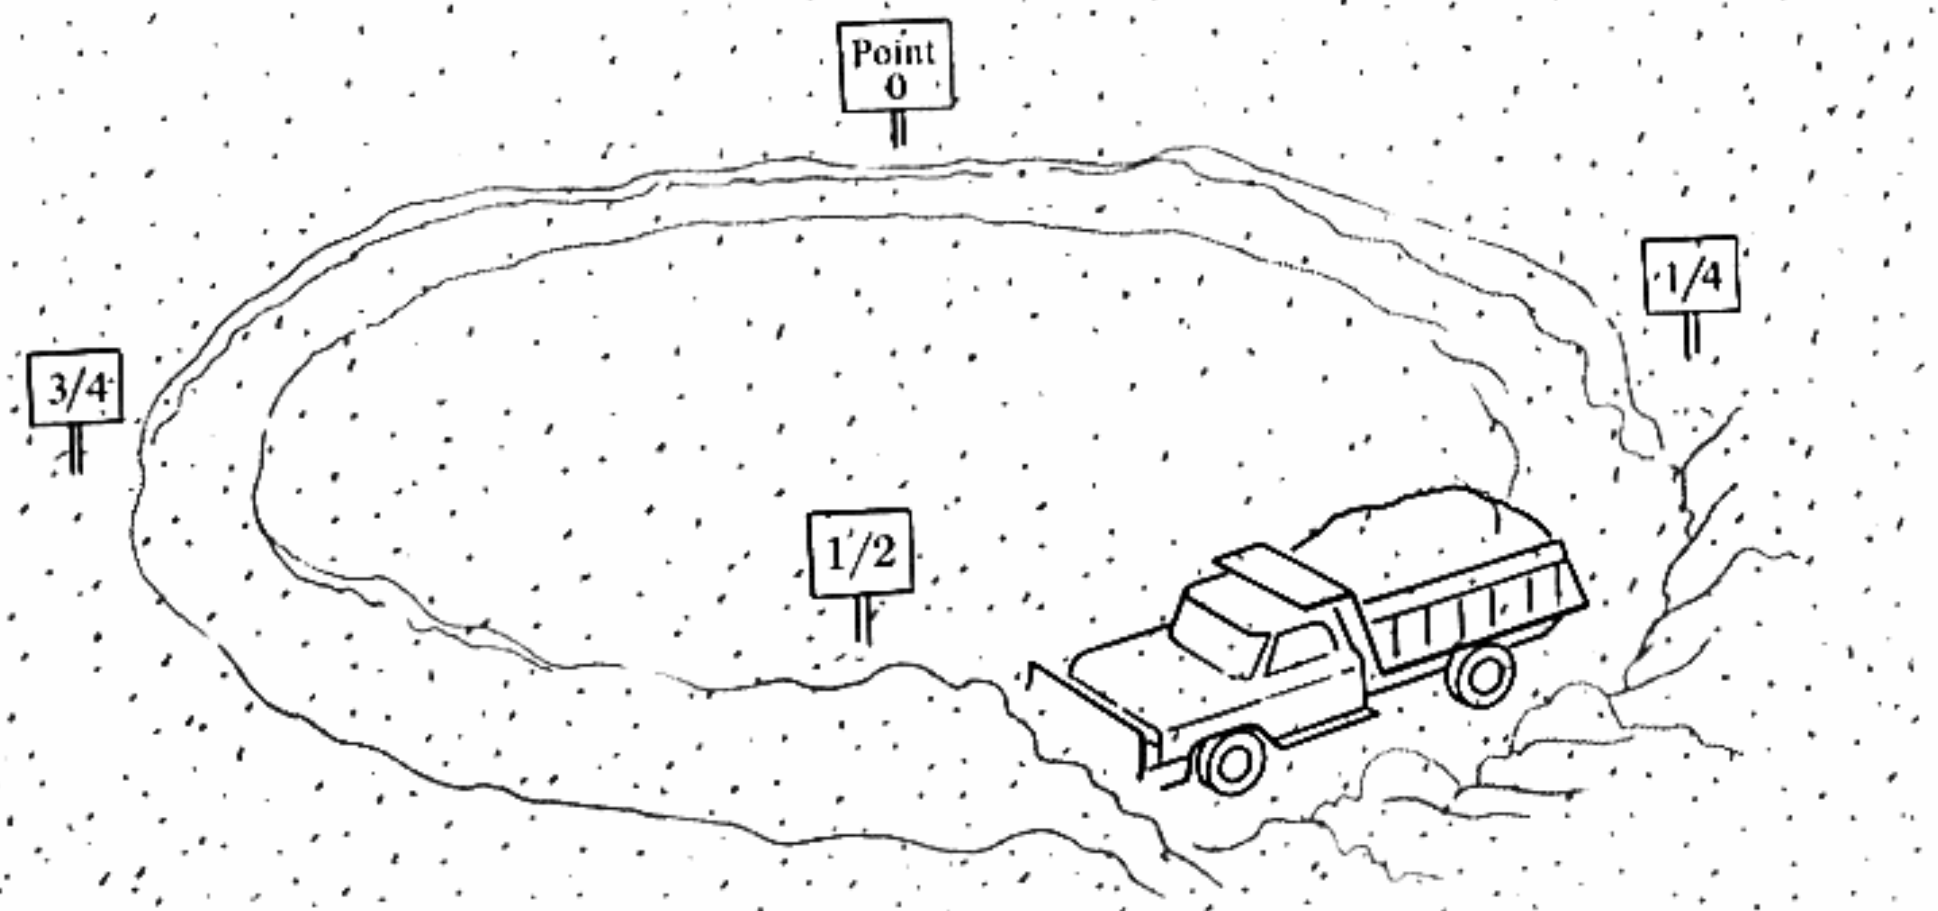

Fig. 64. The perpetual plow on its ceaseless cycle.

off the road, it disappears from the system. Points on the road may be designated by real numbers x, $0 \leq x < 1$; a flake of snow falling at position x represents an input record whose key is x, and the snowplow represents the output of replacement selection. The ground speed of the snowplow is inversely proportional to the height of snow it encounters, and the situation is perfectly balanced so that the total amount of snow on the road at all times is exactly P. A new run is formed in the output whenever the plow passes point 0.

After this system has been in operation for awhile, it is intuitively clear that it will approach a stable situation in which the snowplow runs at constant speed (because of the circular symmetry of the track). This means that the snow is at constant height when it meets the plow, and the height drops off linearly in front of the plow as shown in Fig. 65. It follows that the volume of snow removed in one revolution (namely the run length) is twice the amount present at any one time (namely P).

In many commercial applications the input data is *not* completely random, it already has a certain amount of existing order; therefore the runs produced

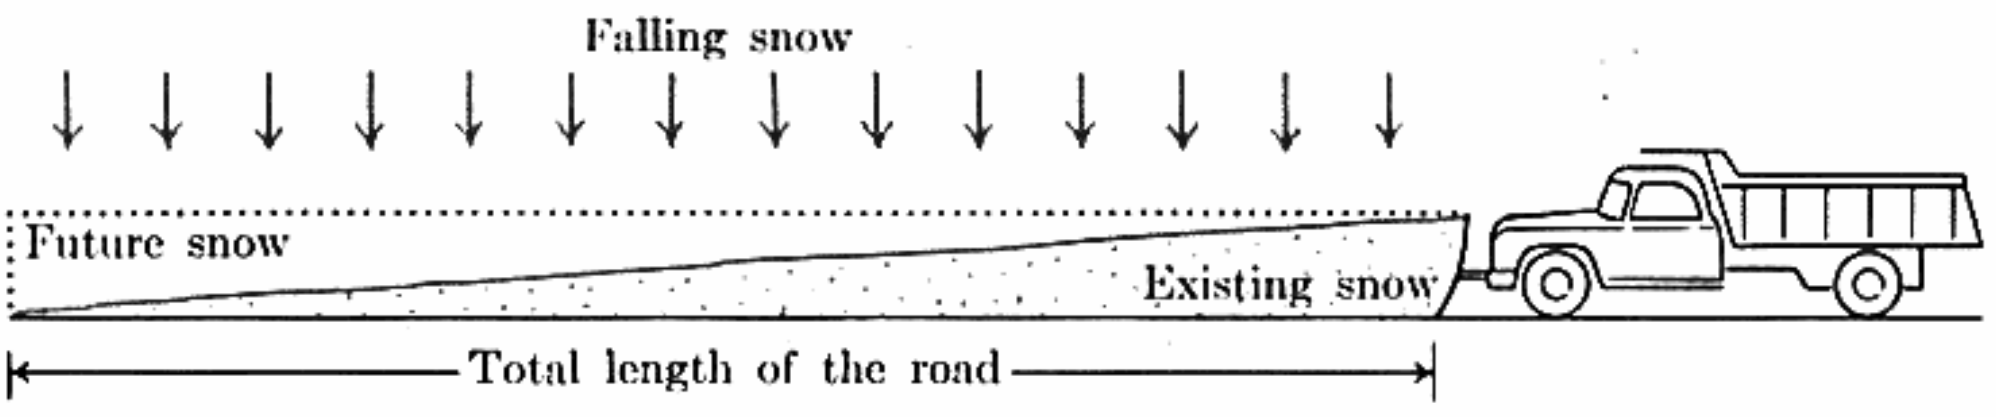

Fig. 65. Cross-section, showing the varying height of snow in front of the plow when the system is in its "steady state."

by replacement selection will tend to contain even more than $2P$ records. We shall see that the time required for external merge sorting is largely governed by the number of runs produced by the initial distribution phase, so that replacement selection becomes especially desirable; other types of internal sorting would produce about twice as many initial runs because of the limitations on memory size.

Let us now consider the process of creating initial runs by replacement selection in detail. The following algorithm is due to John R. Walters, James Painter, and Martin Zalk, who used it in a merge-sort program for the Philco 2000 in 1958. It incorporates a rather nice way to initialize the selection tree and to distinguish records belonging to different runs, as well as to flush out the last run, with comparatively simple and uniform logic. (The proper handling of the last run produced by replacement selection turns out to be a bit tricky, and it has tended to be a stumbling block for programmers.) The principal idea is to consider each key as a pair (S, K), where K is the original key and S is the run number to which this record belongs. When such extended keys are lexicographically ordered, with S as major key and K as minor key, we obtain the output sequence produced by replacement selection.

The algorithm below uses a data structure containing P nodes to represent the selection tree; the jth node $X[j]$ is assumed to contain c words beginning in $\texttt{LOC}(X[j]) = L_0 + cj$, for $0 \le j < P$, and it represents both internal node number j and external node number $P + j$ in Fig. 63. There are several named fields in each node:

KEY = the key stored in this external node;
RECORD = the record stored in this external node (including KEY as a subfield);
LOSER = pointer to the "loser" stored in this internal node;
RN = run number of the record pointed to by LOSER;
FE = pointer to internal node above this external node in the tree;
FI = pointer to internal node above this internal node in the tree.

For example, when $P = 12$, internal node number 5 and external node number 17 of Fig. 63 would both be represented in $X[5]$, by the fields KEY = 170, LOSER = $L_0 + 9c$ (the address of external node number 21), FE = $L_0 + 8c$, FI = $L_0 + 2c$.

The FE and FI fields have constant values, so they need not appear explicitly in memory; however, the initial phase of external sorting sometimes has trouble keeping up with the I/O devices, and it is often worth while to store these redundant values with the data instead of recomputing them each time.

Algorithm R (*Replacement selection.*) This algorithm reads records sequentially from an input file and writes them sequentially onto an output file, producing RMAX runs whose length is P or more (except for the final run). There are $P \ge 2$ nodes, $X[0], \ldots, X[P - 1]$, having fields as described above.

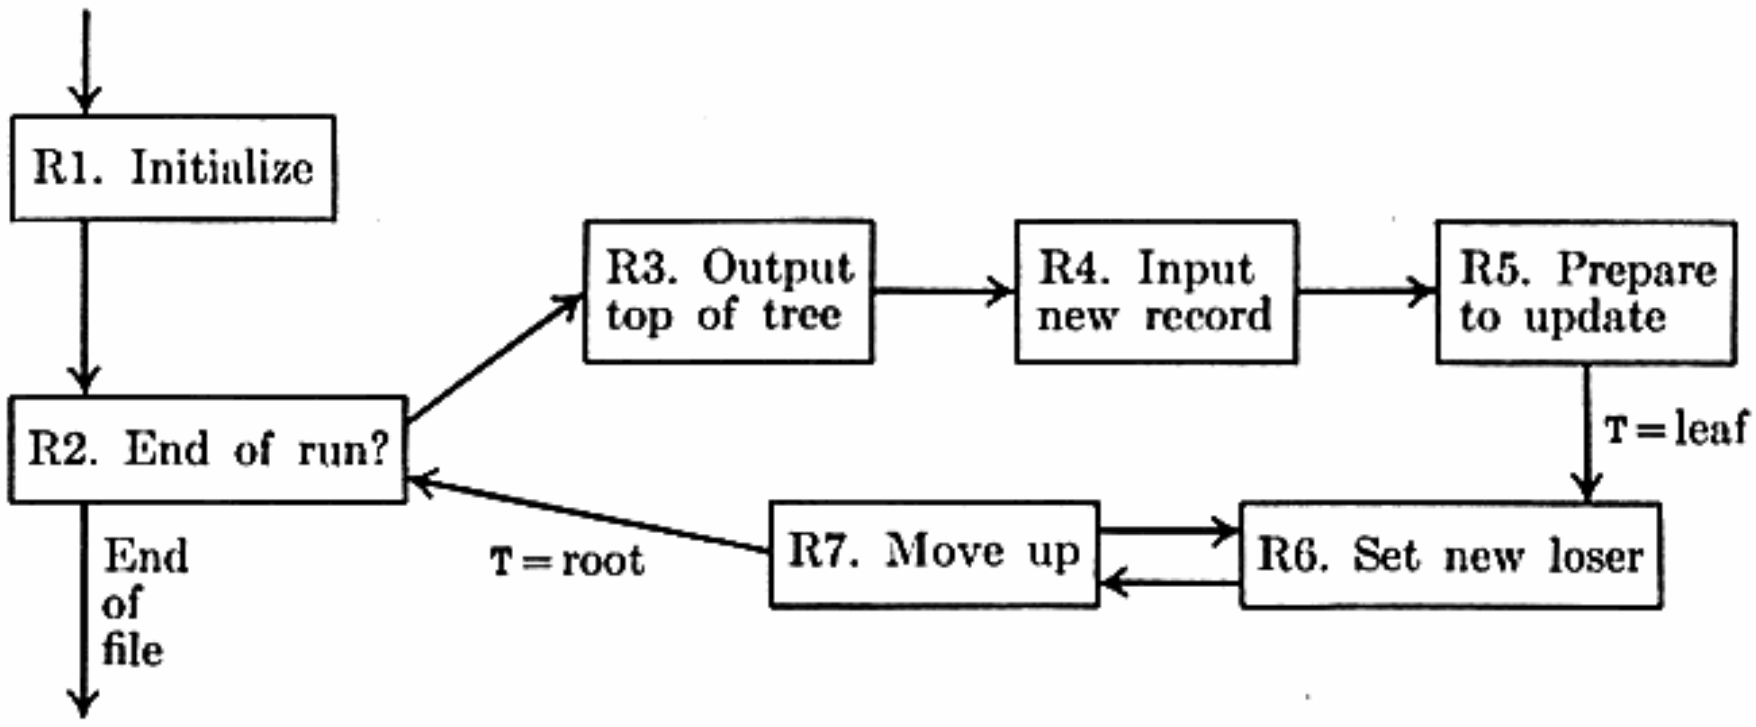

Fig. 66. Making initial runs by replacement selection.

R1. [Initialize.] Set $\texttt{RMAX} \leftarrow 0$, $\texttt{RC} \leftarrow 0$, $\texttt{LASTKEY} \leftarrow \infty$, $\texttt{Q} \leftarrow \texttt{LOC}(X[0])$, and $\texttt{RQ} \leftarrow 0$. (RC is the number of the current run and LASTKEY is the key of the last record output. The initial setting of LASTKEY should be larger than any possible key; cf. exercise 8.) For $0 \le j < P$, set the initial contents of $X[j]$ as follows, when $\texttt{J} = \texttt{LOC}(X[j])$:

$$\texttt{LOSER(J)} \leftarrow \texttt{J}; \qquad \texttt{RN(J)} \leftarrow 0;$$
$$\texttt{FE(J)} \leftarrow \texttt{LOC}(X[\lfloor (P+j)/2 \rfloor]); \qquad \texttt{FI(J)} \leftarrow \texttt{LOC}(X[\lfloor j/2 \rfloor]).$$

(The settings of LOSER(J) and RN(J) are artificial ways to get the tree initialized by considering a fictitious run number 0 which is never output. This is tricky; see exercise 10.)

R2. [End of run?] If $\texttt{RQ} = \texttt{RC}$, go on to step R3. (Otherwise $\texttt{RQ} = \texttt{RC} + 1$ and we have just completed run number RC; any special actions required by a merging pattern for subsequent passes of the sort would be done at this point.) If $\texttt{RQ} > \texttt{RMAX}$, stop; otherwise set $\texttt{RC} \leftarrow \texttt{RQ}$.

R3. [Output top of tree.] (Now Q points to the "champion," and RQ is its run number.) If $\texttt{RQ} \neq 0$, output RECORD(Q) and set $\texttt{LASTKEY} \leftarrow \texttt{KEY(Q)}$.

R4. [Input new record.] If the input file is exhausted, set $\texttt{RQ} \leftarrow \texttt{RMAX+1}$ and go on to step R5. Otherwise set RECORD(Q) to the next record from the input file. If $\texttt{KEY(Q)} < \texttt{LASTKEY}$ (so that this new record does not belong to the current run), set $\texttt{RQ} \leftarrow \texttt{RQ} + 1$ and then if $\texttt{RQ} > \texttt{RMAX}$ set $\texttt{RMAX} \leftarrow \texttt{RQ}$.

R5. [Prepare to update.] (Now Q points to a new record, whose run number is RQ.) Set $\texttt{T} \leftarrow \texttt{FE(Q)}$. (T is a pointer variable which will move up the tree.)

R6. [Set new loser.] If $\texttt{RN(T)} < \texttt{RQ}$ or if $\texttt{RN(T)} = \texttt{RQ}$ and $\texttt{KEY(LOSER(T))} < \texttt{KEY(Q)}$, then interchange $\texttt{LOSER(T)} \leftrightarrow \texttt{Q}$, $\texttt{RN(T)} \leftrightarrow \texttt{RQ}$. (Variables Q and RQ keep track of the current winner and its run number.)

R7. [Move up.] If $\texttt{T} = \texttt{LOC}(X[1])$ then go back to R2, otherwise set $\texttt{T} \leftarrow \texttt{FI(T)}$ and return to R6. ∎

Algorithm R speaks of input and output of records one at a time, while in practice it is best to read and write relatively large blocks of records. Therefore some input and output buffers are actually present in memory, behind the scenes, effectively lowering the size of P. We shall illustrate this in Section 5.4.6.

E. H. Friend [*JACM* **3** (1956), 154] suggested extending replacement selection so that whenever an input key is less than LASTKEY (so that it doesn't fit in the current run), but greater than or equal to the last key actually written onto tape (so that it actually could fit into the current run after all), it should be inserted into the output buffer. Furthermore, some computers have "scatter read" and "gather write" facilities for doing I/O to and from nonconsecutive locations, and this leads to some techniques which overlap buffers with the selection tree.

***Delayed reconstitution of runs.** A very interesting way to improve on replacement selection has been suggested by R. J. Dinsmore [*CACM* **8** (1965), 48] using a concept which we shall call *degrees of freedom*. As we have seen, each block of records on tape within a run is in nondecreasing order, so that its first element is the lowest and its last element is the highest. In the ordinary process of replacement selection, the lowest element of each block within a run is never less than the highest element of the preceding block in that run; this is "1 degree of freedom." Dinsmore suggests relaxing this condition to "m degrees of freedom," where the lowest element of each block may be less than the highest element of the preceding block so long as it is *not less than the highest elements in m different preceding blocks of the same run*. Records within individual blocks are ordered, as before, but adjacent blocks need not be in order.

For example, suppose that there are just two records per block; the following sequence of blocks is a run with three degrees of freedom:

$$\mid 08\ \ 50 \mid 06\ \ 90 \mid 17\ \ 27 \mid 42\ \ 67 \mid 51\ \ 89 \mid \qquad (1)$$

A subsequent block which is to be part of the same run must begin with an element not less than the third largest element of {50, 90, 27, 67, 89}, namely 67. The sequence (1) would not be a run if there were only two degrees of freedom, since 17 is less than both 50 and 90.

A run with m degrees of freedom can be "reconstituted" while it is being read during the next phase of sorting, so that for all practical purposes it is a run in the ordinary sense. We start by reading the first m blocks into m buffers, and doing an m-way merge on them; when one buffer is exhausted, we replace it with the $(m + 1)$st block, and so on. In this way we can recover the run as a single sequence, for the first word of every newly-read block must be greater than or equal to the last word of the just-exhausted block (lest it be less than the highest elements in m different blocks that precede it). This method of reconstituting the run is essentially like an m-way merge using a single tape unit for all the input blocks! The reconstitution procedure acts as a coroutine which is called upon to deliver one record of the run at a time. We could be reconstituting different runs from different tape units with different degrees of

freedom, and merging the resulting runs, all at the same time, in essentially the same way as the four-way merge illustrated at the beginning of this section may be thought of as several two-way merges going on at once.

This ingenious idea has not yet been thoroughly analyzed. Preliminary indications are that when P is large compared to the block size the run length is about $2.1P$ when $m = 2$, $2.3P$ when $m = 4$, $2.5P$ when $m = 8$. This increase may not be enough to justify the added complication; on the other hand, it may be advantageous when there is room for a rather large number of buffers during the second phase of sorting.

***Natural selection.** Another way to increase the run lengths produced by replacement selection has been explored by W. D. Frazer and C. K. Wong. Their idea is to proceed as in Algorithm R, but when `KEY(Q)` $<$ `LASTKEY` in step R4, the new `RECORD(Q)` is not left in the tree, it is output into an external *reservoir* instead, and another new record is read in. This process continues until the reservoir is filled with a certain number of records, P'; at this time the remainder of the current run is output from the tree, and the reservoir items are used as input for the next run.

This method tends to produce longer runs than replacement selection because it avoids "dead" records from the next string, instead of letting them fill up the tree; but it requires extra time for input and output to and from the reservoir. When $P' > P$ it is possible that some records will be placed into the reservoir twice, but when $P' \le P$ this will never happen.

Frazer and Wong made extensive empirical tests of their method, noticing that when P is reasonably large (say $P \ge 32$) and $P' = P$ the average run length for random data is given by eP, where $e \approx 2.718$ is the base of natural logarithms. This phenomenon, and the fact that the method is an evolutionary improvement over simple replacement selection, naturally led them to call their method *natural selection*.

The "natural" law for run lengths can be proved by considering the snowplow of Fig. 64 again, and applying elementary calculus. Let L be the length of the track, and let $x(t)$ be the position of the snowplow at time t, for $0 \le t \le T$. The reservoir is assumed to be full at time T, when the snow stops temporarily while the plow returns to its starting position (clearing the P units of snow remaining in its path). The situation is the same as before except that the "balance condition" is different; instead of P units of snow on the road at all times, we have P units of snow in front of the plow, and the reservoir (behind the plow) gets up to P units. The snowplow advances by dx during a time interval dt if $h(x, t)\,dx$ records are output, where $h(x, t)$ is the height of the snow at time t and position $x = x(t)$, measured in suitable units; hence $h(x, t) = h(x, 0) + Kt$ for all x. Since the number of records in memory stays constant, $h(x, t)\,dx$ is also the number of records that are input *ahead* of the plow, namely $K\,dt(L - x)$, where K is the rate of snowfall (see Fig. 67). Thus

$$\frac{dx}{dt} = \frac{K(L - x)}{h(x, t)}. \tag{2}$$

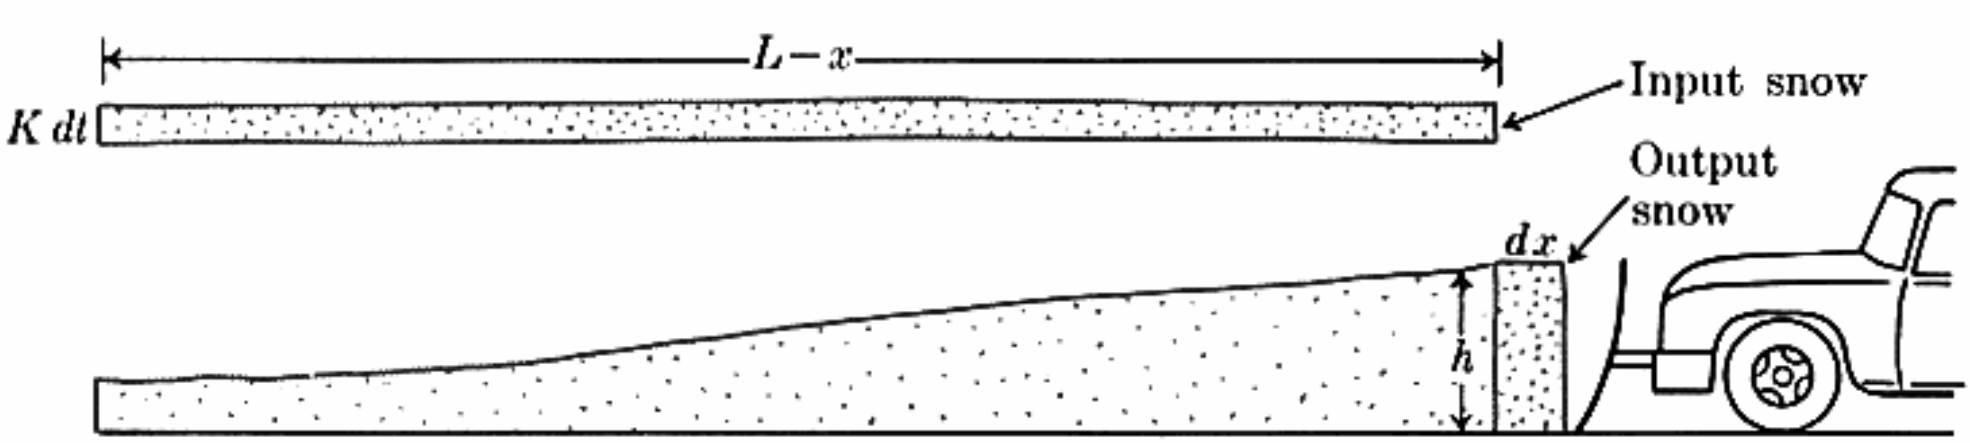

Fig. 67. Equal amounts of snow are input and output; the plow moves dx in time dt.

Fortunately, it turns out that $h(x, t)$ is constant, equal to KT, whenever $x = x(t)$ and $0 \le t \le T$, since the snow falls steadily at position $x(t)$ for $T - t$ units of time after the plow passes that point, plus t units of time before it comes back. In other words, the plow sees all snow at the same height on his journey, assuming that a steady state has been reached where each journey is the same. Hence the total amount of snow cleared (the run length) is KTL; and the amount of snow in memory is the amount cleared after time T, namely $KT(L - x(T))$. The solution to (2) such that $x(0) = 0$ is

$$x(t) = L(1 - e^{-t/T}); \tag{3}$$

hence $P = KTLe^{-1} =$ (run length)$/e$; and this is what we set out to prove.

Exercises 21 through 23 show that this analysis can be extended to the case of general P'; for example, when $P' = 2P$ the average run length turns out to be $e^{\theta}(e - \theta)P$, where $\theta = \frac{1}{2}(e - \sqrt{e^2 - 4})$, a result that probably wouldn't have been guessed offhand! Table 2 shows the dependence of run length on reservoir size; the usefulness of natural selection in a given computer environment can be estimated by referring to this table.

Table 2

RUN LENGTHS BY NATURAL SELECTION

Reservoir size	Run length	Parameter	Reservoir size	Run length	Parameter
1.00000P	2.71828P	1.00000	0.38629P	2.00000P	0.69315
2.00000P	3.53487P	1.43867	1.30432P	3.00000P	1.15881
3.00000P	4.16220P	1.74773	2.72294P	4.00000P	1.66862
4.00000P	4.69445P	2.01212	4.63853P	5.00000P	2.16714
5.00000P	5.16369P	2.24938	21.72222P	10.00000P	4.66667
10.00000P	7.00877P	3.17122	5.29143P	5.29143P	2.31329

The "parameter" $k + \theta$ is defined in exercise 22.

***Analysis of replacement selection.** Let us now return to the case of replacement selection without an auxiliary reservoir. The snowplow analogy gives us a fairly good indication of the average length of runs obtained by replacement

selection "in the limit," but it is possible to get much more precise information about Algorithm R by applying the facts about runs in permutations which we have studied in Section 5.1.3. For this purpose it is convenient to assume that the input file is an arbitrarily long sequence of independent random real numbers between 0 and 1.

Let

$$g_P(z_1, z_2, \ldots, z_k) = \sum_{l_1, l_2, \ldots, l_k \geq 0} a_P(l_1, l_2, \ldots, l_k) z_1^{l_1} z_2^{l_2} \cdots z_k^{l_k}$$

be the generating function for run lengths produced by P-way replacement selection on such a file, where $a_P(l_1, l_2, \ldots, l_k)$ is the probability that the first run has length l_1, the second has length l_2, ..., the kth has length l_k. The following "independence theorem" is basic, since it reduces the analysis to the case $P = 1$:

Theorem K. $g_P(z_1, z_2, \ldots, z_k) = g_1(z_1, z_2, \ldots, z_k)^P$.

Proof. Let the input keys be $X_1, X_2, X_3, \ldots$. Algorithm R partitions them into P subsequences, according to which external node position they land in the tree; the subsequence containing X_n is determined by the values of $X_1, \ldots, X_{n-1}$. Each of these subsequences is therefore an independent sequence of independent random numbers between 0 and 1. Furthermore, the output of replacement selection is precisely what would be obtained by doing a P-way merge on these subsequences; an element belongs to the jth run of a subsequence if and only if it belongs to the jth run produced by replacement selection (since in step R4, `LASTKEY` and `KEY(Q)` belong to the same subsequence).

In other words, we might just as well assume that Algorithm R is being applied to P independent random input files, and that step R4 reads the next record from the file corresponding to external node `Q`; in this sense, the algorithm is equivalent to a P-way merge, with "step-downs" marking the ends of the runs.

Thus the output has runs of lengths $(l_1, \ldots, l_k)$ if and only if the subsequences have runs of respective lengths $(l_{11}, \ldots, l_{1k}), \ldots, (l_{P1}, \ldots, l_{Pk})$, where the l_{ij} are some nonnegative integers satisfying $\sum_{1 \leq i \leq P} l_{ij} = l_j$ for $1 \leq j \leq k$. It follows that

$$a_P(l_1, \ldots, l_k) = \sum_{\substack{l_{11} + \cdots + l_{P1} = l_1 \\ \vdots \\ l_{1k} + \cdots + l_{Pk} = l_k}} a_1(l_{11}, \ldots, l_{1k}) \cdots a_1(l_{P1}, \ldots, l_{Pk}),$$

and this is equivalent to the desired result. ∎

We have discussed the average length L_k of the kth run, when $P = 1$, in Section 5.1.3, where the values are tabulated in Table 5.1.3–2. Theorem K implies that the average length of the kth run for general P is P times as long as the average when $P = 1$, namely $L_k P$; and the variance is also P times as

large, so the standard deviation of the run length is proportional to $\sqrt{P}$. These results were first derived by B. J. Gassner about 1958.

Thus the first run produced by Algorithm R will be about $(e - 1)P \approx 1.718P$ records long, for random data; the second run will be about $(e^2 - 2e)P \approx 1.952P$ records long; the third, about $1.996P$; and subsequent runs will be very close to $2P$ records long until we get to the last two runs (see exercise 14). The standard deviation of most of these run lengths is approximately $(4e - 10)P \approx 0.934\sqrt{P}$ [*CACM* **6** (1963), 685–687]. Furthermore, exercise 5.1.3–10 shows that the *total* length of the first k runs will be fairly close to $(2k - \frac{1}{3})P$, with a standard deviation of $((\frac{2}{3}k + \frac{2}{9})P)^{1/2}$. The generating functions $g_1(z, z, \ldots, z)$ and $g_1(1, \ldots, 1, z)$ are derived in exercises 5.1.3–9 and 11.

The above analysis has assumed that the input file is infinitely long, but the proof of Theorem K shows that the same probability $a_p(l_1, \ldots, l_k)$ would be obtained in any random input sequence containing at least $l_1 + \cdots + l_k + P$ elements. So the above results are applicable for, say, files of size $N > (2k+1)P$, in view of the small standard deviation.

We will be seeing some applications in which the merging pattern wants some of the runs to be ascending and some to be descending. Since the residue accumulated in memory at the end of an ascending run tends to contain numbers somewhat smaller on the average than random data, a change in the direction of ordering decreases the average length of the runs. Consider, for example, a snowplow which must make a U-turn every time it reaches an end of a straight road; it will go very speedily over the area just plowed. The run lengths when directions are reversed vary between $1.5P$ and $2P$ for random data (see exercise 24).

EXERCISES

1. [*10*] What is Step 4, in the example of four-way merging at the beginning of this section?

2. [*12*] What changes would be made to the tree of Fig. 63 if the key 061 were replaced by 612?

3. [*16*] (E. F. Moore.) What output is produced by four-way replacement selection when it is applied to successive words of the following sentence:

```
fourscore and seven years ago our fathers brought forth
on this continent a new nation conceived in liberty and
dedicated to the proposition that all men are created equal.
```

(Use ordinary alphabetic order, treating each word as one key.)

4. [*16*] Apply four-way *natural* selection to the sentence in exercise 3, using a reservoir of capacity 4.

5. [*00*] True or false: Replacement selection using a tree works only when P is a power of 2 or the sum of two powers of 2.

6. [*15*] Algorithm R specifies that P must be ≥ 2; what comparatively small changes to the algorithm would make it valid for all $P \geq 1$?

7. [*17*] What does Algorithm R do when there is no input at all?

8. [*20*] Algorithm R makes use of an artificial key "∞" which must be larger than any possible key. Show that the algorithm might fail if an actual key were equal to ∞, and explain how to modify the algorithm in case the implementation of a true ∞ is inconvenient.

▸ **9.** [*23*] How would you modify Algorithm R so that it causes certain specified runs (depending on RC) to be output in ascending order, and others in descending order?

10. [*26*] The initial setting of the LOSER pointers in step R1 usually doesn't correspond to any actual tournament, since external node $P + j$ may not lie in the subtree below internal node j. Explain why Algorithm R works anyway. [*Hint:* Would the algorithm work if {LOSER(LOC(X[0])), . . . , LOSER(LOC(X[P — 1]))} were set to an *arbitrary* permutation of {LOC(X[0]), . . . , LOC(X[P — 1])} in step R1?]

11. [*M25*] True or false: The probability that KEY(Q) < LASTKEY in step R4 is approximately $\frac{1}{2}$, assuming random input.

12. [*M46*] Carry out a detailed analysis of the number of times each portion of Algorithm R is executed; for example, how often are interchanges made in step R6?

13. [*18*] Why is the second run produced by replacement selection usually longer than the first run?

▸ **14.** [*HM25*] Use the snowplow analogy to estimate the average length of the *last two runs* produced by replacement selection on a long sequence of input data.

15. [*20*] True or false: The final run produced by replacement selection never contains more than P records. Discuss your answer.

16. [*M26*] Find a "simple" necessary and sufficient condition that a file $R_1\ R_2 \ldots R_N$ will be completely sorted in one pass by P-way replacement selection. What is the probability that this happens, as a function of P and N, when the input is a random permutation of $\{1, 2, \ldots, N\}$?

17. [*20*] What is output by Algorithm R when the input keys are in decreasing order, $K_1 \geq K_2 \geq \cdots \geq K_N$?

▸ **18.** [*22*] What happens if Algorithm R is applied *again* to an output file that was produced by Algorithm R?

19. [*HM22*] Use the snowplow analogy to prove that the first run produced by replacement selection is approximately $(e - 1)P$ records long.

20. [*HM24*] Approximately how long is the first run produced by natural selection, when $P = P'$?

▸ **21.** [*HM23*] Determine the approximate length of runs produced by natural selection when $P' < P$.

22. [*HM40*] The purpose of this exercise is to determine the average run length obtained in natural selection, when $P' > P$. Let $\kappa = k + \theta$ be a real number ≥ 1,

where $k = \lfloor \kappa \rfloor$ and $\theta = \kappa \bmod 1$, and consider the function $F(\kappa) = F_k(\theta)$, where $F_k(\theta)$ is the polynomial defined by the generating function

$$\sum_{k \geq 0} F_k(\theta) z^k = e^{-\theta z}/(1 - ze^{1-z}).$$

Thus, $F_0(\theta) = 1$, $F_1(\theta) = e - \theta$, $F_2(\theta) = e^2 - e - e\theta + \frac{1}{2}\theta^2$, etc.

Suppose that a snowplow starts out at time 0 to simulate the process of natural selection, and suppose that after T units of time exactly P snowflakes have fallen behind it. At this point a second snowplow begins on the same journey, occupying the same position at time $t + T$ as the first snowplow did at time t. Finally, at time κT, exactly P' snowflakes have fallen behind the first snowplow; he instantaneously plows the rest of the road and disappears.

Using this model to represent the process of natural selection, show that a run length equal to $e^\theta F(\kappa) P$ is obtained when

$$P'/P = k + 1 + e^\theta \left(\kappa F(\kappa) - \sum_{0 \leq j \leq \kappa} F(\kappa - j) \right).$$

23. [*HM35*] The preceding exercise analyzes natural selection when the records from the reservoir are always read in the same order that they were written, first-in-first-out. Find the approximate run length which would be obtained if the reservoir contents from the preceding run were read in completely *random* order, as if the records in the reservoir had been thoroughly shuffled between runs.

24. [*HM39*] The purpose of this exercise is to analyze the effect caused by haphazardly changing the direction of runs in replacement selection.

a) Let $g_P(z_1, z_2, \ldots, z_k)$ be a generating function defined as in Theorem K, but with each of the k runs specified as to whether they are to be ascending or descending. For example, we might say that all odd-numbered runs are ascending, all even-numbered runs are descending. Show that Theorem K is valid for each of the 2^k generating functions of this type.

b) As a consequence of (a), we may assume that $P = 1$. We may also assume that the input is a uniformly distributed sequence of independent random numbers between 0 and 1. Let

$$a(x, y) = \begin{cases} e^{1-x} - e^{y-x}, & \text{if } x \leq y; \\ e^{1-x}, & \text{if } x > y. \end{cases}$$

Given that $f(x)\,dx$ is the probability that a certain ascending run begins with x, prove that $(\int_0^1 a(x, y) f(x)\,dx)\,dy$ is the probability that the following run beings with y. [*Hint:* Consider, for each $n \geq 0$, the probability that $x \leq X_1 \leq \cdots \leq X_n > y$, when x and y are given.]

c) Consider runs that change direction with probability p; in other words, the direction of each run after the first is randomly chosen to be the same as that of the previous run, $q = (1 - p)$ of the time, but it is to be in the opposite direction p of the time. (Thus when $p = 0$, all runs have the same direction; when $p = 1$,

the runs alternate in direction; and when $p = \frac{1}{2}$, the runs are independently random.) Let

$$f_1(x) = 1, \qquad f_{n+1}(y) = p\int_0^1 a(x, y)f_n(1 - x)\,dx + q\int_0^1 a(x, y)f_n(x)\,dx.$$

Show that the probability that the nth run begins with x is $f_n(x)\,dx$ when the $(n - 1)$st run is ascending, $f_n(1 - x)\,dx$ when the $(n - 1)$st run is descending.

d) Find a solution f to the "steady state" equations

$$f(y) = p\int_0^1 a(x, y)f(1 - x)\,dx + q\int_0^1 a(x, y)f(x)\,dx, \qquad \int_0^1 f(x)\,dx = 1.$$

[*Hint:* Show that $f''(x)$ is independent of x.]

e) Show that the sequence $f_n(x)$ in part (c) converges rather rapidly to the function $f(x)$ in part (d). [*Hint:* See, for example, the proof of Theorem 4.5.3L.]

f) Show that the average length of an ascending run starting with x is e^{1-x}.

g) Finally, put the above results together to prove the following theorem: *If the directions of consecutive runs are independently reversed with probability p in replacement selection, the average run length approaches* $(6/(3 + p))P$.

(The case $p = 1$ of this theorem was first derived by Knuth [*CACM* **6** (1963), 685–688]; the case $p = \frac{1}{2}$ was first proved by A. G. Konheim in 1970.)

25. [*HM40*] Consider the following procedure:

N1. Read a record into a one-word "reservoir." Then read another record, R, and let K be its key.

N2. Output the reservoir, set LASTKEY to its key, and set the reservoir empty.

N3. If K < LASTKEY then output R and set LASTKEY ← K and go to N5.

N4. If the reservoir is nonempty, return to N2; otherwise enter R into the reservoir.

N5. Read in a new record, R, and let K be its key. Go to N3. ▮

This is essentially equivalent to natural selection with $P = 1$ and with $P' = 1$ or 2 (depending on whether you choose to empty the reservoir at the moment it fills or at the moment it is about to overfill), except that it produces *descending* runs, and it never stops. The latter anomalies are convenient and harmless assumptions for the purposes of this problem.

Proceeding as in exercise 24, let $f_n(x, y)\,dy\,dx$ be the probability that (x, y) are the respective values of (LASTKEY, K) just after the nth time step N2 is performed. Prove that there is a function $g_n(x)$ of one variable such that $f_n(x, y) = g_n(x)$ when $x < y$, and $f_n(x, y) = g_n(x) - e^{-y}(g_n(x) - g_n(y))$ when $x > y$. This function $g_n(x)$ is defined by the relations $g_1(x) = 1$,

$$g_{n+1}(x) = \int_0^x e^u g_n(u)\,du + \int_0^x dv(v + 1)\int_v^1 du((e^v - 1)g_n(u) + g_n(v))$$
$$+ x\int_x^1 dv\int_v^1 du((e^v - 1)g_n(u) + g_n(v)).$$

Show further that the expected length of the nth run is

$$\int_0^1 dx \int_0^x dy(g_n(x)(e^y - 1) + g_n(y))(2 - \tfrac{1}{2}y^2) + \int_0^1 dx(1 - x)g_n(x)e^x.$$

[*Note:* The "steady state" solution to these equations appears to be very complicated; it has been obtained numerically by J. McKenna, showing that the run lengths approach a limiting value of 2.61307209. Theorem K does not apply to natural selection, so the case $P = 1$ does not carry over to other P.

26. [*M33*] Considering the algorithm in exercise 25 as a definition of natural selection when $P' = 1$, find the expected length of the *first* run when $P' = r$, for any $r \geq 0$, as follows.

a) Show that the first run has length n with probability

$$(n + r)\begin{bmatrix} n + r \\ n \end{bmatrix} / (n + r + 1)!.$$

b) Define "second order Stirling numbers" $\left[\!\left[{n \atop m} \right]\!\right]$ by the rules

$$\left[\!\left[{0 \atop m} \right]\!\right] = \delta_{m0}, \qquad \left[\!\left[{n \atop m} \right]\!\right] = (n + m - 1)\left(\left[\!\left[{n - 1 \atop m} \right]\!\right] + \left[\!\left[{n - 1 \atop m - 1} \right]\!\right]\right) \quad \text{for} \quad n > 0.$$

Prove that

$$\begin{bmatrix} n + r \\ n \end{bmatrix} = \sum_{0 \leq k \leq r} \binom{n + r}{k + r} \left[\!\left[{r \atop k} \right]\!\right].$$

c) Prove that the average length of the first run is therefore $c_r e - r - 1$, where

$$c_r = \sum_{0 \leq k \leq r} \left[\!\left[{r \atop k} \right]\!\right] (r + k + 1)/(r + k)!.$$

27. [*25*] The text considers only the case that all records to be sorted have a fixed size. How can replacement selection be done reasonably well on *variable-length* records?

5.4.2. The Polyphase Merge

Now that we have seen how initial runs can be built up, we shall consider various patterns which can be used to distribute them onto tapes and to merge them together until only a single run remains.

Let us begin by assuming that there are three tape units, T1, T2, and T3, available; the technique of "balanced merging," described near the beginning of Section 5.4, can be used with $P = 2$ and $T = 3$, when it takes the following form:

B1. Distribute initial runs alternately on tapes T1 and T2.

B2. Merge runs from T1 and T2 onto T3; then stop if T3 contains only one run.

B3. Copy the runs of T3 alternately onto T1 and T2, then return to B2. ▮

If the initial distribution pass produces S runs, the first merge pass will produce $\lceil S/2 \rceil$ runs on T3, the second will produce $\lceil S/4 \rceil$, etc. Thus if, say, $17 \le S \le 32$, we will have 1 distribution pass, 5 merge passes, and 4 copy passes; in general, if $S > 1$, the number of passes over all the data is $2\lceil \log_2 S \rceil$.

The copying passes in this procedure are undesirable, since they do not reduce the number of runs. Half of the copying can be avoided if we use a *two-phase* procedure:

A1. Distribute initial runs alternately on tapes T1 and T2.

A2. Merge runs from T1 and T2 onto T3; then stop if T3 contains only one run.

A3. Copy *half* of the runs from T3 onto T1.

A4. Merge runs from T1 and T3 onto T2; then stop if T2 contains only one run.

A5. Copy *half* of the runs from T2 onto T1. Return to A2. ▮

The number of passes over the data has been reduced to $\frac{3}{2}\lceil \log_2 S \rceil + \frac{1}{2}$, since steps A3 and A5 do only "half a pass"; about 25 percent of the time has therefore been saved.

The copying can actually be eliminated *entirely*, if we start with F_n runs on T1 and F_{n-1} runs on T2, where F_n and F_{n-1} are consecutive Fibonacci numbers. Consider, for example, the case $n = 7$, $S = F_n + F_{n-1} = 13 + 8 = 21$:

	Contents of T1	Contents of T2	Contents of T3	Remarks
Phase 1.	1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1	1, 1, 1, 1, 1, 1, 1, 1		Initial distribution
Phase 2.	1, 1, 1, 1, 1	—	2, 2, 2, 2, 2, 2, 2, 2	Merge 8 runs to T3
Phase 3.	—	3, 3, 3, 3, 3	2, 2, 2	Merge 5 runs to T2
Phase 4.	5, 5, 5	3, 3	—	Merge 3 runs to T1
Phase 5.	5	—	8, 8	Merge 2 runs to T3
Phase 6.	—	13	8	Merge 1 run to T2
Phase 7.	21	—	—	Merge 1 run to T1

Here, for example, "2, 2, 2, 2, 2, 2, 2, 2" denotes eight runs of relative length 2, considering each initial run to be of relative length 1. Fibonacci numbers are omnipresent in this chart!

Only phases 1 and 7 are complete passes over the data; phase 2 processes only 16/21 of the initial runs, phase 3 only 15/21, etc., and so the total number of "passes" comes to $(21 + 16 + 15 + 15 + 16 + 13 + 21)/21 = 5\frac{4}{7}$ if we assume that the initial runs have approximately equal length. By comparison, the two-phase procedure above would have required 8 passes to sort these 21 initial runs. We shall see that in general this "Fibonacci" pattern requires approximately $1.04 \log_2 S + 0.99$ passes, making it competitive with a *four*-tape balanced merge although it requires only three tapes.

The same idea can be generalized to T tapes, for any $T \ge 3$, using $(T - 1)$-way merging. We shall see, for example, that the four-tape case requires only about $.703 \log_2 S + 0.96$ passes over the data. The generalized pattern involves generalized Fibonacci numbers. Consider the following six-tape example:

	T1	T2	T3	T4	T5	T6	Initial runs processed
Phase 1.	1^{31}	1^{30}	1^{28}	1^{24}	1^{16}	—	$31 + 30 + 28 + 24 + 16 = 129$
Phase 2.	1^{15}	1^{14}	1^{12}	1^{8}	—	5^{16}	$16 \times 5 = 80$
Phase 3.	1^{7}	1^{6}	1^{4}	—	9^{8}	5^{8}	$8 \times 9 = 72$
Phase 4.	1^{3}	1^{2}	—	17^{4}	9^{4}	5^{4}	$4 \times 17 = 68$
Phase 5.	1^{1}	—	33^{2}	17^{2}	9^{2}	5^{2}	$2 \times 33 = 66$
Phase 6.	—	65^{1}	33^{1}	17^{1}	9^{1}	5^{1}	$1 \times 65 = 65$
Phase 7.	129^{1}	—	—	—	—	—	$1 \times 129 = 129$

Here 1^{31} stands for 31 runs of relative length 1, etc.; five-way merges have been used throughout. This general pattern was developed by R. L. Gilstad [*Proc. AFIPS Eastern Jt. Computer Conf.* **18** (1960), 143–148], who called it the *polyphase merge*. The three-tape case had been discovered earlier by B. K. Betz [unpublished memorandum, Minneapolis-Honeywell Regulator Co. (1956)].

In order to make polyphase merging work as in the above examples, we need to have a "perfect Fibonacci distribution" of runs on the tapes after each phase. By reading the above table from bottom to top, we can see that the first seven perfect Fibonacci distributions when $T = 6$ are $\{1, 0, 0, 0, 0\}$, $\{1, 1, 1, 1, 1\}$, $\{2, 2, 2, 2, 1\}$, $\{4, 4, 4, 3, 2\}$, $\{8, 8, 7, 6, 4\}$, $\{16, 15, 14, 12, 8\}$, and $\{31, 30, 28, 24, 16\}$. The big questions now facing us are

1. What is the rule underlying these perfect Fibonacci distributions?

2. What do we do if S does not correspond to a perfect Fibonacci distribution?

3. How should we design the initial distribution pass so that it produces the desired configuration on the tapes?

4. How many "passes" over the data will a T-tape polyphase merge require, as a function of S (the number of initial runs)?

We shall discuss these four questions in turn, first giving "easy answers" and then making a more intensive analysis.

The perfect Fibonacci distributions can be obtained by running the pattern backwards, cyclically rotating the tape contents. For example, when $T = 6$ we have the following distributions of runs:

Level	T1	T2	T3	T4	T5	Total	Final output will be on
0	1	0	0	0	0	1	T1
1	1	1	1	1	1	5	T6
2	2	2	2	2	1	9	T5
3	4	4	4	3	2	17	T4

$$\begin{array}{cccccccc}
\cdots & \cdots & \cdots & \cdots & \cdots & \cdots & \cdots & \cdots \\
n & a_n & b_n & c_n & d_n & e_n & t_n & \mathrm{T}(k) \\
n+1 & a_n+b_n & a_n+c_n & a_n+d_n & a_n+e_n & a_n & t_n+4a_n & \mathrm{T}(k-1) \\
\cdots & \cdots & \cdots & \cdots & \cdots & \cdots & \cdots & \cdots
\end{array} \tag{1}$$

(Tape T6 will always be empty after the initial distribution.)

The rule for going from level n to level $n+1$ shows that the condition

$$a_n \geq b_n \geq c_n \geq d_n \geq e_n \tag{2}$$

will hold in every level. In fact, it is easy to see from (1) that

$$\begin{aligned}
e_n &= a_{n-1}, \\
d_n &= a_{n-1} + e_{n-1} = a_{n-1} + a_{n-2}, \\
c_n &= a_{n-1} + d_{n-1} = a_{n-1} + a_{n-2} + a_{n-3}, \\
b_n &= a_{n-1} + c_{n-1} = a_{n-1} + a_{n-2} + a_{n-3} + a_{n-4}, \\
a_n &= a_{n-1} + b_{n-1} = a_{n-1} + a_{n-2} + a_{n-3} + a_{n-4} + a_{n-5},
\end{aligned} \tag{3}$$

where $a_0 = 1$ and where we let $a_n = 0$ for $n = -1, -2, -3, -4$.

The *pth order Fibonacci numbers* $F_n^{(p)}$ are defined by the rules

$$\begin{gathered}
F_n^{(p)} = F_{n-1}^{(p)} + F_{n-2}^{(p)} + \cdots + F_{n-p}^{(p)}, \qquad \text{for} \qquad n \geq p; \\
F_n^{(p)} = 0 \qquad \text{for} \qquad 0 \leq n \leq p-2; \qquad F_{p-1}^{(p)} = 1.
\end{gathered} \tag{4}$$

In other words, we start with $p-1$ 0's, then 1, and then each number is the sum of the preceding p values. When $p = 2$, this is the usual Fibonacci sequence; for larger values of p the sequence was apparently first studied by V. Schlegel in *El Progreso Matemático* **4** (1894), 173–174. Schlegel derived the generating function

$$\sum_{n \geq 0} F_n^{(p)} z^n = \frac{z^{p-1}}{1 - z - z^2 - \cdots - z^p} = \frac{z^{p-1} - z^p}{1 - 2z + z^{p+1}}. \tag{5}$$

Equation (3) shows that the number of runs on T1 during a six-tape polyphase merge is a fifth-order Fibonacci number: $a_n = F_{n+4}^{(5)}$.

In general, if we set $P = T - 1$, the polyphase merge distributions for T tapes will correspond to Pth order Fibonacci numbers in the same way. The kth tape gets

$$F_{n+P-2}^{(P)} + F_{n+P-3}^{(P)} + \cdots + F_{n+k-2}^{(P)}$$

initial runs in the perfect nth level distribution, for $1 \leq k \leq P$, and the total number of initial runs on all tapes is therefore

$$t_n = PF_{n+P-2}^{(P)} + (P-1)F_{n+P-3}^{(P)} + \cdots + F_{n-1}^{(P)}. \tag{6}$$

This settles the issue of "perfect Fibonacci distributions." But what should we do if S is not exactly equal to t_n, for any n? And how do we get the runs onto the tapes in the first place?

When S isn't perfect (and so few values are), we can do just as we did in balanced P-way merging, adding artificial "dummy runs" so that we can pretend S is perfect after all. There are several ways to add the dummy runs, and we aren't ready yet to analyze the "best" way of doing this. We shall discuss first a method of distribution and dummy-run assignment which isn't strictly optimal, although it has the virtue of simplicity and appears to be better than all other equally simple methods.

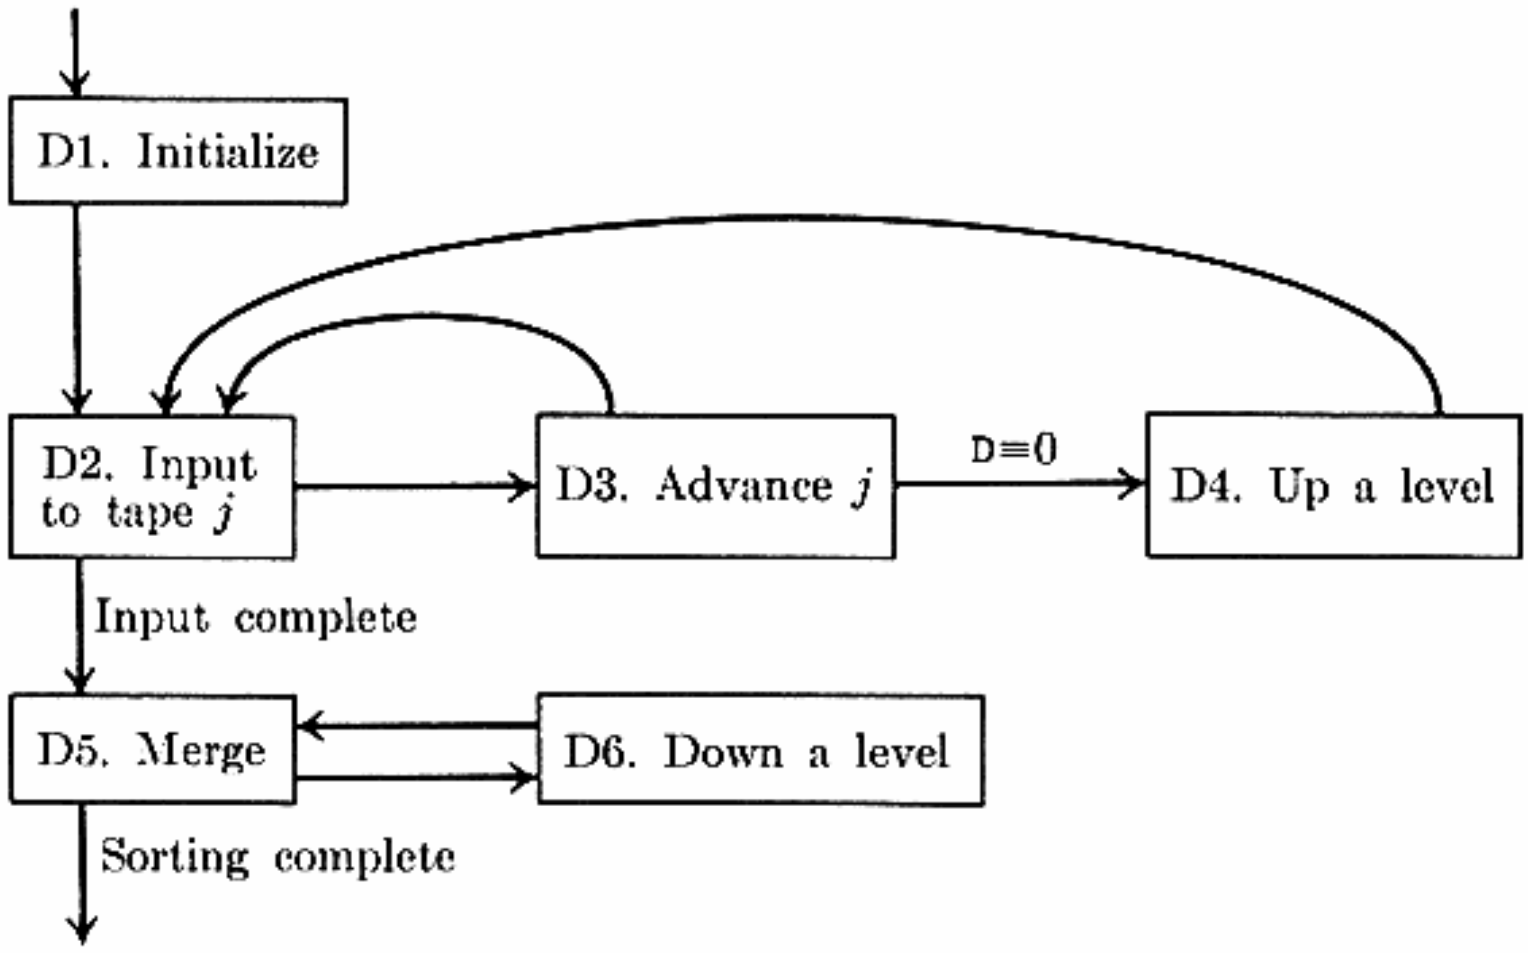

Fig. 68. Polyphase merge sorting.

Algorithm D (*Polyphase merge sorting with "horizontal" distribution*). This algorithm takes initial runs and disperses them to tapes, one run at a time, until the supply of initial runs is exhausted. Then it specifies how the tapes are to be merged, assuming that there are $T = P + 1 \geq 3$ available tape units, using P-way merging. Tape T may be used to hold the input, since it does not receive any initial runs. The following tables are maintained:

A[j], $1 \leq j \leq T$: The perfect Fibonacci distribution we are striving for.

D[j], $1 \leq j \leq T$: Number of dummy runs assumed to be present at the beginning of logical tape unit number j.

TAPE[j], $1 \leq j \leq T$: Number of the physical tape unit corresponding to logical tape unit number j.

(It is convenient to deal with "logical tape unit numbers" whose assignment to physical tape units varies as the algorithm proceeds.)

D1. [Initialize.] Set A[j] $\leftarrow$ D[j] $\leftarrow 1$ and TAPE[j] $\leftarrow j$, for $1 \leq j < T$. Set A[T] $\leftarrow$ D[T] $\leftarrow 0$ and TAPE[T] $\leftarrow T$. Then set $l \leftarrow 1$; $j \leftarrow 1$.

D2. [Input to tape j.] Write one run on tape number j, and decrease D[j] by 1. Then if the input is exhausted, rewind all the tapes and go to step D5.

D3. [Advance j.] If D[j] < D[$j+1$], increase j by 1 and return to D2. Otherwise if D[j] = 0, go on to D4. Otherwise set $j \leftarrow 1$ and return to D2.

D4. [Up a level.] Set $l \leftarrow l+1$, $a \leftarrow$ A[1], and then for $j = 1, 2, \ldots, P$ (in this order) set D[j] $\leftarrow a +$ A[$j+1$] $-$ A[j] and A[j] $\leftarrow a +$ A[$j+1$]. (See (1) and note that A[$P+1$] is always zero. At this point we will have D[1] $\geq$ D[2] $\geq \cdots \geq$ D[T].)
Now set $j \leftarrow 1$ and return to D2.

D5. [Merge.] If $l = 0$, sorting is complete and the output is on TAPE[1]. Otherwise, merge runs from TAPE[1], ..., TAPE[P] onto TAPE[T] until TAPE[P] is empty and D[P] = 0. The merging process should operate as follows, for each run merged: If D[j] > 0 for all j, $1 \leq j \leq P$, then increase D[T] by 1 and decrease each D[j] by 1 for $1 \leq j \leq P$; otherwise merge one run from each TAPE[j] such that D[j] = 0, and decrease D[j] by 1 for each other j. (Thus the dummy runs are imagined to be at the *beginning* of the tape instead of at the ending.)

D6. [Down a level.] Set $l \leftarrow l-1$. Rewind TAPE[P] and TAPE[T]. (Actually the rewinding of TAPE[P] could have been initiated during step D5, just after its last block was input.) Then set (TAPE[1], TAPE[2], ..., TAPE[T]) $\leftarrow$ (TAPE[T], TAPE[1], ..., TAPE[$T-1$]), (D[1], D[2], ..., D[T]) $\leftarrow$ (D[T], D[1], ..., D[$T-1$]), and return to step D5. ∎

The distribution rule which is stated so succinctly in step D3 of this algorithm is intended to equalize the number of dummies on each tape as well as possible. Figure 69 illustrates the order of distribution when we go from level 4

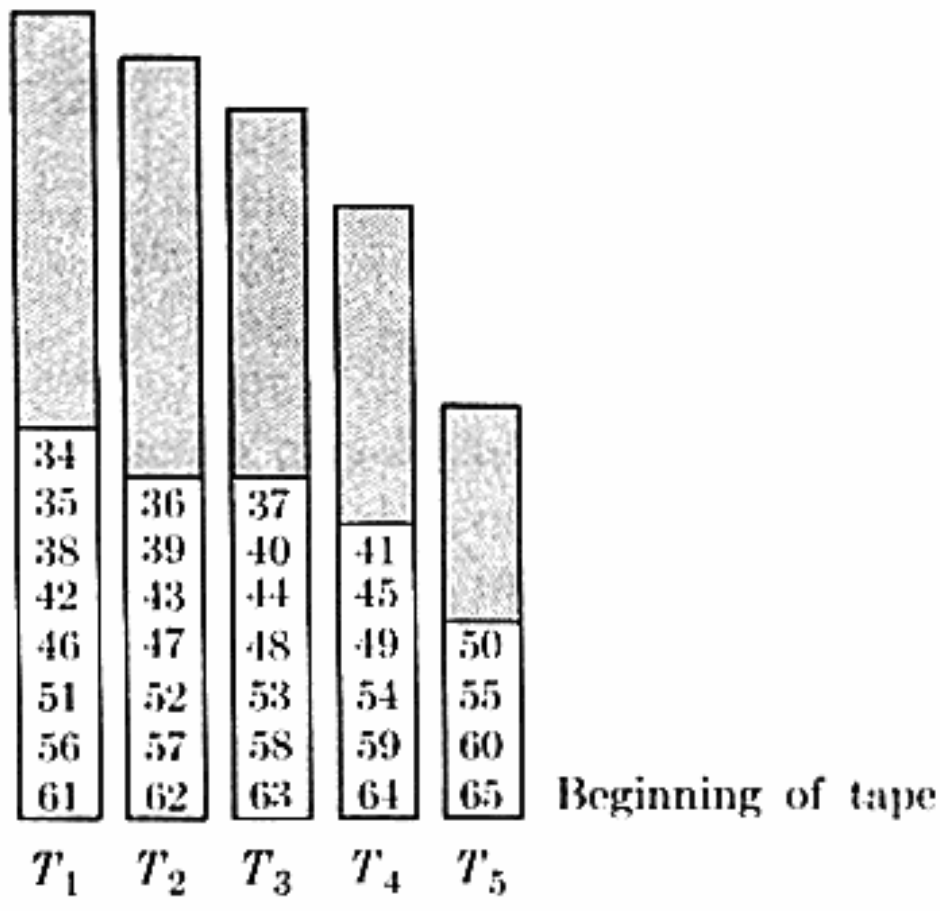

Fig. 69. The order in which runs 34 through 65 are distributed to tapes, when advancing from level 4 to level 5. (See the table of perfect distributions at the bottom of page 268.) Shaded areas represent the first 33 runs which were distributed when level 4 was reached.

(33 runs) to level 5 (65 runs) in a six-tape sort; if there were only, say, 53 initial runs, all runs numbered 54 and higher would be treated as dummies. (The runs are actually being written at the end of the tape, but it is best to imagine them being written at the beginning, since the dummies are assumed to be at the beginning.)

We have now discussed the first three questions listed above, and it remains to consider the number of "passes" over the data. Comparing our six-tape example to the table (1), we see that the total number of initial runs processed when $S = t_6$ was $a_5t_1 + a_4t_2 + a_3t_3 + a_2t_4 + a_1t_5 + a_0t_6$, excluding the initial distribution pass. Exercise 4 derives the generating functions

$$a(z) = \sum_{n\geq 0} a_n z^n = \frac{1}{1 - z - z^2 - z^3 - z^4 - z^5},$$
$$t(z) = \sum_{n\geq 1} t_n z^n = \frac{5z + 4z^2 + 3z^3 + 2z^4 + z^5}{1 - z - z^2 - z^3 - z^4 - z^5}. \tag{7}$$

It follows that, in general, the number of initial runs processed when $S = t_n$ is exactly the coefficient of z^n in $a(z) \cdot t(z)$, plus t_n (for the initial distribution pass). This makes it possible to calculate the asymptotic behavior of polyphase merging, as shown in exercises 5–7, and we obtain the results displayed in Table 1.

Table 1

APPROXIMATE BEHAVIOR OF POLYPHASE MERGE SORTING

Tapes	Phases	Passes	Pass/phase, percent	Growth ratio
3	$2.078 \ln S + 0.672$	$1.504 \ln S + 0.992$	72	1.6180340
4	$1.641 \ln S + 0.364$	$1.015 \ln S + 0.965$	62	1.8392868
5	$1.524 \ln S + 0.078$	$0.863 \ln S + 0.921$	57	1.9275620
6	$1.479 \ln S - 0.185$	$0.795 \ln S + 0.864$	54	1.9659482
7	$1.460 \ln S - 0.424$	$0.762 \ln S + 0.797$	52	1.9835828
8	$1.451 \ln S - 0.642$	$0.744 \ln S + 0.723$	51	1.9919642
9	$1.447 \ln S - 0.838$	$0.734 \ln S + 0.646$	51	1.9960312
10	$1.445 \ln S - 1.017$	$0.728 \ln S + 0.568$	50	1.9980295
20	$1.443 \ln S - 2.170$	$0.721 \ln S - 0.030$	50	1.9999981

In Table 1, the "growth ratio" is $\lim_{n\to\infty} t_{n+1}/t_n$, the approximate factor by which the number of runs increases at each level. "Passes" denotes the average number of times each record is processed, namely $(1/S)$ times the total number

of initial runs processed during the distribution and merge phases. The stated number of passes and phases is correct in each case up to $O(S^{-\epsilon})$, for some $\epsilon > 0$, for perfect distributions as $S \to \infty$.

Figure 70 shows the average number of times each record is merged, as a function of S, when Algorithm D is used to handle the case of nonperfect numbers. Note that with three tapes there are "peaks" of relative inefficiency occurring just after the perfect distributions, but this phenomenon largely disappears when there are four or more tapes. The use of eight or more tapes gives comparatively little improvement over six or seven tapes.

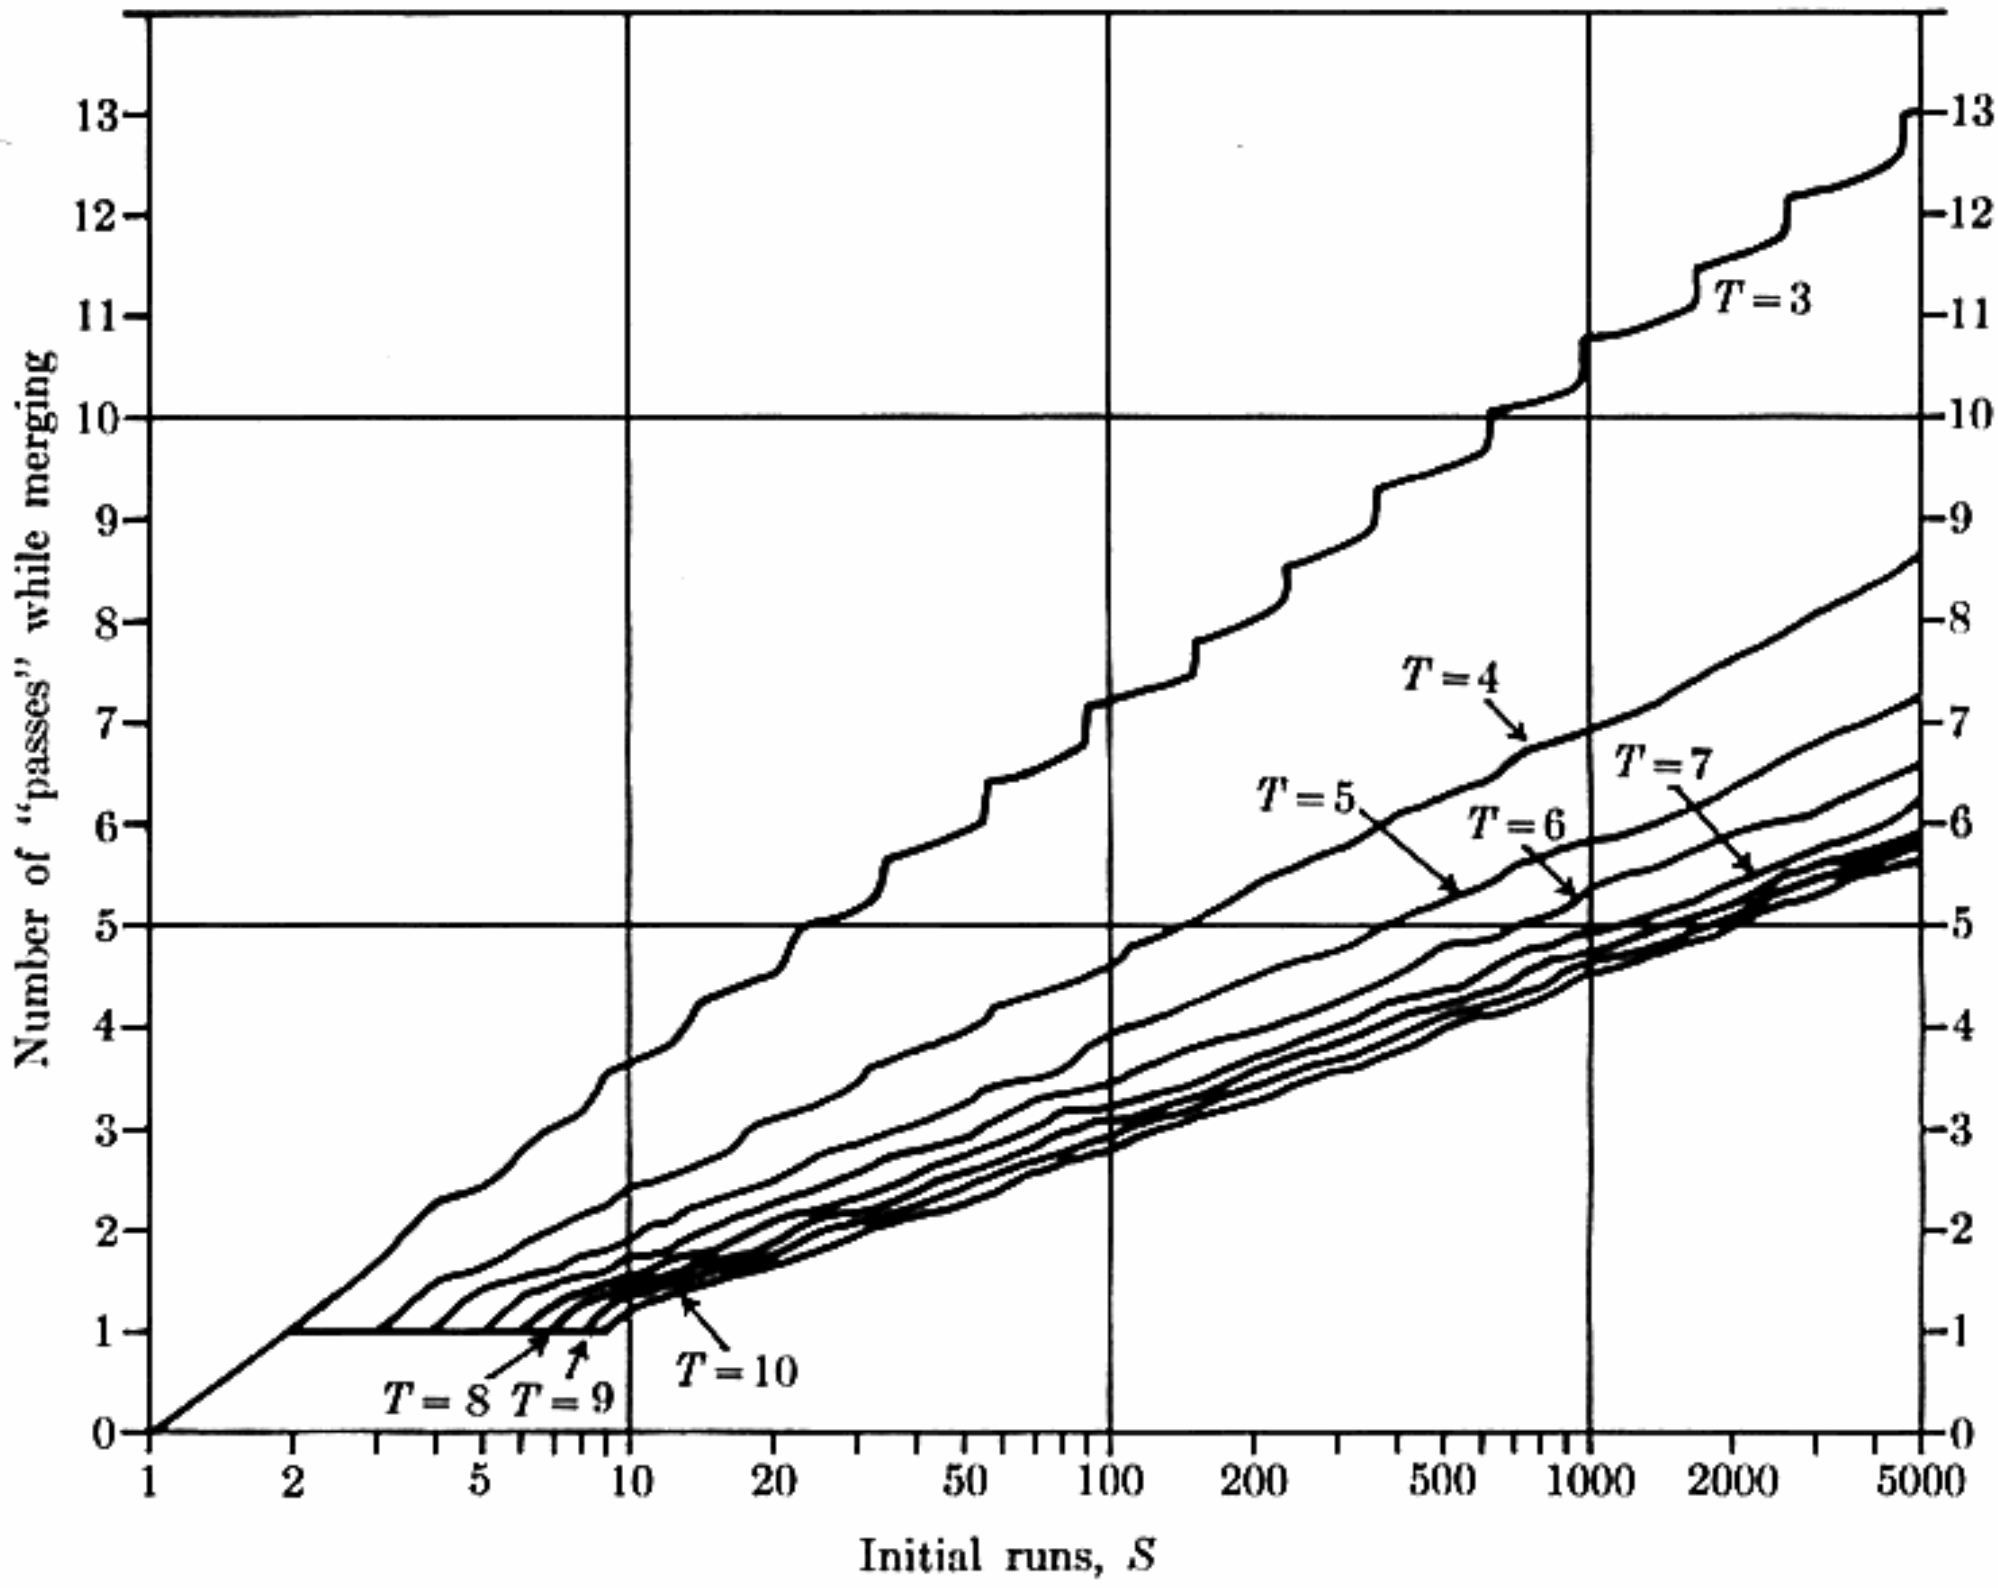

Fig. 70. Efficiency of polyphase merge using Algorithm D.

***A closer look.** In a balanced merge requiring k passes, every record is processed exactly k times during the course of the sort. But the polyphase procedure does not have this lack of bias; some records may get processed many more times than others, and we can gain speed if we arrange to put dummy runs into the oft-processed positions.

Let us therefore study the polyphase distribution more closely; instead of merely looking at the number of runs on each tape, as in (1), let us associate

with each run its *merge number*, the number of times it will be processed during the complete polyphase sort. We get the following table in place of (1):

Level	T1	T2	T3	T4	T5
0	0	—	—	—	—
1	1	1	1	1	1
2	21	21	21	21	2
3	3221	3221	3221	322	32
4	43323221	43323221	4332322	433232	4332
5	544343243323221	544343324332322	54434332433232	544343324332	54434332
. . . . .					
n	A_n	B_n	C_n	D_n	E_n
$n+1$	$(A_n+1)B_n$	$(A_n+1)C_n$	$(A_n+1)D_n$	$(A_n+1)E_n$	A_n+1
. . . . .					

(8)

Here A_n is a string of a_n values representing the merge numbers for each run on T1, if we begin with the level n distribution; B_n is the corresponding string for T2; etc. The notation "$(A_n + 1)B_n$" means, "A_n with all values increased by 1, followed by B_n."

Figure 71(a) shows A_5, B_5, C_5, D_5, E_5 tipped on end, showing how the merge numbers for each run appear on tape; note, for example, that the run at the beginning of each tape will be processed five times, while the run at the end of T1 will be processed only once. This discriminatory practice of the polyphase merge makes it much better to put a dummy run at the beginning of the tape than at the end. Figure 71(b) shows an optimum order in which to distribute runs for a five-level polyphase merge, placing each new run into a position with the smallest available merge number. Note that Algorithm D (Fig. 69) is not quite as good, since it fills some "4" positions before all of the "3" positions are used up.

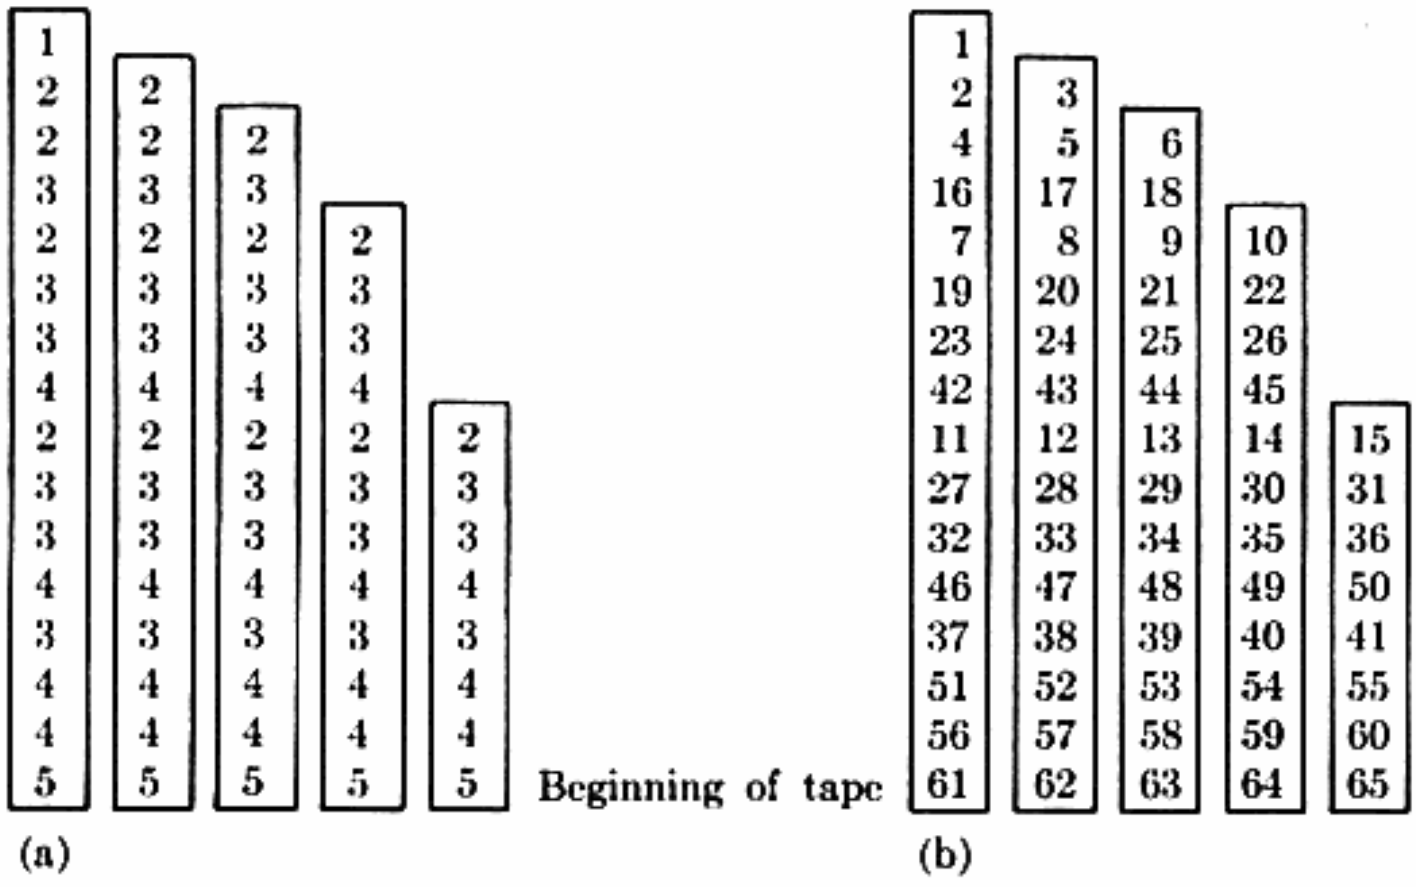

Fig. 71. Analysis of the fifth-level polyphase distribution for six tapes: (a) merge numbers, (b) optimum distribution order.

The recurrence relations (8) show that each of B_n, C_n, D_n, E_n are initial substrings of A_n. In fact, we can use (8) to derive the formulas

$$\begin{aligned} E_n &= (A_{n-1}) + 1, \\ D_n &= (A_{n-1}A_{n-2}) + 1, \\ C_n &= (A_{n-1}A_{n-2}A_{n-3}) + 1, \\ B_n &= (A_{n-1}A_{n-2}A_{n-3}A_{n-4}) + 1, \\ A_n &= (A_{n-1}A_{n-2}A_{n-3}A_{n-4}A_{n-5}) + 1, \end{aligned} \tag{9}$$

generalizing Eqs. (3), which treated only the lengths of these strings. Furthermore, the rule defining the A's implies that essentially the same structure is present at the beginning of every level; we have

$$A_n = n - Q_n, \tag{10}$$

where Q_n is a string of a_n values defined by the law

$$Q_n = Q_{n-1}(Q_{n-2}+1)(Q_{n-3}+2)(Q_{n-4}+3)(Q_{n-5}+4), \quad \text{for} \quad n \geq 1;$$
$$Q_0 = \text{'0'}; \qquad Q_n = (\text{empty}) \qquad \text{for} \qquad n < 0. \tag{11}$$

Since Q_n begins with Q_{n-1}, we can consider the *infinite* string Q_∞, whose first a_n elements are equal to Q_n; this string Q_∞ essentially characterizes all the merge numbers in the polyphase distribution. In the six-tape case,

$$Q_\infty = 01121223122323341223233423343441223233423343445233434453445451223 2\cdots. \tag{12}$$

Exercise 11 contains an interesting interpretation of this string.

Given that A_n is the string $m_1 m_2 \ldots m_{a_n}$, let $A_n(x) = x^{m_1} + x^{m_2} + \cdots + x^{m_{a_n}}$ be the corresponding generating function which counts the number of times each merge number appears; and define $B_n(x)$, $C_n(x)$, $D_n(x)$, $E_n(x)$ similarly. For example, $A_4(x) = x^4 + x^3 + x^3 + x^2 + x^3 + x^2 + x^2 + x = x^4 + 3x^3 + 3x^2 + x$. Relations (9) tell us that

$$\begin{aligned} E_n(x) &= x\big(A_{n-1}(x)\big), \\ D_n(x) &= x\big(A_{n-1}(x) + A_{n-2}(x)\big), \\ C_n(x) &= x\big(A_{n-1}(x) + A_{n-2}(x) + A_{n-3}(x)\big), \\ B_n(x) &= x\big(A_{n-1}(x) + A_{n-2}(x) + A_{n-3}(x) + A_{n-4}(x)\big), \\ A_n(x) &= x\big(A_{n-1}(x) + A_{n-2}(x) + A_{n-3}(x) + A_{n-4}(x) + A_{n-5}(x)\big), \end{aligned} \tag{13}$$

for $n \geq 1$, where $A_0(x) = 1$ and $A_n(x) = 0$ for $n = -1, -2, -3, -4$. Consequently,

$$\begin{aligned} \sum_{n\geq 0} A_n(x)z^n &= \frac{1}{1 - x(z + z^2 + z^3 + z^4 + z^5)} \\ &= \sum_{k\geq 0} x^k(z + z^2 + z^3 + z^4 + z^5)^k. \end{aligned} \tag{14}$$

Considering the runs on all tapes, we let

$$T_n(x) = A_n(x) + B_n(x) + C_n(x) + D_n(x) + E_n(x), \qquad n \geq 1; \tag{15}$$

from (13) we immediately have

$$T_n(x) = 5A_{n-1}(x) + 4A_{n-2}(x) + 3A_{n-3}(x) + 2A_{n-4}(x) + A_{n-5}(x),$$

hence

$$\sum_{n\geq 1} T_n(x)z^n = \frac{x(5z + 4z^2 + 3z^3 + 2z^4 + z^5)}{1 - x(z + z^2 + z^3 + z^4 + z^5)}, \tag{16}$$

The form of (16) shows that it is easy to compute the coefficients of $T_n(x)$:

	z	z^2	z^3	z^4	z^5	z^6	z^7	z^8	z^9	z^{10}	z^{11}	z^{12}	z^{13}	z^{14}	
x	5	4	3	2	1	0	0	0	0	0	0	0	0	0	
x^2	0	5	9	12	14	15	10	6	3	1	0	0	0	0	
x^3	0	0	5	14	26	40	55	60	57	48	35	20	10	4	(17)
x^4	0	0	0	5	19	45	85	140	195	238	260	255	220	170	
x^5	0	0	0	0	5	24	69	154	294	484	703	918	1088	1168	

The columns of this tableau give $T_n(x)$; for example, $T_4(x) = 2x + 12x^2 + 14x^3 + 5x^4$. After the first row, each entry in the tableau is the sum of the five entries just above and to the left in the previous row.

The number of runs in a "perfect" nth level distribution is $T_n(1)$, and the total amount of processing as these runs are merged is the derivative, $T_n'(1)$. Now

$$\sum_{n\geq 1} T_n'(x)z^n = \frac{5z + 4z^2 + 3z^3 + 2z^4 + z^5}{(1 - x(z + z^2 + z^3 + z^4 + z^5))^2}; \tag{18}$$

setting $x = 1$ in (16) and (18) gives a result in agreement with our earlier demonstration that the merge processing for a perfect nth level distribution is the coefficient of z^n in $a(z)t(z)$ [cf. (7)].

We can use the functions $T_n(x)$ to determine the work involved when dummy runs are added in an optimum way. Let $\Sigma_n(m)$ be the sum of the smallest m merge numbers in an nth level distribution. These values are readily calculated by looking at the columns of (17), and we find that $\Sigma_n(m) =$

$m =$	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20	21
$n = 1$	1	2	3	4	5	∞	∞	∞	∞	∞	∞	∞	∞	∞	∞	∞	∞	∞	∞	∞	∞
$n = 2$	1	2	3	4	6	8	10	12	14	∞	∞	∞	∞	∞	∞	∞	∞	∞	∞	∞	∞
$n = 3$	1	2	3	5	7	9	11	13	15	17	19	21	24	27	30	33	36	∞	∞	∞	∞
$n = 4$	1	2	4	6	8	10	12	14	16	18	20	22	24	26	29	32	35	38	41	44	47
$n = 5$	1	3	5	7	9	11	13	15	17	19	21	23	25	27	29	32	35	38	41	44	47
$n = 6$	2	4	6	8	10	12	14	16	18	20	22	24	26	28	30	33	36	39	42	45	48
$n = 7$	2	4	6	8	10	12	14	16	18	20	23	26	29	32	35	38	41	44	47	50	53

(19)

For example, if we wish to sort 17 runs using a level-3 distribution, the total amount of processing is $\Sigma_3(17) = 36$; but if we use a level-4 or level-5 distribution and position the dummy runs optimally, the total amount of processing during the merge phases is only $\Sigma_4(17) = \Sigma_5(17) = 35$. It is better to use level 4, even though 17 corresponds to a "perfect" level-3 distribution! Indeed, as S gets large it turns out that the optimum number of levels is many more than that used in Algorithm D.

Exercise 14 shows that there is a nondecreasing sequence of numbers M_n such that level n is "optimum" for $M_n \le S < M_{n+1}$, but not for $S \ge M_{n+1}$. In the six-tape case the table of $\Sigma_n(m)$ we have just calculated shows that

$$M_0 = 0, \qquad M_1 = 2, \qquad M_2 = 6, \qquad M_3 = 10, \qquad M_4 = 14.$$

The above discussion treats only the case of six tapes, but it is clear that the same ideas apply to polyphase merging with T tapes for any $T \ge 3$; we simply replace 5 by $P = T - 1$ in all appropriate places. Table 2 shows the sequences M_n obtained for various values of T. Table 3 and Fig. 72 indicate the total number of initial runs that are processed after making an optimum

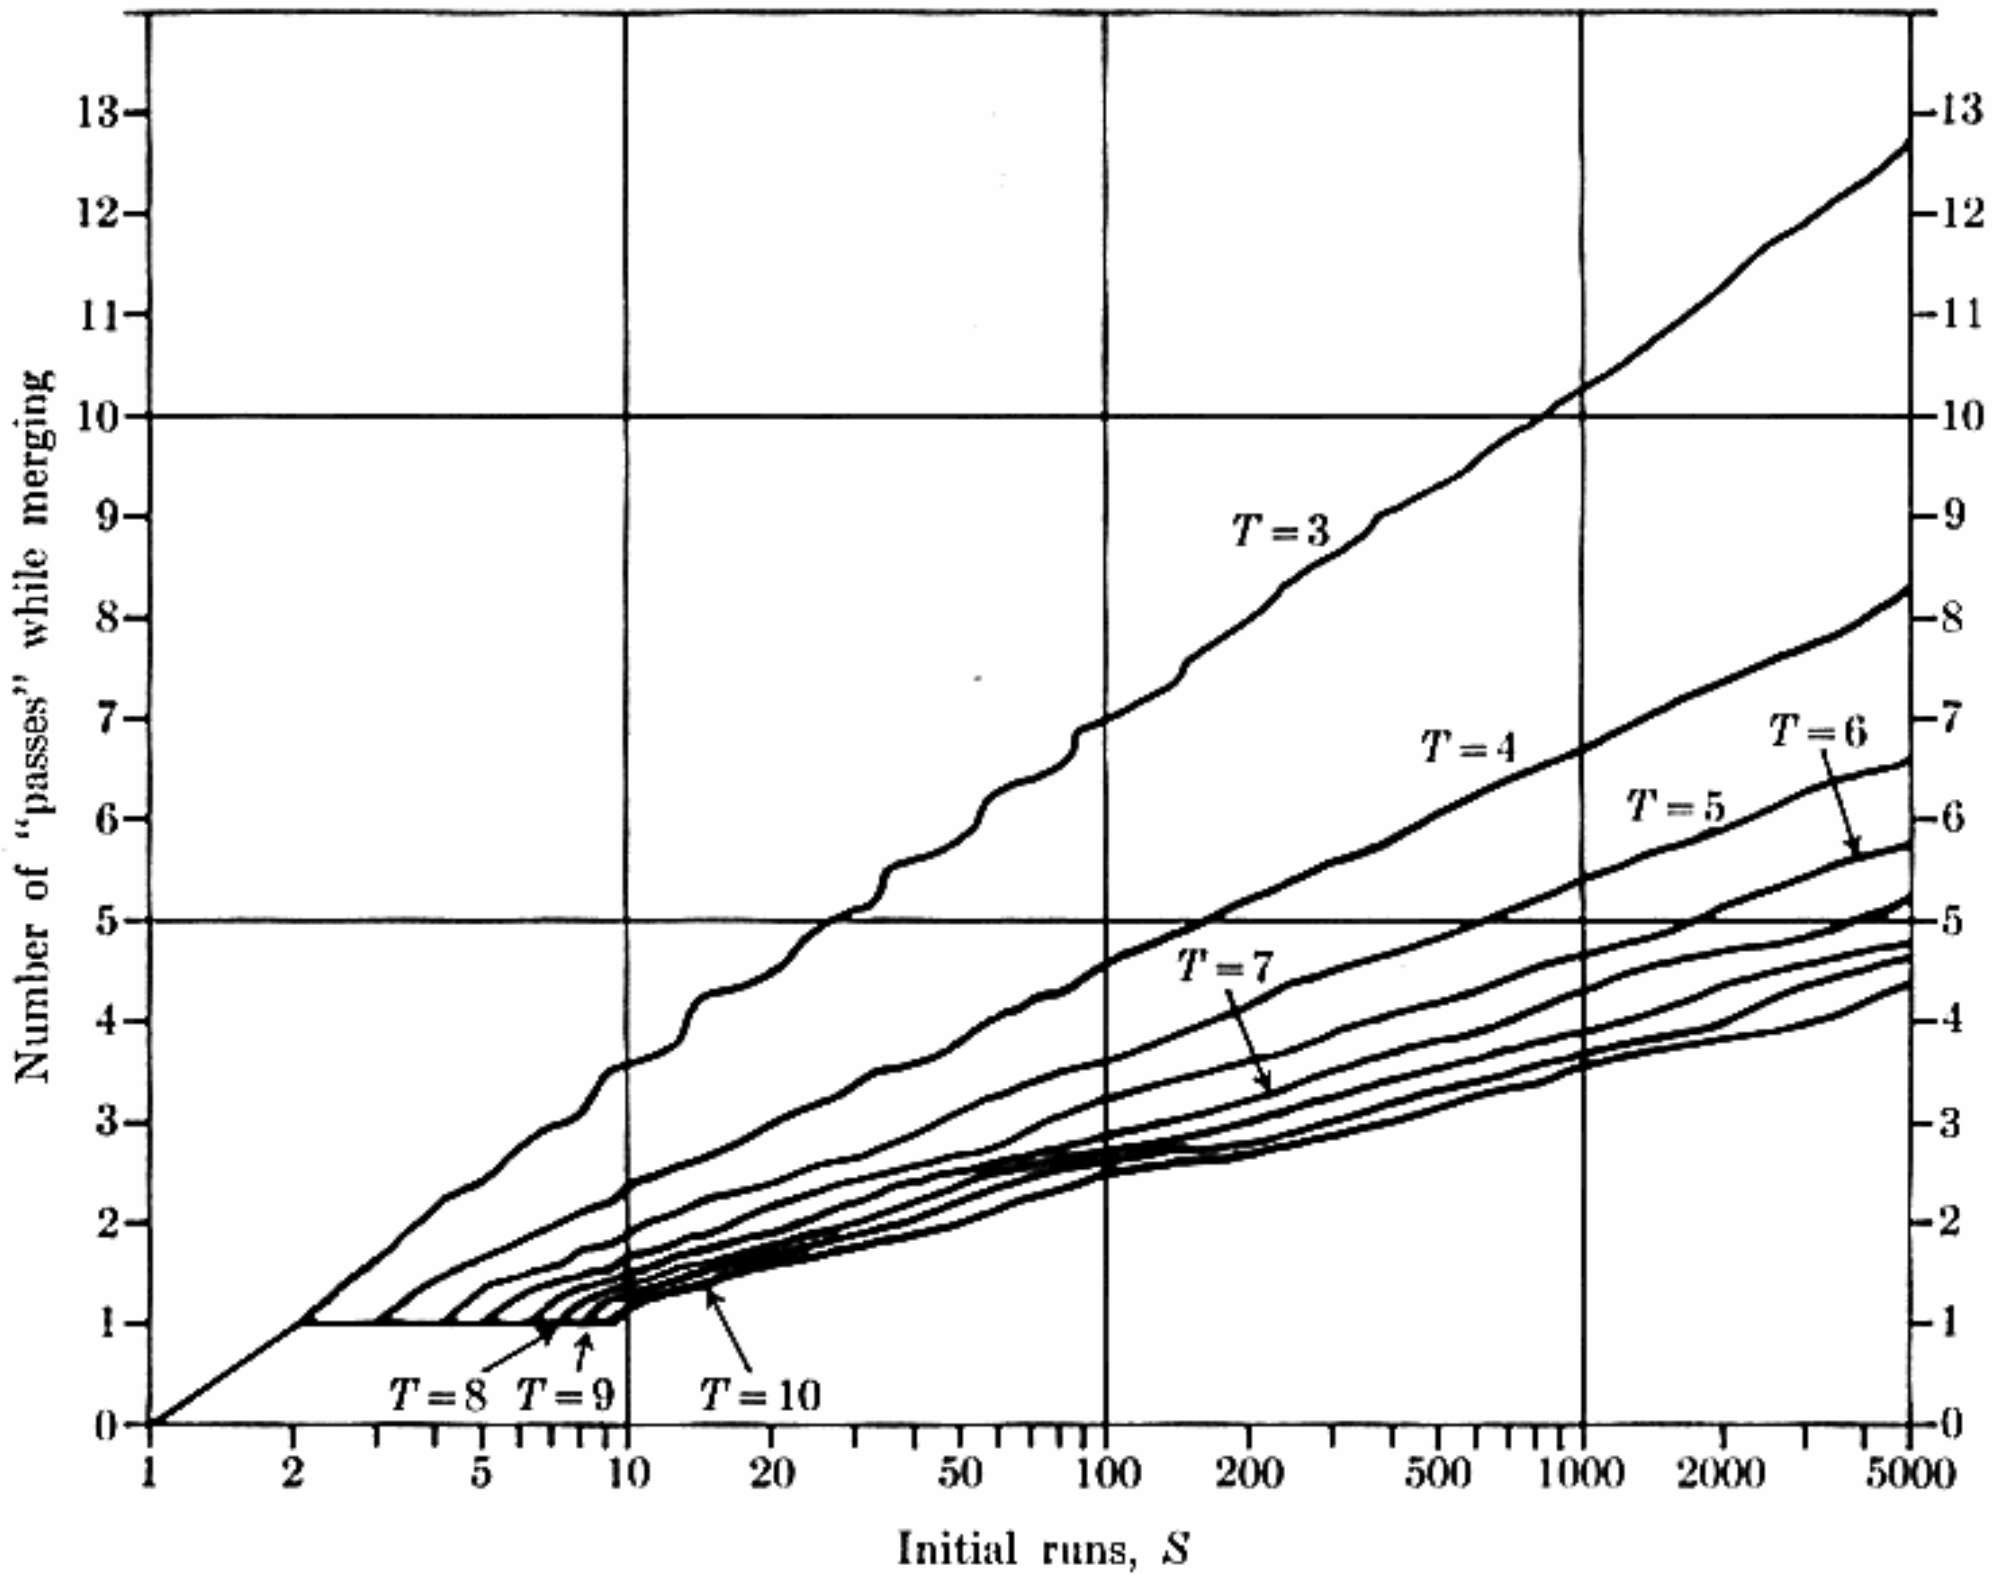

Fig. 72. Efficiency of polyphase merge with optimum initial distribution (cf. Fig. 70).

distribution of dummy runs. (Formulas which appear at the bottom of Table 3 should be taken with a grain of salt, since they are "least-squares fits" over the range $1 \leq S \leq 5000$ ($1 \leq S \leq 10000$ for $T = 3$); this leads to somewhat erratic behavior because the given range of S values is not equally favorable for all T. As $S \to \infty$, the number of initial runs processed after an optimum polyphase distribution is asymptotically $S \log_P S$, but convergence to this asymptotic limit is extremely slow.)

Table 2

NUMBER OF RUNS FOR WHICH A GIVEN LEVEL IS OPTIMUM

Level	$T = 3$	$T = 4$	$T = 5$	$T = 6$	$T = 7$	$T = 8$	$T = 9$	$T = 10$

S	$(1.51$	0.951	0.761	0.656	0.589	0.548	0.539	$0.488) \cdot S \ln S$
	$+ (- .11$	$+ .14$	$+ .16$	$+ .19$	$+ .21$	$+ .20$	$+ .02$	$+ .18) \cdot S$

Table 4 shows how the distribution method of Algorithm D compares with the results of optimum distribution in Table 3. It is clear that Algorithm D is not very close to the optimum when S and T become large; but it is not clear how to do much better than Algorithm D without considerable complication in such cases, especially if we do not know S in advance. Fortunately, we rarely have to worry about large S (see Section 5.4.6), so Algorithm D is not too bad in practice; in fact, it's pretty good.

Table 4

INITIAL RUNS PROCESSED DURING STANDARD POLYPHASE MERGE

S	$T = 3$	$T = 4$	$T = 5$	$T = 6$	$T = 7$	$T = 8$	$T = 9$	$T = 10$

Polyphase sorting was first analyzed mathematically by W. C. Carter [*Proc. IFIP Congress* (1962), 62–66]. Many of the above results about optimal dummy run placement are due originally to B. Sackman and T. Singer ["A vector model for merge sort analysis," unpublished paper presented at the ACM Sort Symposium (November, 1962), 21 pp.]. Sackman later suggested the horizontal method of distribution used in Algorithm D. Donald Shell [*CACM* **14** (1971), 713–719; **15** (1972), 28] developed the theory independently, noted relation (10), and made a detailed study of several different distribution algorithms. Further instructive developments and refinements have been made by Derek A. Zave [*JACM* (to appear)]. The generating function (16) was first investigated by W. Burge [*Proc. IFIP Congress* (1971), to appear].

But what about rewind time? So far we have taken "initial runs processed" as the sole measure of efficiency for comparing tape merge strategies. But after each of phases 2 through 6, in the examples at the beginning of this section, it is necessary for the computer to wait for two tapes to rewind; both the previous output tape and the new current output tape must be repositioned at the beginning, before the next phase can proceed. This can cause a significant delay, since the previous output tape generally contains a significant percentage of the records being sorted (see the "Pass/Phase" column in Table 1). It is a shame to have the computer twiddling its thumbs during all these rewind operations, since useful work could be done with the other tapes if we used a different merging pattern.

A simple modification of the polyphase procedure will overcome this problem, although it requires at least five tapes [see Y. Cesari, thesis, U. of Paris (1968), 25–27, where the idea is credited to J. Caron]. Each phase in Caron's scheme merges runs from $T - 3$ tapes onto another tape, while the remaining two tapes are rewinding.

For example, consider the case of six tapes and 49 initial runs. In the following tableau, R denotes rewinding during the phase, and T5 is assumed to contain the original input:

Phase	T1	T2	T3	T4	T5	T6	Write time	Rewind time
1	1^{11}	1^{17}	1^{13}	1^{8}	—	(R)	49	17
2	(R)	1^{9}	1^{5}	—	R	3^{8}	$8 \times 3 = 24$	$49 - 17 = 32$
3	1^{6}	1^{4}	—	R	3^{5}	R	$5 \times 3 = 15$	max (8, 24)
4	1^{2}	—	R	5^{4}	R	3^{4}	$4 \times 5 = 20$	max (13, 15)
5	—	R	7^{2}	R	3^{3}	3^{2}	$2 \times 7 = 14$	max (17, 20)
6	R	11^{2}	R	5^{2}	3^{1}	—	$2 \times 11 = 22$	max (11, 14)
7	15^{1}	R	7^{1}	5^{1}	—	R	$1 \times 15 = 15$	max (22, 24)
8	R	11^{1}	7^{0}	—	R	23^{1}	$1 \times 23 = 23$	max (15, 15)
9	15^{1}	11^{1}	—	R	33^{0}	R	$0 \times 33 = 0$	max (20, 23)
10	(15^{0})	—	R	49^{1}	(R)	(23^{0})	$1 \times 49 = 49$	14

Here all the rewind time is essentially overlapped, except in phase 9 (a "dummy phase" which prepares for the final merge), and after the initial distribution phase (when all tapes are rewound). If t is the time to merge the number of records in one initial run, and if r is the time to rewind over one initial run, this process takes about $182t + 40r$ plus the time for initial distribution and final rewind. The corresponding figures for standard polyphase using Algorithm D are $140t + 104r$, which is slightly worse when $r = \frac{3}{4}t$, slightly better when $r = \frac{1}{2}t$.

Everything we have said about standard polyphase can be adapted to Caron's polyphase; for example, the sequence a_n now satisfies the recurrence

$$a_n = a_{n-2} + a_{n-3} + a_{n-4} \tag{20}$$

instead of (3). The reader will find it instructive to analyze this method in the same way we analyzed standard polyphase, since it will enhance an understanding of both methods. (See, for example, exercises 19 and 20.)

Table 5 gives facts about Polyphase Caron which are analogous to the facts about Polyphase Ordinaire in Table 1. Note that Caron's method actually becomes *superior* to polyphase on eight or more tapes, in the number of runs processed as well as in the rewind time, even though it does $(T - 3)$-way merging instead of $(T - 1)$-way merging!

Table 5

APPROXIMATE BEHAVIOR OF CARON'S POLYPHASE MERGE SORT

Tapes	Phases	Passes	Pass/phase, percent	Growth ratio
5	$3.556 \ln S + 0.158$	$1.463 \ln S + 1.016$	41	1.3247180
6	$2.616 \ln S - 0.166$	$0.951 \ln S + 1.014$	36	1.4655712
7	$2.337 \ln S - 0.472$	$0.781 \ln S + 1.001$	33	1.5341577
8	$2.216 \ln S - 0.762$	$0.699 \ln S + 0.980$	32	1.5701473
9	$2.156 \ln S - 1.034$	$0.654 \ln S + 0.954$	30	1.5900054
10	$2.124 \ln S - 1.290$	$0.626 \ln S + 0.922$	29	1.6013473
20	$2.078 \ln S - 3.093$	$0.575 \ln S + 0.524$	28	1.6179086

This may seem paradoxical until we realize that *a high order of merge does not necessarily imply an efficient sort.* As an extreme example, consider placing 1 run on T1 and n runs on T2, T3, T4, T5; if we alternately do five-way merging to T6 and T1 until T2, T3, T4, T5 are empty, the processing time is $(2n^2 + 3n)$ initial run lengths, essentially proportional to S^2 instead of $S \log S$, although five-way merging was done throughout.

Tape splitting. Efficient overlapping of rewind time is a problem which arises in many applications, not just sorting, and there is a general approach which can often be used. Consider an iterative process which uses two tapes in the following way:

	T1	T2
Phase 1	Output 1	—
	Rewind	—
Phase 2	Input 1	Output 2
	Rewind	Rewind
Phase 3	Output 3	Input 2
	Rewind	Rewind
Phase 4	Input 3	Output 4
	Rewind	Rewind

and so on, where "Output k" means write the kth output file and "Input k" means read it. The rewind time can be avoided when three tapes are used, as suggested by C. Weisert [*CACM* **5** (1962), 102]:

	T1	T2	T3
Phase 1	Output 1.1	—	—
	Output 1.2	—	—
	Rewind	Output 1.3	—
Phase 2	Input 1.1	Output 2.1	—
	Input 1.2	Rewind	Output 2.2
	Rewind	Input 1.3	Output 2.3
Phase 3	Output 3.1	Input 2.1	Rewind
	Output 3.2	Rewind	Input 2.2
	Rewind	Output 3.3	Input 2.3
Phase 4	Input 3.1	Output 4.1	Rewind
	Input 3.2	Rewind	Output 4.2
	Rewind	Input 3.3	Output 4.3

and so on. Here "Output $k.j$" means, write the jth third of the kth output file, and "Input $k.j$" means, read it. Virtually all of the rewind time will be eliminated if rewinding is at least twice as fast as the read/write speed. Such a procedure, in which the output of each phase is divided between tapes, is called "tape-splitting."

R. L. McAllester [*CACM* 7 (1964), 158–159] has shown that tape-splitting leads to an efficient way of overlapping the rewind time in a polyphase merge. His method can be used with four or more tapes, and it does $(T - 2)$-way merging.

Assuming once again that we have six tapes, let us try to design a merge pattern that operates as follows, splitting the output on each level, where "I", "O", and "R," respectively, denote input, output, and rewinding:

Level	T1	T2	T3	T4	T5	T6	Number of runs output	
7	I	I	I	I	R	O	u_7	
	I	I	I	I	O	R	v_7	
6	I	I	I	R	O	I	u_6	
	I	I	I	O	R	I	v_6	
5	I	I	R	O	I	I	u_5	
	I	I	O	R	I	I	v_5	
4	I	R	O	I	I	I	u_4	
	I	O	R	I	I	I	v_4	
3	R	O	I	I	I	I	u_3	
	O	R	I	I	I	I	v_3	
2	O	I	I	I	I	R	u_2	
	R	I	I	I	I	O	v_2	
1	I	I	I	I	R	O	u_1	
	I	I	I	I	O	R	v_1	
0	I	I	I	R	O	I	u_0	
	I	I	I	O	R	I	v_0	(21)

In order to end with one run on T4 and all other tapes empty, we need to have

$$\begin{aligned}
v_0 &= 1,\\
u_0 + v_1 &= 0,\\
u_1 + v_2 &= u_0 + v_0,\\
u_2 + v_3 &= u_1 + v_1 + u_0 + v_0,\\
u_3 + v_4 &= u_2 + v_2 + u_1 + v_1 + u_0 + v_0,\\
u_4 + v_5 &= u_3 + v_3 + u_2 + v_2 + u_1 + v_1 + u_0 + v_0,\\
u_5 + v_6 &= u_4 + v_4 + u_3 + v_3 + u_2 + v_2 + u_1 + v_1,
\end{aligned}$$

etc.; in general, the requirement is that

$$u_n + v_{n+1} = u_{n-1} + v_{n-1} + u_{n-2} + v_{n-2} + u_{n-3} + v_{n-3} + u_{n-4} + v_{n-4} \qquad (22)$$

for all $n \geq 0$, if we regard $u_j = v_j = 0$ for all $j < 0$.

There is no unique solution to these equations; indeed, if we let all the u's be zero, we get the usual polyphase merge with one tape wasted! But if we choose $u_n \approx v_{n+1}$, the rewind time will be satisfactorily overlapped.

McAllester suggested taking $u_n = v_{n-1} + v_{n-2} + v_{n-3} + v_{n-4}$, $v_{n+1} = u_{n-1} + u_{n-2} + u_{n-3} + u_{n-4}$, so that the sequence

$$\langle x_0, x_1, x_2, x_3, x_4, x_5, \ldots \rangle = \langle v_0, u_0, v_1, u_1, v_2, u_2, \ldots \rangle$$

satisfies the uniform recurrence $x_n = x_{n-3} + x_{n-5} + x_{n-7} + x_{n-9}$. However, it turns out to be better to let

$$\begin{aligned}
v_{n+1} &= u_{n-1} + v_{n-1} + u_{n-2} + v_{n-2},\\
u_n &= u_{n-3} + v_{n-3} + u_{n-4} + v_{n-4};
\end{aligned} \qquad (23)$$

this sequence is not only slightly better in its merging time, it also has the great virtue that the corresponding merging time can be analyzed mathematically. [McAllester's choice is extremely difficult to analyze because runs of different lengths may occur during a single phase; we shall see that this does not happen with (23).]

We can deduce the number of runs on each tape on each level, by working backwards in the pattern (21), and we obtain the following sorting scheme:

Level	T1	T2	T3	T4	T5	T6	Write time	Rewind time
	1^{23}	1^{21}	1^{17}	1^{10}	—	1^{11}	82	23
7	1^{19}	1^{17}	1^{13}	1^{6}	R	$1^{11}4^{4}$	$4 \times 4 = 16$	82 – 23
	1^{13}	1^{11}	1^{7}	—	4^{6}	R	$6 \times 4 = 24$	25
6	1^{10}	1^{8}	1^{4}	R	4^{9}	$1^{8}4^{4}$	$3 \times 4 = 12$	10
	1^{6}	1^{4}	—	4^{4}	R	$1^{4}4^{4}$	$4 \times 4 = 16$	36
5	1^{5}	1^{3}	R	$4^{4}7^{1}$	4^{8}	$1^{3}4^{4}$	$1 \times 7 = 7$	17
	1^{2}	—	7^{3}	R	4^{5}	4^{4}	$3 \times 7 = 21$	23
4	1^{1}	R	$7^{3}13^{1}$	$4^{3}7^{1}$	4^{4}	4^{3}	$1 \times 13 = 13$	21
	—	13^{1}	R	$4^{2}7^{1}$	4^{3}	4^{2}	$1 \times 13 = 13$	34
3	R	$13^{1}19^{1}$	$7^{2}13^{1}$	$4^{1}7^{1}$	4^{2}	4^{1}	$1 \times 19 = 19$	23
	19^{1}	R	$7^{1}13^{1}$	7^{1}	4^{1}	—	$1 \times 19 = 19$	32
2	$19^{1}31^{0}$	$13^{1}19^{1}$	$7^{1}13^{1}$	7^{1}	4^{1}	R	$0 \times 31 = 0$	25
	R	19^{1}	13^{1}	7^{0}	—	31^{1}	$1 \times 31 = 31$	19
1	$19^{1}31^{0}$	19^{1}	13^{1}	7^{0}	R	$31^{1}52^{0}$	$0 \times 52 = 0$	
	$19^{1}31^{0}$	19^{1}	13^{1}	—	52^{0}	R	$0 \times 52 = 0$	max (36, 31, 23)
0	$19^{1}31^{0}$	19^{1}	13^{1}	R	$52^{0}82^{0}$	$31^{1}52^{0}$	$0 \times 82 = 0$	
	(31^{0})	(19^{0})	—	82^{1}	(R)	(52^{0})	$1 \times 82 = 82$	0

Unoverlapped rewinding occurs when the input tape T5 is being rewound (82 units), during the first half of the level 2 phase (25 units), and during the final "dummy merge" phases in levels 1 and 0 (36 units). So we may estimate the time as $273t + 143r$; the corresponding amount for Algorithm D, $268t + 208r$, is almost always inferior.

It is not difficult to see (cf. exercise 23) that the run lengths output during each phase are successively

$$4, 4, 7, 13, 19, 31, 52, 82, 133, \ldots \tag{24}$$

a sequence $\langle t_1, t_2, t_3, \ldots \rangle$ satisfying the law

$$t_n = t_{n-2} + 2t_{n-3} + t_{n-4} \tag{25}$$

if we regard $t_n = 1$ for $n \leq 0$. We can also analyze the optimum placement of dummy runs, by looking at strings of merge numbers as we did for standard polyphase [cf. (8)]:

Level	T1	T2	T3	T4	T6	Final output on
1	1	1	1	1	—	T5
2	1	1	1	—	1	T4
3	21	21	2	2	1	T3
4	2221	222	222	22	2	T2
5	23222	23222	2322	23	222	T1
6	33332322	33332322	333323	3333	2322	T6
. . . . .						
n	A_n	B_n	C_n	D_n	E_n	T(k)
$n+1$	$(A_n''E_n + 1)B_n$	$(A_n''E_n + 1)C_n$	$(A_n''E_n + 1)D_n$	$A_n''E_n + 1$	A_n'	T($k-1$)
. . . . .						

(26)

where $A_n = A'_n A''_n$, and A''_n consists of the last u_n merge numbers of A_n. The above rule for going from level n to level $n+1$ is valid for *any* scheme satisfying (22). When we define the u's and v's by (23), the strings $A_n, \ldots, E_n$ can be expressed in the following rather simple way [cf. (9)]:

$$\begin{aligned} A_n &= (W_{n-1}W_{n-2}W_{n-3}W_{n-4}) + 1, \\ B_n &= (W_{n-1}W_{n-2}W_{n-3}) + 1, \\ C_n &= (W_{n-1}W_{n-2}) + 1, \\ D_n &= (W_{n-1}) + 1, \\ E_n &= (W_{n-2}W_{n-3}) + 1, \end{aligned} \tag{27}$$

where

$$\begin{aligned} &W_n = (W_{n-3}W_{n-4}W_{n-2}W_{n-3}) + 1 \quad \text{for} \quad n > 0, \\ &W_0 = \text{'0'}, \quad \text{and} \quad W_n = (\text{empty}) \quad \text{for} \quad n < 0. \end{aligned} \tag{28}$$

From these relations it is easy to make a detailed analysis of the six-tape case.

In general, when there are $T \geq 5$ tapes, we let $P = T - 2$, and we define the sequences $\langle u_n \rangle$, $\langle v_n \rangle$ by the rules

$$\begin{aligned} v_{n+1} &= u_{n-1} + v_{n-1} + \cdots + u_{n-r} + v_{n-r}, \\ u_n &= u_{n-r-1} + v_{n-r-1} + \cdots + u_{n-P} + v_{n-P}, \quad \text{for} \quad n \geq 0, \end{aligned} \tag{29}$$

where $r = \lfloor P/2 \rfloor$; $v_0 = 1$, and $u_n = v_n = 0$ for $n < 0$. If $w_n = u_n + v_n$, we therefore have

$$w_n = w_{n-2} + \cdots + w_{n-r} + 2w_{n-r-1} + w_{n-r-2} + \cdots + w_{n-P}, \quad n > 0; \tag{30}$$

$w_0 = 1$; and $w_n = 0$ for $n < 0$. The initial distribution on tapes for level $n+1$ places $w_n + w_{n-1} + \cdots + w_{n-P+k}$ runs on tape k, for $1 \leq k \leq P$, and $w_{n-1} + \cdots + w_{n-r}$ on tape T; tape $T-1$ is used for input. Then u_n runs are merged to tape T while $T-1$ is being rewound; v_n are merged to $T-1$ while T is rewinding; u_{n-1} to $T-1$ while $T-2$ is rewinding; etc.

Table 6 shows the approximate behavior of this procedure when S is not too small. The "Pass/Phase" column indicates approximately how much of the entire file is being rewound during each half of a phase, and approximately how much of the file is being written during each full phase. *The tape-splitting method is superior to standard polyphase on six or more tapes*, and probably also on five, at least for large S.

When $T = 4$ the above procedure would become essentially equivalent to balanced two-way merging, *without* overlapping the rewind time, since w_{2n+1} would be 0 for all n. So the entries in Table 6 for $T = 4$ have been obtained by making a slight modification, letting $v_2 = 0$, $u_1 = 1$, $v_1 = 0$, $u_0 = 0$, $v_0 = 1$, and $v_{n+1} = u_{n-1} + v_{n-1}$, $u_n = u_{n-2} + v_{n-2}$ for $n \geq 2$. This leads to a very interesting sorting scheme (see exercises 25 and 26).

Table 6

APPROXIMATE BEHAVIOR OF POLYPHASE MERGE WITH TAPE SPLITTING

Tapes	Phases	Passes	Pass/phase, percent	Growth ratio
4	$2.885 \ln S + 0.000$	$1.443 \ln S + 1.000$	50	1.4142136
5	$2.078 \ln S + 0.232$	$0.929 \ln S + 1.022$	45	1.6180340
6	$2.078 \ln S - 0.170$	$0.752 \ln S + 1.024$	36	1.6180340
7	$1.958 \ln S - 0.408$	$0.670 \ln S + 1.007$	34	1.6663019
8	$2.008 \ln S - 0.762$	$0.624 \ln S + 0.994$	31	1.6454116
9	$1.972 \ln S - 0.987$	$0.595 \ln S + 0.967$	30	1.6604077
10	$2.013 \ln S - 1.300$	$0.580 \ln S + 0.941$	29	1.6433803
20	$2.069 \ln S - 3.164$	$0.566 \ln S + 0.536$	27	1.6214947

EXERCISES

1. [*16*] Figure 69 shows the order in which runs 34 through 65 are distributed to five tapes with Algorithm D; in what order are runs 1 through 33 distributed?

▸ **2.** [*21*] True or false: After two merge phases in Algorithm D, i.e., on the second time we reach step D6, all dummy runs have disappeared.

▸ **3.** [*22*] Prove that the condition $\texttt{D}[1] \geq \texttt{D}[2] \geq \cdots \geq \texttt{D}[T]$ is always satisfied at the conclusion of step D4. Explain why this condition is important, in the sense that the mechanism of steps D2 and D3 would not work properly otherwise.

4. [*M20*] Derive the generating functions (7).

5. [*HM26*] (E. P. Miles, Jr., 1960.) For all $p \geq 2$, prove that the polynomial $f_p(z) = z^p - z^{p-1} - \cdots - z - 1$ has p distinct roots, of which exactly one has magnitude greater than unity. [*Hint:* Consider the polynomial $z^{p+1} - 2z^p + 1$.]

6. [*HM24*] The purpose of this exercise is to consider how Tables 1, 5, and 6 can be prepared. Assume that we have a merging pattern whose properties are characterized by polynomials $p(z)$ and $q(z)$ in the following way: (1) The number of initial runs present in a "perfect distribution" requiring n merging phases is the coefficient of z^n in $p(z)/q(z)$. (2) The number of initial runs processed during these n merging phases is the coefficient of z^n in $p(z)/q(z)^2$. (3) There is a "dominant root" α of $q(z^{-1})$ such that $q(\alpha^{-1}) = 0$, $q'(\alpha^{-1}) \neq 0$, $p(\alpha^{-1}) \neq 0$, and $q(\beta^{-1}) = 0$ implies that $\beta = \alpha$ or $|\beta| < |\alpha|$.

Prove that there is a number $\epsilon > 0$ such that, if S is the number of runs in a perfect distribution requiring n merging phases, and if ρS initial runs are processed during those phases, we have $n = a \ln S + b + O(S^{-\epsilon})$, $\rho = c \ln S + d + O(S^{-\epsilon})$, where

$$a = (\ln \alpha)^{-1}, \qquad b = -a \ln \left(\frac{p(\alpha^{-1})}{-q'(\alpha^{-1})} \right) - 1, \qquad c = a \frac{\alpha}{-q'(\alpha^{-1})},$$

$$d = \frac{(b+1)\alpha - p'(\alpha^{-1})/p(\alpha^{-1}) + q''(\alpha^{-1})/q'(\alpha^{-1})}{-q'(\alpha^{-1})}.$$

7. [*HM22*] Let α_p be the dominant root of the polynomial $f_p(z)$ in exercise 5. What is the asymptotic behavior of α_p as $p \longrightarrow \infty$?

8. [*M20*] (E. Netto, 1901.) Let $N_m^{(p)}$ be the number of ways to express m as an ordered sum of the integers $\{1, 2, \ldots, p\}$. For example, when $p = 3$ and $m = 5$, there are 13 ways, namely $1+1+1+1+1 = 1+1+1+2 = 1+1+2+1 = 1+1+3 = 1+2+1+1 = 1+2+2 = 1+3+1 = 2+1+1+1 = 2+1+2 = 2+2+1 = 2+3 = 3+1+1 = 3+2$. Show that $N_m^{(p)}$ is a generalized Fibonacci number.

9. [*M20*] Let $K_m^{(p)}$ be the number of sequences of m 0's and 1's such that there are no p consecutive 1's. For example, when $p = 3$ and $m = 5$ there are 24 ways: 00000, 00001, 00010, 00011, 00100, 00101, 00110, 01000, 01001, ..., 11011. Show that $K_m^{(p)}$ is a generalized Fibonacci number.

10. [*M27*] (*Generalized Fibonacci number system.*) Prove that every nonnegative integer n has a unique representation as a sum of distinct pth order Fibonacci numbers $F_j^{(p)}$, for $j \geq p$, subject to the condition that no p consecutive Fibonacci numbers are used.

11. [*M24*] Prove that the nth element of the string Q_∞ in (12) is equal to the number of distinct Fibonacci numbers in the fifth-order Fibonacci representation of $n - 1$. (Cf. exercise 10.)

►**12.** [*M20*] Find a connection between powers of the matrix

$$\begin{pmatrix} 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 1 \\ 1 & 1 & 1 & 1 & 1 \end{pmatrix}$$

and the perfect Fibonacci distributions in (1).

►**13.** [*22*] Prove the following rather odd property of perfect Fibonacci distributions: When the final output will be on tape number T, the number of runs on each other tape is *odd;* when the final output will be on some tape other than T, the number of runs will be *odd* on that tape, and it will be *even* on the others. [Cf. (1).]

14. [*M35*] Let $T_n(x) = \sum_{k\geq 0} T_{nk}x^k$, where $T_n(x)$ is the polynomial defined in (16). (a) Show that for each k there is a number $n(k)$ such that $T_{1k} \leq T_{2k} \leq \cdots \leq T_{n(k)k} > T_{n(k)+1,k} \geq \cdots$. (b) Given that $T_{n'k'} < T_{nk'}$ and $n' < n$, prove that $T_{n'k} \leq T_{nk}$ for all $k \geq k'$. (c) Prove that there is a nondecreasing sequence $\langle M_n \rangle$ such that $\Sigma_n(S) = \min_{j\geq 1} \Sigma_j(S)$ when $M_n \leq S < M_{n+1}$, but $\Sigma_n(S) > \min_{j\geq 1} \Sigma_j(S)$ when $S \geq M_{n+1}$. [Cf. (19).]

15. [*M43*] Prove or disprove: $\Sigma_{n-1}(m) < \Sigma_n(m)$ implies that $\Sigma_n(m) \leq \Sigma_{n+1}(m) \leq \Sigma_{n+2}(m) \leq \cdots$. [Such a result would greatly simplify the calculation of Table 2.]

16. [*M43*] Determine the asymptotic behavior of the polyphase merge with optimum distribution of dummy runs.

17. [*32*] Prove or disprove: There is a way to disperse runs for an optimum polyphase distribution in such a way that the distribution for $S+1$ initial runs is formed by adding one run (on an appropriate tape) to the distribution for S initial runs.

18. [*30*] Does the optimum polyphase distribution produce the best possible merging pattern, in the sense that the total number of initial runs processed is minimized, if we insist that the initial runs be placed on at most $T-1$ of the tapes? (Ignore rewind time.)

19. [*21*] Make a table analogous to (1), for Caron's polyphase sort on six tapes.

20. [*M24*] What generating functions for Caron's polyphase sort on six tapes correspond to (7) and to (16)? What relations, analogous to (9) and (27), define the strings of merge numbers?

21. [*11*] What should appear on level 7 in (26)?

22. [*M21*] Each term of the sequence (24) is approximately equal to the sum of the previous two. Does this phenomenon hold for the remaining numbers of the sequence? Formulate and prove a theorem about $t_n - t_{n-1} - t_{n-2}$.

▸**23.** [*29*] What changes would be made to (25), (27), and (28), if (23) were changed to $v_{n+1} = u_{n-1} + v_{n-1} + u_{n-2}$, $u_n = v_{n-2} + u_{n-3} + v_{n-3} + u_{n-4} + v_{n-4}$?

24. [*HM41*] Compute the asymptotic behavior of the tape-splitting polyphase procedure, when v_{n+1} is defined to be the sum of the first q terms of $u_{n-1} + v_{n-1} + \cdots + u_{n-P} + v_{n-P}$, for various $P = T-2$ and for $0 \le q \le 2P$. (The text treats only the case $q = 2\lfloor P/2 \rfloor$; cf. exercise 23.)

25. [*19*] Show how the tape-splitting polyphase merge on four tapes, mentioned at the end of this section, would sort 32 initial runs. (Give a phase-by-phase analysis like the 82-run six-tape example in the text.)

26. [*M21*] Analyze the behavior of the tape-splitting polyphase merge on four tapes, when $S = 2^n$ and when $S = 2^n + 2^{n-1}$. (See exercise 25.)

27. [*28*] Once the initial runs have been distributed to tapes in a perfect distribution, the polyphase strategy is simply to "merge until empty." We merge runs from all nonempty input tapes until one of them becomes empty; then we use that tape as the next output tape, and let the previous output tape serve as an input.

Does this merge-until-empty strategy always sort, no matter how the initial runs are distributed, as long as we distribute them onto at least two tapes? (One tape will, of course, be left empty so that it can be the first output tape.)

28. [*M26*] The previous exercise defines a rather large family of merging patterns. Show that polyphase is the *best* of these, in the following sense: If there are six tapes, and if we consider the class of all initial distributions (a, b, c, d, e) such that the merge-until-empty strategy requires n or less phases to sort, then $a + b + c + d + e \le t_n$, where t_n is the corresponding value for polyphase sorting (1).

29. [*M47*] Exercise 28 shows that the polyphase distribution is optimal among all "merge until empty" patterns in the minimum-phase sense. But is it optimal also in the minimum-pass sense?

Let a be relatively prime to b, and assume that $a + b$ is the Fibonacci number F_n. Prove or disprove the following conjecture due to R. M. Karp: The number of initial runs processed during the merge-until-empty pattern starting with distribution (a, b)

is greater than or equal to $((n-5)F_{n+1}+(2n+2)F_n)/5$. (The latter figure is achieved when $a = F_{n-1}$, $b = F_{n-2}$.)

30. [*42*] Prepare a table analogous to Table 2, for the tape-splitting polyphase merge.

5.4.3. The Cascade Merge

Another basic pattern, called the "cascade merge," was actually discovered before polyphase [B. K. Betz and W. C. Carter, *ACM Nat'l Conference* **14** (1959), Paper 14]. This approach is illustrated for six tapes and 190 initial runs in the following table, using the notation developed in Section 5.4.2:

	T1	T2	T3	T4	T5	T6	Initial runs processed
Pass 1.	1^{55}	1^{50}	1^{41}	1^{29}	1^{15}	—	190
Pass 2.	—	$1^{5}{}_{*}$	2^{9}	3^{12}	4^{14}	5^{15}	190
Pass 3.	15^{5}	14^{4}	12^{3}	9^{2}	$5^{1}{}_{*}$	—	190
Pass 4.	—	$15^{1}{}_{*}$	29^{1}	41^{1}	50^{1}	55^{1}	190
Pass 5.	190^{1}	—	—	—	—	—	190

A cascade merge, like polyphase, starts out with a "perfect distribution" of runs on tapes, although the rule for perfect distributions is somewhat different from those in Section 5.4.2. Each line in the table represents a complete pass over *all* the data. Pass 2, for example, is obtained by doing a five-way merge from T1, T2, T3, T4, T5 to T6, until T5 is empty (this puts 15 runs of relative length 5 on T6), then a four-way merge from T1, T2, T3, T4 to T5, then a three-way merge to T4, a two-way merge to T3, and finally a one-way merge (a copying operation) from T1 to T2. Pass 3 is obtained in the same way, first doing a five-way merge until one tape becomes empty, then a four-way merge, and so on. (Perhaps the present section of this book should be numbered 5.4.3.2.1 instead of 5.4.3!)

It is clear that the copying operations are unnecessary, and they could be omitted. Actually, however, in the six-tape case this copying takes only a small percentage of the total time. The items marked with an asterisk in the above table are those which were simply copied; only 25 of the 950 runs processed are of this type. Most of the time is devoted to five-way and four-way merging.

At first it may seem that the cascade pattern is a rather poor choice, by comparison with polyphase, since standard polyphase uses $(T - 1)$-way merging throughout while the cascade uses $(T - 1)$-way, $(T - 2)$-way, $(T - 3)$-way, etc. But in fact it is asymptotically *better* than polyphase, on six or more tapes! As we have observed in Section 5.4.2, a high order of merge is not a guarantee of efficiency. Table 1 shows the performance characteristics of cascade merge, by analogy with the similar tables in Section 5.4.2.

Table 1

APPROXIMATE BEHAVIOR OF CASCADE MERGE SORTING

Tapes	Passes (with copying)	Passes (without copying)	Growth Ratio
3	$2.078 \ln S + 0.672$	$1.504 \ln S + 0.992$	1.6180340
4	$1.235 \ln S + 0.754$	$1.102 \ln S + 0.820$	2.2469796
5	$0.946 \ln S + 0.796$	$0.897 \ln S + 0.800$	2.8793852
6	$0.796 \ln S + 0.821$	$0.773 \ln S + 0.808$	3.5133371
7	$0.703 \ln S + 0.839$	$0.691 \ln S + 0.822$	4.1481149
8	$0.639 \ln S + 0.852$	$0.632 \ln S + 0.834$	4.7833861
9	$0.592 \ln S + 0.861$	$0.587 \ln S + 0.845$	5.4189757
10	$0.555 \ln S + 0.869$	$0.552 \ln S + 0.854$	6.0547828
20	$0.397 \ln S + 0.905$	$0.397 \ln S + 0.901$	12.4174426

It is not hard to derive the "perfect distributions" for a cascade merge. With six tapes, they are

Level	T1	T2	T3	T4	T5
0	1	0	0	0	0
1	1	1	1	1	1
2	5	4	3	2	1
3	15	14	12	9	5
4	55	50	41	29	15
5	190	175	146	105	55
. . . . .					
n	a_n	b_n	c_n	d_n	e_n
$n+1$	$a_n+b_n+c_n+d_n+e_n$	$a_n+b_n+c_n+d_n$	$a_n+b_n+c_n$	a_n+b_n	a_n

(1)

It is interesting to note that the relative magnitudes of these numbers appear also in the diagonals of a regular $(2T - 1)$-sided polygon. For example, the five diagonals in the undecagon of Fig. 73 have relative lengths very nearly equal to 190, 175, 146, 105, and 55! We shall prove this remarkable fact later in this section, and we shall also see that the relative amount of time spent in $(T - 1)$-way merging, $(T - 2)$-way merging, . . . , 1-way merging is approximately proportional to the *squares* of the lengths of these diagonals.

***Initial distribution of runs.** When the actual number of initial runs isn't perfect, we can insert dummy runs as usual. A superficial analysis of this situation indicates that the method of dummy run assignment is immaterial, since cascade merging operates by complete passes; if we have 190 initial runs, each record is processed five times as in the above example, but if there are 191 we must apparently go up a level so that every record is processed six times.

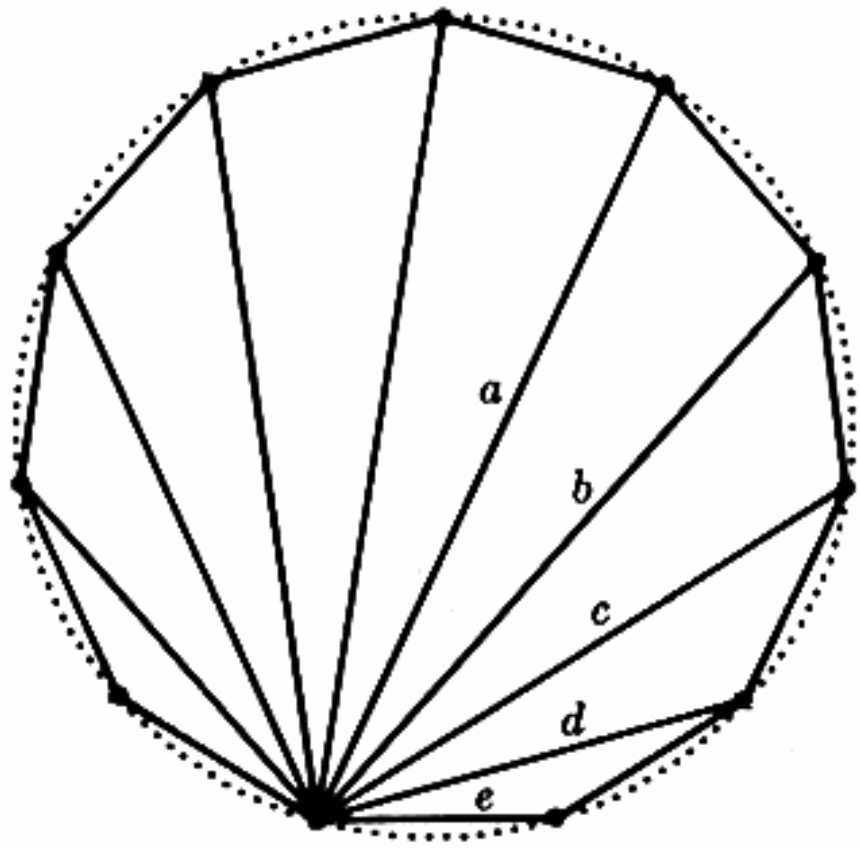

Fig. 73. Geometrical interpretation of cascade numbers.

Fortunately this abrupt change is not actually necessary; David E. Ferguson has found a way to distribute initial runs so that many of the operations during the first merge pass reduce to copying the contents of a tape. When such copying relations are bypassed (by simply changing "logical" tape unit numbers relative to the "physical" numbers as in Algorithm 5.4.2D), we obtain a relatively smooth transition from level to level, as shown in Fig. 74.

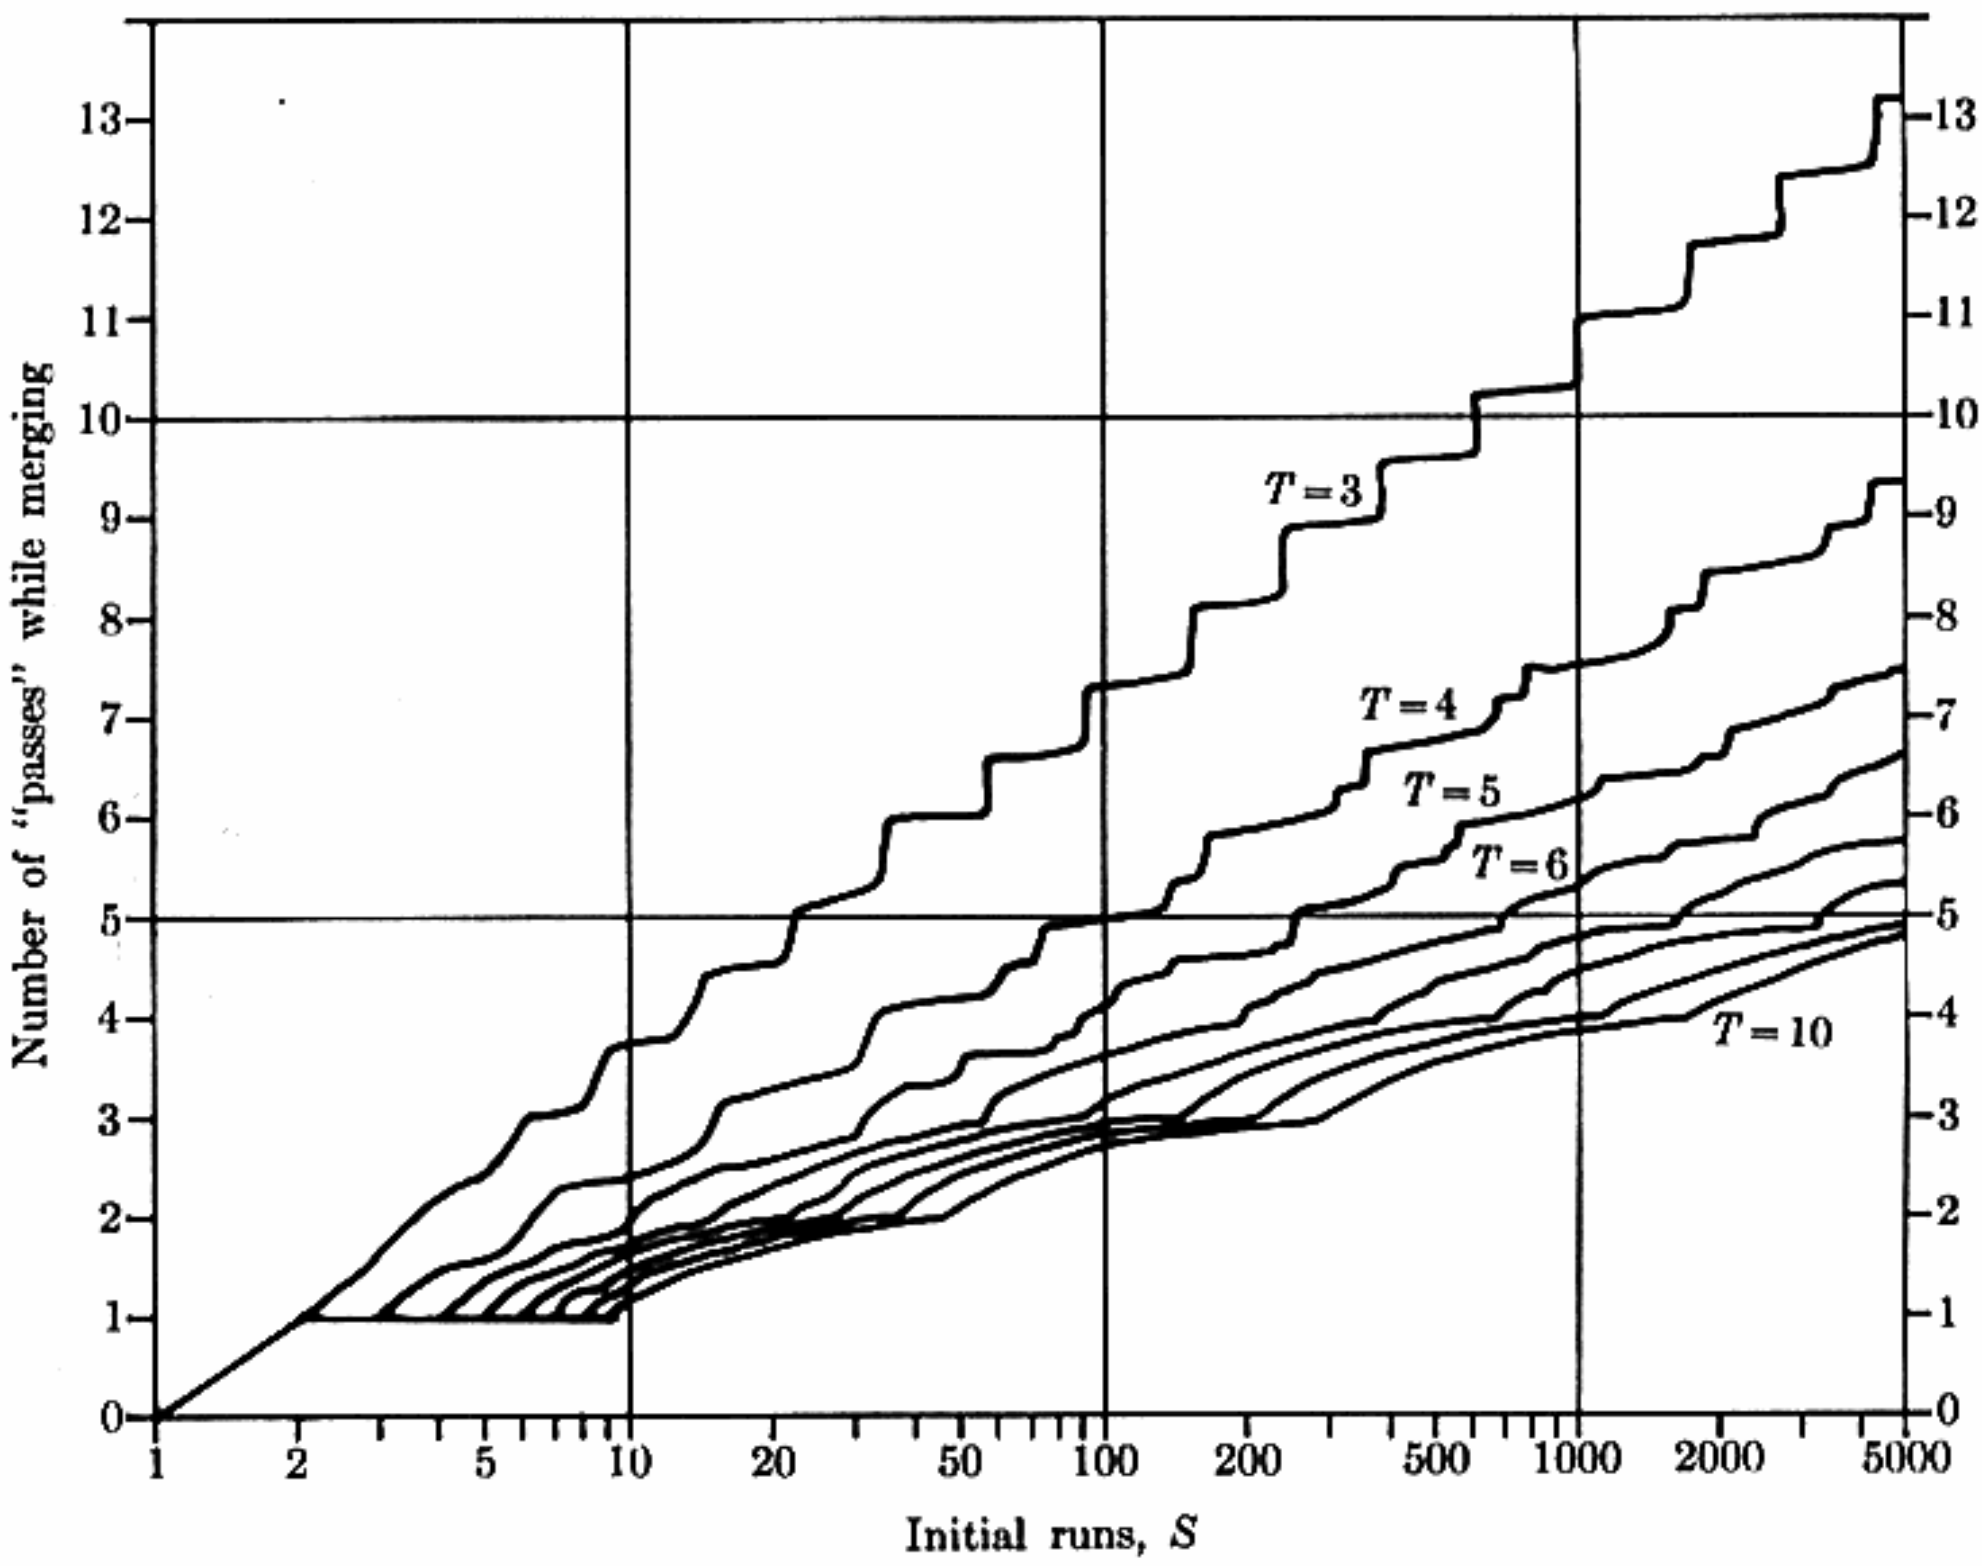

Fig. 74. Efficiency of cascade merge with the distribution of Algorithm D.

Suppose that (a, b, c, d, e) is a perfect distribution, where $a \geq b \geq c \geq d \geq e$. By redefining the correspondence between logical and physical tape units, we can imagine that the distribution is actually (e, d, c, b, a), with a runs on T5, b on T4, etc. The next perfect distribution is $(a + b + c + d + e, a + b + c + d, a + b + c, a + b, a)$; and if the input is exhausted before we reach this next level, let us assume that the tapes contain, respectively, $(D_1, D_2, D_3, D_4, D_5)$ dummy runs, where

$$D_1 \leq a + b + c + d, \qquad D_2 \leq a + b + c, \qquad D_3 \leq a + b,$$
$$D_4 \leq a, \qquad D_5 = 0; \qquad D_1 \geq D_2 \geq D_3 \geq D_4 \geq D_5. \tag{2}$$

We are free to imagine that the dummy runs appear in any convenient place on the tapes. The first merge pass is supposed to produce a runs by five-way merging, then b by four-way merging, etc., and our goal is to arrange the dummies so as to replace merging by copying. It is convenient to do the first merge pass as follows:

1. If $D_4 = a$, subtract a from each of D_1, D_2, D_3, D_4 and pretend that T5 is the result of the merge. If $D_4 < a$, merge a runs from tapes T1 through T5, using the minimum possible number of dummies on tapes T1 through T5 so that the new values of D_1, D_2, D_3, D_4 will satisfy

$$D_1 \leq b + c + d, \qquad D_2 \leq b + c, \qquad D_3 \leq b,$$
$$D_4 = 0; \qquad D_1 \geq D_2 \geq D_3 \geq D_4. \tag{3}$$

Thus, if D_2 was originally $\leq b + c$, we use no dummies from it at this step, while if $b + c < D_2 \leq a + b + c$ we use exactly $D_2 - b - c$ of them.

2. (This step is similar to step 1, but "shifted.") If $D_3 = b$, subtract b from each of D_1, D_2, D_3 and pretend that T4 is the result of the merge. If $D_3 < b$, merge b runs from tapes T1 through T4, reducing the number of dummies if necessary in order to make

$$D_1 \leq b + c, \qquad D_2 \leq b, \qquad D_3 = 0; \qquad D_1 \geq D_2 \geq D_3.$$

3. And so on.

Ferguson's method of distributing runs to tapes can be illustrated by considering the process of going from level 3 to level 4 in (1). Assume that "logical" tapes (T1, . . . , T5) contain respectively (5, 9, 12, 14, 15) runs, and that we want eventually to bring this up to (55, 50, 41, 29, 15). The procedure may be summarized as shown at the top of the facing page.

	Add to T1	Add to T2	Add to T3	Add to T4	Add to T5	"Amount saved"
Step (1, 1)	9	0	0	0	0	$15 + 14 + 12 + 5$
Step (2, 2)	3	12	0	0	0	$15 + 14 + 9 + 5$
Step (2, 1)	9	0	0	0	0	$15 + 14 + 5$
Step (3, 3)	2	2	14	0	0	$15 + 12 + 5$
Step (3, 2)	3	12	0	0	0	$15 + 9 + 5$
Step (3, 1)	9	0	0	0	0	$15 + 5$
Step (4, 4)	1	1	1	15	0	$14 + 5$
Step (4, 3)	2	2	14	0	0	$12 + 5$
Step (4, 2)	3	12	0	0	0	$9 + 5$
Step (4, 1)	9	0	0	0	0	5

We first put nine runs on T1, then (3, 12) on T1 and T2, etc. If the input becomes exhausted during, say, Step (3, 2), then the "amount saved" is $15 + 9 + 5$, meaning that the five-way merge of 15 runs, the two-way merge of 9 runs, and the one-way merge of 5 runs, are avoided by the dummy run assignment. In other words, $15 + 9 + 5$ of the runs present at level 3 are not processed during the first merge phase.

The following algorithm defines the process in detail.

Algorithm C (*Cascade merge sorting with special distribution*). This algorithm takes initial runs and disperses them to tapes, one run at a time, until the supply of initial runs is exhausted. Then it specifies how the tapes are to be merged, assuming that there are $T \geq 3$ available tape units, using at most $(T - 1)$-way merging and avoiding unnecessary one-way merging. Tape T may be used to hold the input, since it does not receive any initial runs. The following tables are maintained:

A[j], $1 \leq j \leq T$: The perfect cascade distribution we have most recently reached.

AA[j], $1 \leq j \leq T$: The perfect cascade distribution we are striving for.

D[j], $1 \leq j \leq T$: Number of dummy runs assumed to be present on logical tape unit number j.

M[j], $1 \leq j \leq T$: Maximum number of dummy runs desired on logical tape unit number j.

TAPE[j], $1 \leq j \leq T$: Number of the physical tape unit corresponding to logical tape unit number j.

C1. [Initialize.] Set A[k] $\leftarrow$ AA[k] $\leftarrow$ D[k] $\leftarrow 0$ for $2 \leq k \leq T$; and set A[1] $\leftarrow 0$, AA[1] $\leftarrow 1$, D[1] $\leftarrow 1$. Set TAPE[k] $\leftarrow k$ for $1 \leq k \leq T$. Finally set $i \leftarrow T - 2$, $j \leftarrow 1$, $k \leftarrow 1$, $l \leftarrow 0$, $m \leftarrow 1$, and go to step C5. (This maneuvering is one way to get everything started, by jumping right into the inner loop with appropriate settings of the control variables.)

C2. [Begin new level.] (We have just reached a perfect distribution, and since there is more input we must get ready for the next level.) Increase l by 1.

Set A[k] ← AA[k], for $1 \le k \le T$; then set AA[$T-k$] ← AA[$T-k+1$] + A[k], for $k = 1, 2, \ldots, T-1$ in this order. Set (TAPE[1], TAPE[2], ..., TAPE[$T-1$]) ← (TAPE[$T-1$], ..., TAPE[2], TAPE[1]), and set D[k] ← AA[$k+1$] for $1 \le k < T$. Finally set $i \leftarrow 1$.

C3. [Begin ith sublevel.] Set $j \leftarrow i$. (The variables i and j represent "Step (i, j)" in the example shown on page 293.)

C4. [Begin Step (i, j).] Set $k \leftarrow j$ and $m \leftarrow$ A[$T-j-1$]. If $m = 0$ and $i = j$, set $i \leftarrow T-2$ and return to C3; if $m = 0$ and $i \neq j$, return to C2. (Variable m represents the number of runs to be written onto TAPE[k]; $m = 0$ occurs only when $l = 1$.)

C5. [Input to TAPE[k].] Write one run on tape number TAPE[k], and decrease D[k] by 1. Then if the input is exhausted, rewind all the tapes and go to step C7.

C6. [Advance.] Decrease m by 1. If $m > 0$, return to C5. Otherwise decrease k by 1; if $k > 0$, set $m \leftarrow$ A[$T-j-1$] − A[$T-j$] and return to C5. Otherwise decrease j by 1; if $j > 0$, go to C4. Otherwise increase i by 1; if $i < T-1$, return to C3. Otherwise go to C2.

C7. [Prepare to merge.] (At this point the initial distribution is complete, and the A, AA, D, and TAPE tables describe the present states of the tapes.) Set M[k] ← AA[$k+1$] for $1 \le k < T$, and set FIRST ← 1. (Variable FIRST is nonzero only during the first merge pass.)

C8. [Cascade.] If $l = 0$, stop; sorting is complete and the output is on TAPE[1]. Otherwise, for $p = T-1, T-2, \ldots, 1$, in this order, do a p-way merge from TAPE[1], ..., TAPE[p] to TAPE[$p+1$] as follows:

If $p = 1$, simulate the one-way merge by simply rewinding TAPE[2], then interchanging TAPE[1] ↔ TAPE[2].
Otherwise if FIRST = 1 and D[$p-1$] = M[$p-1$], simulate the p-way merge by simply interchanging TAPE[p] ↔ TAPE[$p+1$], rewinding TAPE[p], and subtracting M[$p-1$] from each of D[1], ..., D[$p-1$], M[1], ..., M[$p-1$].
Otherwise, subtract M[$p-1$] from each of M[1], ..., M[$p-1$]. Then merge one run from each TAPE[j] such that $1 \le j \le p$ and D[j] ≤ M[j]; subtract one from each D[j] such that $1 \le j \le p$ and D[j] > M[j]; and put the output run on TAPE[$p+1$]. Continue doing this until TAPE[p] is empty. Then rewind TAPE[p] and TAPE[$p+1$].

C9. [Down a level.] Decrease l by 1, set FIRST ← 0, and set (TAPE[1], ..., TAPE[T]) ← (TAPE[T], ..., TAPE[1]). (At this point all D's and M's are zero and will remain so.) Return to C8. ∎

Steps C1–C6 of this algorithm do the distribution, and steps C7–C9 do the merging; the two parts are fairly independent of each other, and it would be possible to store M[k] and AA[$k+1$] in the same memory locations.

***Analysis of cascade merging.** The cascade merge is somewhat harder to analyze than polyphase, but the analysis is especially interesting because so

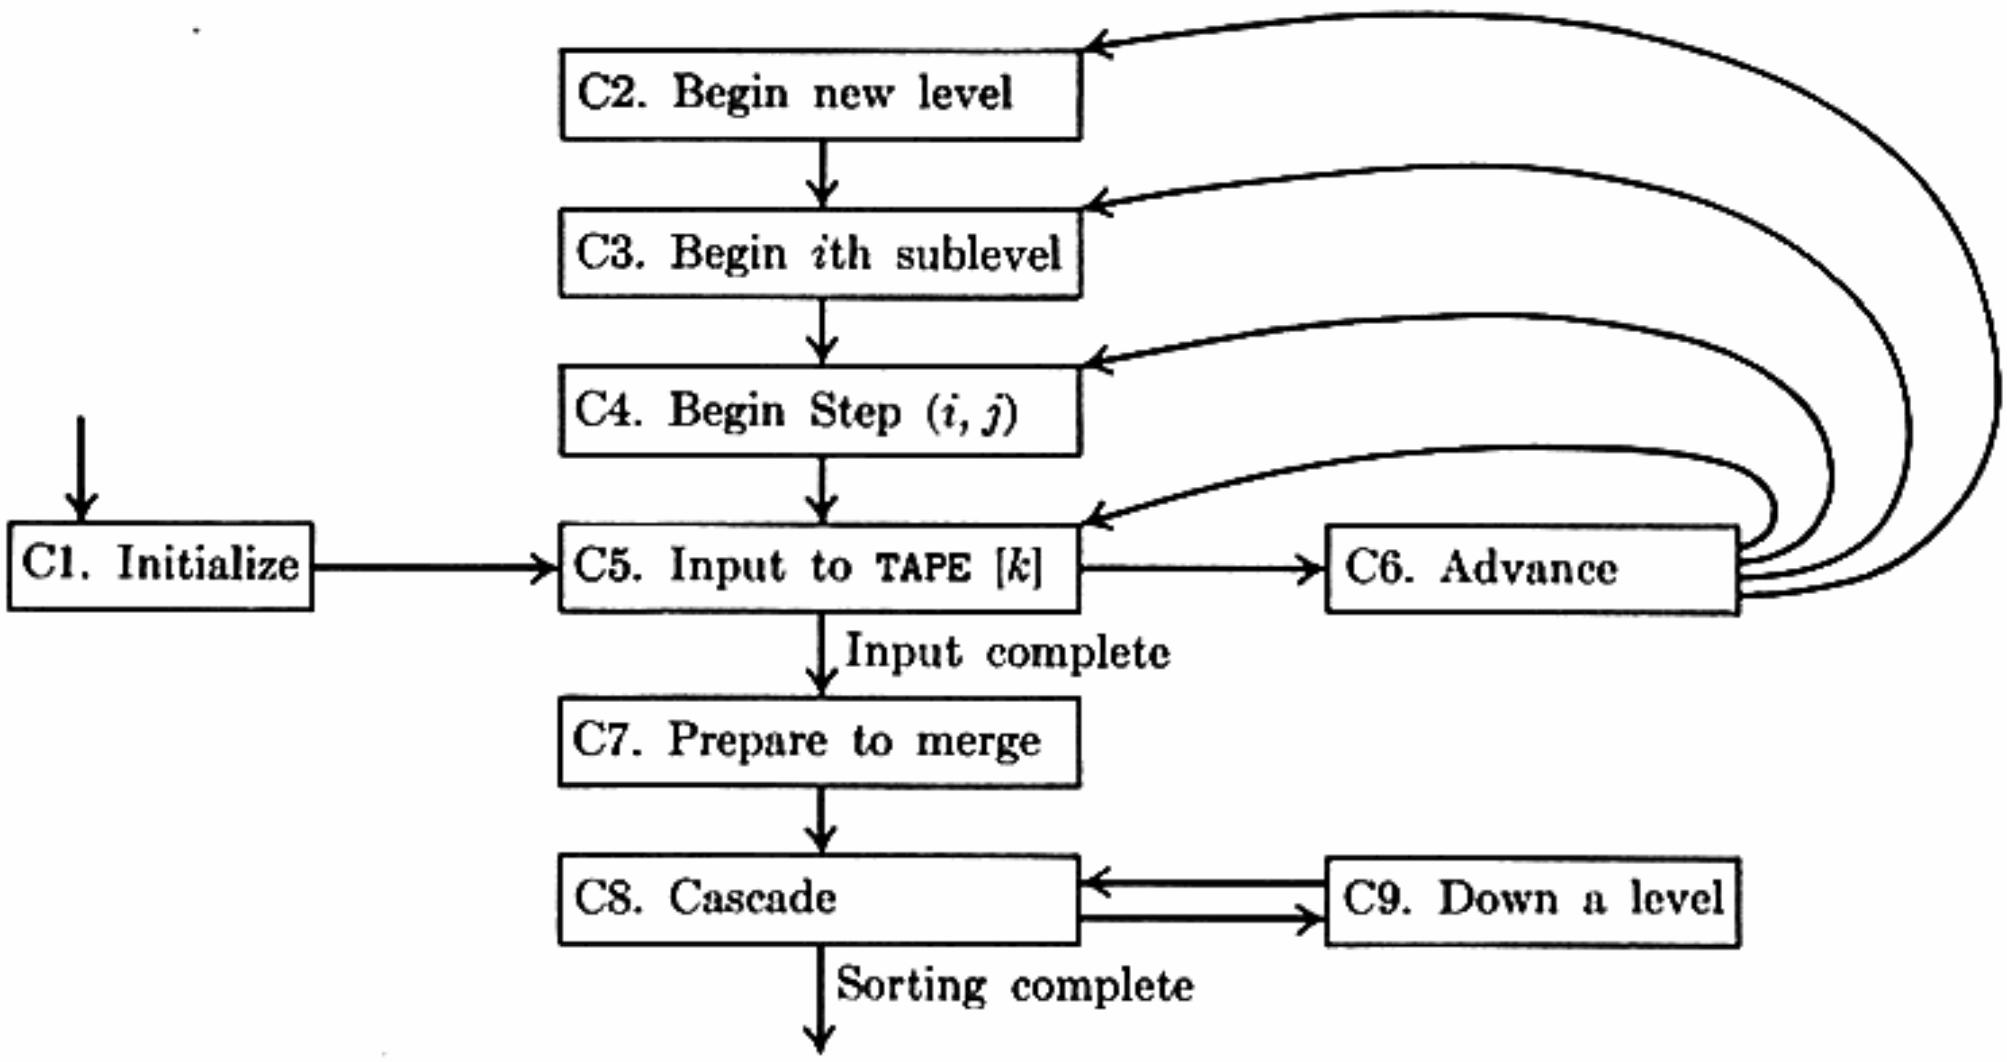

Fig. 75. The cascade merge, with special distribution.

many remarkable formulas are present. Readers who enjoy discrete mathematics are urged to study the cascade distribution for themselves, *before reading further*, since the numbers have so many extraordinary properties which are a pleasure to discover! We shall discuss here one of the many ways to approach the analysis, emphasizing the way in which the results might be discovered.

For convenience, let us consider the six-tape case, looking for formulas which generalize to all T. Relations (1) lead to the first basic pattern:

$$\begin{aligned}
a_n &= a_n && = \binom{0}{0} a_n, \\
b_n &= a_n - e_{n-1} = a_n - a_{n-2} && = \binom{1}{0} a_n - \binom{2}{2} a_{n-2}, \\
c_n &= b_n - d_{n-1} = b_n - a_{n-2} - b_{n-2} && = \binom{2}{0} a_n - \binom{3}{2} a_{n-2} + \binom{4}{4} a_{n-4}, \\
d_n &= c_n - e_{n-1} = c_n - a_{n-2} - b_{n-2} - c_{n-2} && = \binom{3}{0} a_n - \binom{4}{2} a_{n-2} + \binom{5}{4} a_{n-4} - \binom{6}{6} a_{n-6}, \\
e_n &= d_n - b_{n-1} = d_n - a_{n-2} - b_{n-2} - c_{n-2} - d_{n-2} && = \binom{4}{0} a_n - \binom{5}{2} a_{n-2} + \binom{6}{4} a_{n-4} - \binom{7}{6} a_{n-6} + \binom{8}{8} a_{n-8}.
\end{aligned} \tag{4}$$

Let $A(z) = \sum_{n \geq 0} a_n z^n, \ldots, E(z) = \sum_{n \geq 0} e_n z^n$, and define the polynomials

$$\begin{aligned}
q_m(z) &= \binom{m}{0} - \binom{m+1}{2} z^2 + \binom{m+2}{4} z^4 - \cdots \\
&= \sum_{k \geq 0} \binom{m+k}{2k} (-1)^k z^{2k} = \sum_{0 \leq k \leq m} \binom{2m-k}{k} (-1)^{m-k} z^{2m-2k}.
\end{aligned} \tag{5}$$

The result of (4) can be summarized by saying that $B(z) - q_1(z)A(z), \ldots, E(z) - q_4(z)A(z)$ reduce to finite sums corresponding to the boundary conditions, namely the values of $a_{-1}, a_{-2}, a_{-3}, \ldots$ which appear in (4) for small n

but not in $A(z)$. In order to supply appropriate boundary conditions, let us run the recurrence backwards to negative levels, through level -8:

n	a_n	b_n	c_n	d_n	e_n
0	1	0	0	0	0
−1	0	0	0	0	1
−2	1	−1	0	0	0
−3	0	0	0	−1	2
−4	2	−3	1	0	0
−5	0	0	1	−4	5
−6	5	−9	5	−1	0
−7	0	−1	6	−14	14
−8	14	−28	20	−7	1

(On seven tapes the table would be similar, with entries for odd n shifted right one column.) The sequence $a_0, a_{-2}, a_{-4}, \ldots = 1, 1, 2, 5, 14, \ldots$ is a dead giveaway for computer scientists, since it occurs in connection with so many recursive algorithms (e.g. exercise 2.2.1–4 and Eq. 2.3.4.4–13); we therefore conjecture that in the T-tape case

$$\begin{aligned} a_{-2n} &= \binom{2n}{n}\frac{1}{n+1}, \qquad \text{for} \qquad 0 \le n \le T-2; \\ a_{-2n-1} &= 0, \qquad\qquad\quad \text{for} \qquad 0 \le n \le T-3. \end{aligned} \tag{6}$$

To verify that this choice is correct, it suffices to show that (6) and (4) yield the correct results for levels 0 and 1. On level 1 this is obvious, and on level 0 we have to verify that

$$\binom{m}{0}a_0 - \binom{m+1}{2}a_{-2} + \binom{m+2}{4}a_{-4} - \binom{m+3}{6}a_{-6} + \cdots = \sum_{k\ge 0}\binom{m+k}{2k}\binom{2k}{k}\frac{(-1)^k}{k+1} = \delta_{m0} \tag{7}$$

for $0 \le m \le T-2$. Fortunately this sum can be evaluated by standard techniques (it is "Problem 2," one of the basic examples in the text of Section 1.2.6).

Now we can compute the coefficients of $B(z) - q_1(z)A(z)$, etc. For example, consider the coefficient of z^{2m} in $D(z) - q_3(z)A(z)$: it is

$$\begin{aligned} \sum_{k\ge 0}\binom{3+m+k}{2m+2k}(-1)^{m+k}a_{-2k} &= \sum_{k\ge 0}\binom{3+m+k}{2m+2k}\binom{2k}{k}\frac{(-1)^{m+k}}{k+1} \\ &= (-1)^m\left(\binom{2+m}{2m-1} - \binom{3+m}{2m}\right) \\ &= (-1)^{m+1}\binom{2+m}{2m}, \end{aligned}$$

by the result of "Problem 3" in Section 1.2.6. Therefore we have deduced that

$$\begin{aligned} A(z) &= q_0(z)A(z), \\ B(z) &= q_1(z)A(z) - q_0(z), \\ C(z) &= q_2(z)A(z) - q_1(z), \\ D(z) &= q_3(z)A(z) - q_2(z), \\ E(z) &= q_4(z)A(z) - q_3(z). \end{aligned} \tag{8}$$

Furthermore we have $e_{n+1} = a_n$; hence $zA(z) = E(z)$, and

$$A(z) = q_3(z)/(q_4(z) - z). \tag{9}$$

The generating functions have now been derived in terms of the q polynomials, and so we want to understand the q's better. Exercise 1.2.9–15 is useful in this regard, since it gives us a "closed form" which may be written

$$q_m(z) = \frac{((\sqrt{4 - z^2} + iz)/2)^{2m+1} + ((\sqrt{4 - z^2} - iz)/2)^{2m+1}}{\sqrt{4 - z^2}}. \tag{10}$$

Everything simplifies if we now set $z = 2 \sin \theta$:

$$\begin{aligned} q_m(2 \sin \theta) &= \frac{(\cos \theta + i \sin \theta)^{2m+1} + (\cos \theta - i \sin \theta)^{2m+1}}{2 \cos \theta} \\ &= \frac{\cos (2m + 1)\theta}{\cos \theta}. \end{aligned} \tag{11}$$

(This coincidence leads us to suspect that the polynomial $q_m(z)$ is well known in mathematics; and indeed, a glance at appropriate tables will show that $q_m(z)$ is essentially a Chebyshev polynomial of the second kind, namely $(-1)^m U_{2m}(z/2)$ in conventional notation.)

We can now determine the roots of the denominator in (9): $q_4(2 \sin \theta) = 2 \sin \theta$ reduces to

$$\cos 9\theta = 2 \sin \theta \cos \theta = \sin 2\theta.$$

We can obtain solutions to this relation whenever $\pm 9\theta = 2\theta + (2n - \frac{1}{2})\pi$; and all such θ yield roots of the denominator in (9) provided that $\cos \theta \neq 0$. (When $\cos \theta = 0$, $q_m(\pm 2) = \pm(2m + 1)$ is never equal to ± 2.) The following eight distinct roots are therefore obtained:

$$q_4(z) - z = 0 \qquad \text{when} \qquad z = 2 \sin \frac{-5}{14}\pi,\ 2 \sin \frac{-1}{14}\pi,\ 2 \sin \frac{3}{14}\pi;$$

$$2 \sin \frac{-7}{22}\pi,\ 2 \sin \frac{-3}{22}\pi,\ 2 \sin \frac{1}{22}\pi,\ 2 \sin \frac{5}{22}\pi,\ 2 \sin \frac{9}{22}\pi.$$

Since $q_4(z)$ is a polynomial of degree 8, this accounts for all the roots. The first three of these values make $q_3(z) = 0$, so $q_3(z)$ and $q_4(z) - z$ have a polynomial of degree three as a common factor. The other five roots govern the asymptotic behavior of the coefficients of $A(z)$, if we expand (9) in partial fractions.

Considering the general T-tape case, let $\theta_k = (4k + 1)\pi/(4T - 2)$. The generating function $A(z)$ for the T-tape cascade distribution numbers takes the form

$$\frac{4}{2T-1} \sum_{-T/2<k<\lfloor T/2 \rfloor} \frac{\cos^2 \theta_k}{1 - z/(2 \sin \theta_k)} \tag{12}$$

(see exercise 8); hence

$$a_n = \frac{4}{2T-1} \sum_{-T/2<k<\lfloor T/2 \rfloor} \cos^2 \theta_k \left(\frac{1}{2 \sin \theta_k}\right)^n. \tag{13}$$

Eqs. (8) now lead to the similar formulas

$$b_n = \frac{4}{2T-1} \sum_{-T/2<k<\lfloor T/2 \rfloor} \cos \theta_k \cos 3\theta_k \left(\frac{1}{2 \sin \theta_k}\right)^n,$$

$$c_n = \frac{4}{2T-1} \sum_{-T/2<k<\lfloor T/2 \rfloor} \cos \theta_k \cos 5\theta_k \left(\frac{1}{2 \sin \theta_k}\right)^n, \tag{14}$$

$$d_n = \frac{4}{2T-1} \sum_{-T/2<k<\lfloor T/2 \rfloor} \cos \theta_k \cos 7\theta_k \left(\frac{1}{2 \sin \theta_k}\right)^n,$$

and so on. Exercise 9 shows that these equations hold for all $n \geq 0$, not only for large n. In each sum the term for $k = 0$ dominates all the others, especially when n is reasonably large; therefore the "growth ratio" is

$$\frac{1}{2 \sin \theta_0} = \frac{2}{\pi} T - \frac{1}{\pi} + \frac{\pi}{48T} + O(T^{-2}). \tag{15}$$

Cascade sorting was first analyzed by W. C. Carter [*Proc. IFIP Congress* (1962), 62–66], who obtained numerical results for small T, and by David E. Ferguson [see *CACM* **7** (1964), 297], who discovered the first two terms in the asymptotic behavior (15) of the growth ratio. During the summer of 1964, R. W. Floyd discovered the explicit form $1/(2 \sin \theta_0)$ of the growth ratio, so that exact formulas could be used for all T. An intensive analysis of the cascade numbers was independently carried out by G. N. Raney [*Canadian J. Math.* **18** (1966), 332–349], who came across them in quite another way having nothing to do with sorting. Raney observed the "ratio of diagonals" principle of Fig. 73, and derived many other interesting properties of the numbers. Floyd and Raney used matrix manipulations in their proofs (cf. exercise 6).

Modifications of cascade sorting. If one more tape is added, it is possible to overlap nearly all of the rewind time during a cascade sort. For example, we can merge T1–T5 to T7, then T1–T4 to T6, then T1–T3 to T5 (which by now is rewound), then T1–T2 to T4, and the next pass can begin when the comparatively short data on T4 has been rewound. The efficiency of this process can be predicted from the above analysis of cascade. (See Section 5.4.6 for further information.)

A "compromise merge" scheme, which includes both polyphase and cascade as special cases, was suggested by D. E. Knuth in *CACM* **6** (1963), 585–587. Each phase consists of $(T-1)$-way, $(T-2)$-way, ..., P-way merges, where P is any fixed number between 1 and $T-1$. When $P = T-1$, this is polyphase, and when $P = 1$ it is "pure cascade"; when $P = 2$ it is cascade without copy phases. Analyses of this scheme have been made by C. E. Radke [*IBM Systems J.* **5** (1966), 226–247] and by W. H. Burge [*Proc. IFIP Congress* (1971), to appear]. Burge found the generating function $\sum T_n(x)z^n$ for each (P, T) compromise merge, generalizing Eq. 5.4.2–16; he showed that the best value of P, from the standpoint of least initial runs processed as a function of S as $S \to \infty$ (using a straightforward distribution scheme and ignoring rewind time), is respectively (2, 3, 3, 4, 4, 4, 3, 3, 4) for $T = (3, 4, 5, 6, 7, 8, 9, 10, 11)$. These values of P lean more towards cascade than polyphase as T increases; and it turns out that the compromise merge is never substantially better than cascade itself. On the other hand, with an optimum choice of levels and distribution of dummy runs, as described in Section 5.4.2, pure polyphase seems to be best of all the compromise merges; unfortunately the optimum distribution is comparatively difficult to implement.

Th. L. Johnsen [*BIT* **6** (1966), 129–143] has studied a combination of balanced and polyphase merging; a rewind-overlap variation of balanced merging has been proposed by M. A. Goetz [*Digital Computer User's Handbook*, ed. by M. Klerer and G. A. Korn (New York: McGraw-Hill, 1967), 1.311–1.312]; and many other hybrid schemes can be imagined.

EXERCISES

1. [*10*] Using Table 1, compare cascade merging with the "tape-splitting" version of polyphase described in Section 5.4.2. Which is better? (Ignore rewind time.)

▶ **2.** [*22*] Compare cascade sorting on three tapes, using Algorithm C, to polyphase sorting on three tapes, using Algorithm 5.4.2D. What similarities and differences are there?

3. [*20*] Prepare a table which shows what happens when 100 initial runs are sorted on six tapes using Algorithm C.

4. [*M20*] (G. N. Raney.) An "nth level cascade distribution" is a multiset defined as follows (in the case of six tapes): $\{1, 0, 0, 0, 0\}$ is a 0th level cascade distribution; and if $\{a, b, c, d, e\}$ is an nth level cascade distribution, $\{a + b + c + d + e, a + b +$

$c+d,\ a+b+c,\ a+b,\ a\}$ is an $(n+1)$st level cascade distribution. (Since a multiset is unordered, up to 5! different $(n+1)$st level distributions can be formed from a single nth level distribution.) (a) Prove that *any* multiset $\{a, b, c, d, e\}$ of relatively prime integers is an nth level cascade distribution, for some n. (b) Prove that the distribution defined for cascade sorting is *optimum*, in the sense that, if $\{a, b, c, d, e\}$ is any nth level distribution with $a \geq b \geq c \geq d \geq e$, we have $a \leq a_n$, $b \leq b_n$, $c \leq c_n$, $d \leq d_n$, $e \leq e_n$, where $\{a_n, b_n, c_n, d_n, e_n\}$ is the distribution defined in (1).

▶ **5.** [*20*] Prove that the cascade numbers defined in (1) satisfy the law

$$a_k a_{n-k} + b_k b_{n-k} + c_k c_{n-k} + d_k d_{n-k} + e_k e_{n-k} = a_n, \qquad \text{for} \qquad 0 \leq k \leq n.$$

[*Hint:* Interpret this relation by considering how many runs of various lengths are output during the kth pass of a complete cascade sort.]

6. [*M20*] Find a 5×5 matrix Q such that the first row of Q^n contains the six-tape cascade numbers $a_n\ b_n\ c_n\ d_n\ e_n$, for all $n \geq 0$.

7. [*M20*] Given that cascade merge is being applied to a perfect distribution of a_n initial runs, find a formula for the amount of processing saved when one-way merging is suppressed.

8. [*HM23*] Derive (12).

9. [*HM26*] Derive (14).

▶ **10.** [*M28*] Instead of using the pattern (4) to begin the study of the cascade numbers, start with the identities

$$\begin{aligned}
e_n &= a_{n-1} &&= \binom{1}{1} a_{n-1},\\
d_n &= 2a_{n-1} - e_{n-2} &&= \binom{2}{1} a_{n-1} - \binom{3}{3} a_{n-3},\\
c_n &= 3a_{n-1} - d_{n-2} - 2e_{n-2} &&= \binom{3}{1} a_{n-1} - \binom{4}{3} a_{n-3} + \binom{5}{5} a_{n-5},
\end{aligned}$$

etc. Letting

$$r_m(z) = \binom{m}{1} z - \binom{m+1}{3} z^3 + \binom{m+2}{5} z^5 - \cdots,$$

express $A(z)$, $B(z)$, etc. in terms of these r polynomials.

11. [*M38*] Let

$$f_m(z) = \sum_{0 \leq k \leq m} \binom{\lfloor (m+k)/2 \rfloor}{k} (-1)^{\lceil k/2 \rceil} z^k.$$

Prove that the generating function $A(z)$ for the T-tape cascade numbers is equal to $f_{T-3}(z)/f_{T-1}(z)$, where the numerator and denominator in this expression have no common factor.

12. [*M40*] Prove that Ferguson's distribution scheme is optimum, in the sense that no method of placing the dummy runs, satisfying (2), will cause less initial runs to be processed during the first pass, *provided* that the strategy of steps C7–C9 is used during this pass.

13. [*40*] The text suggests overlapping most of the rewind time, by adding an extra tape. Explore this idea. (For example, the text's scheme involves waiting for T4 to rewind; would it be better to omit T4 from the first merge phase of the next pass?)

5.4.4. Reading Tape Backwards

Many magnetic tape units have the ability to read tape in the opposite direction from which it was written. The merging patterns we have encountered so far always write information onto tape in the "forward" direction, then rewind the tape, read it forwards, and rewind again. (The tape files therefore behave as queues, operating in a first-in-first-out manner.) Backwards reading allows us to eliminate both of these rewind operations: We write the tape forwards and read it backwards. (In this case the files behave as stacks, since they are used in a last-in-first-out manner.)

The balanced, polyphase, and cascade merge patterns can all be adapted to backward reading. The main difference is that *merging reverses the order of the runs* when we read backward and write forward. If two runs are in ascending order on tape, we can merge them while reading backwards, but this produces descending order. The descending runs produced in this way will subsequently become ascending on the next pass; so the merging algorithms must be capable of dealing with runs in either order. A programmer confronted with read-backwards for the first time will often find himself standing on his head!

As an example of backwards reading, consider the process of merging 8 initial runs, using a *balanced* merge on four tapes. The operations can be summarized as follows:

	T1	T2	T3	T4	
Pass 1.	$A_1A_1A_1A_1$	$A_1A_1A_1A_1$	—	—	Initial distribution.
Pass 2.	—	—	D_2D_2	D_2D_2	Merge to T3 and T4.
Pass 3.	A_4	A_4	—	—	Merge to T1 and T2.
Pass 4.	—	—	D_8	—	Final merge to T3.

Here A_r stands for a run which appears on tape in ascending order, if the tape is read forwards as in our previous examples, having relative length r; D_r is the corresponding notation for a descending run of length r. During Pass 2 the ascending runs become descending: they appear to be descending in the input since we are reading backwards. They switch orientation again on Pass 3.

Note that the above process finishes with the result on tape T3, in *descending* order. If this is bad (depending on whether the output is to be read backwards, or to be dismounted and put away for future use), we could copy it to another tape, reversing the direction. A faster way would be to rewind T1 and T2 after Pass 3, producing A_8 during Pass 4. Still faster would be to start with eight *descending* runs during Pass 1, since this would interchange all the A's and D's. However, the balanced merge on 16 initial runs would

require the initial runs to be ascending; and since we usually don't know in advance how many initial runs will be formed, it is necessary to choose one consistent direction. Therefore the idea of rewinding after Pass 3 is probably best.

The *cascade* merge carries over in the same way. For example, consider sorting 14 initial runs on four tapes:

	T1	T2	T3	T4
Pass 1.	$A_1A_1A_1A_1A_1A_1$	$A_1A_1A_1A_1A_1$	$A_1A_1A_1$	—
Pass 2.	—	D_1	D_2D_2	$D_3D_3D_3$
Pass 3.	A_6	A_5	A_3	—
Pass 4.	—	—	—	D_{14}

Again, we could produce A_{14} instead of D_{14}, if we rewound T1, T2, T3 just before the final pass. Note that this is a "pure" cascade merge, in the sense that all of the one-way merges have explicitly been performed. If we had suppressed the copying operations, as in Algorithm 5.4.3D, we would have been confronted with the situation

$$A_1 \qquad — \qquad D_2D_2 \qquad D_3D_3D_3$$

after Pass 2, and it would have been impossible to continue with a three-way merge since we cannot merge runs that are in opposite directions! The operation of copying T1 to T2 could be avoided if we rewound T1 and proceeded to read it forward during the next merge phase (while reading T3 and T4 backwards). But it would then be necessary to rewind T1 again after merging, so this trick trades one copy for two rewinds.

Thus the distribution method of Algorithm 5.4.3C does not work as efficiently for read-backwards as for read-forwards; the amount of time required jumps rather sharply every time the number of initial runs passes a "perfect" cascade distribution number. Another dispersion technique can be used to give a smoother transition between perfect cascade distributions (see exercise 17).

Read-backward polyphase. At first glance (and even at second and third glance!), the polyphase merge scheme seems to be totally unfit for reading backwards. For example, suppose that we have 13 initial runs and three tapes:

	T1	T2	T3
Phase 1.	$A_1A_1A_1A_1A_1$	$A_1A_1A_1A_1A_1A_1A_1A_1$	—
Phase 2.	—	$A_1A_1A_1$	$D_2D_2D_2D_2D_2$.

Now we're stuck; we could rewind either T2 or T3 and then read it forwards, while reading the other tape backwards, but this would get things rather mixed up and we would have gained comparatively little by reading backwards.

An ingenious idea which saves the situation is to *alternate the direction of runs on each tape.* Then the merging can proceed in perfect synchronization:

Phase 1.	$A_1D_1A_1D_1A_1$	$D_1A_1D_1A_1D_1A_1D_1A_1$	—
Phase 2.	—	$D_1A_1D_1$	$D_2A_2D_2A_2D_2$
Phase 3.	$A_3D_3A_3$	—	D_2A_2
Phase 4.	A_3	D_5A_5	—
Phase 5.	—	D_5	D_8
Phase 6.	A_{13}	—	—

This principle was mentioned briefly by R. L. Gilstad in his original article on polyphase merging, and he described it more fully in *CACM* **6** (1963), 220–223.

The $ADA\cdots$ technique works properly for polyphase merging on *any* number of tapes; for we can show that the A's and D's will be properly synchronized at each phase, provided only that the initial distribution pass produces alternating A's and D's on each tape and that each tape ends with A (or each tape ends with D): Since the last run written on the output file during one phase is in the opposite direction from the last runs used from the input files, the next phase always finds its runs in the proper orientation. Furthermore we have seen in exercise 5.4.2–13 that most of the perfect Fibonacci distributions call for an *odd* number of runs on one tape (the eventual output tape), and an *even* number of runs on each other tape. If T1 is designated as the final output tape, we can therefore guarantee that all tapes end with an A run, if we start T1 with an A and let the remaining tapes start with a D. A distribution method analogous to Algorithm 5.4.2D can be used, modified so that the distributions on each level have T1 as the final output tape. (We skip levels $1, T+1, 2T+1, \ldots$, since they are the levels in which the initially empty tape is the final output tape.) For example, in the six-tape case, we can use the following distribution numbers in place of 5.4.2–(1):

Level	T1	T2	T3	T4	T5	Total	Final output will be on	
0	1	0	0	0	0	1	T1	
2	1	2	2	2	2	9	T1	
3	3	4	4	4	2	17	T1	
4	7	8	8	6	4	33	T1	(1)
5	15	16	14	12	8	65	T1	
6	31	30	28	24	16	129	T1	
8	61	120	116	108	92	497	T1	

Thus, T1 always get an odd number of runs, while T2 through T5 get the even numbers, in decreasing order for flexibility in dummy run assignment. Such a distribution has the advantage that the final output tape is known in advance, regardless of the number of initial runs that happen to be present. It turns

out (see exercise 3) that the output will always appear in *ascending* order on T1 when this scheme is used.

Another way to handle the distribution for read-backward polyphase has been suggested by D. T. Goodwin and J. L. Venn [*CACM* **7** (1964), 315]. We can distribute runs almost as in Algorithm 5.4.2D, beginning with a D run on each tape. When the input is exhausted, a dummy A run is imagined to be at the beginning of the unique "odd" tape, unless a distribution with all odd numbers has been reached. Other dummies are imagined at the end of the tapes, or grouped into pairs in the middle. The question of optimum placement of dummy runs is analyzed in exercise 5 below.

Optimum merge patterns. So far we have been discussing various patterns for merging on tape, without asking for "best possible" methods. It appears to be quite difficult to determine the optimal patterns, especially in the read-forward case where the interaction of rewind time with merge time is hard to handle. On the other hand, when merging is done by reading backwards and writing forwards, all rewinding is essentially eliminated, and it is possible to get a fairly good characterization of optimal merging patterns. Richard M. Karp has introduced some very interesting ways to attack this problem, and we shall conclude this section by discussing the theory he has developed.

In the first place we need a more satisfactory way to describe merging patterns, instead of the rather mysterious "tape contents" charts which have been used above. Karp has suggested two ways to do this, the *vector representation* and the *tree representation* of a merge pattern. Both forms of representation are useful in practice, so we shall describe them in turn.

The vector representation of a merge pattern consists of a sequence of "merge vectors" $y^{(m)} \ldots y^{(1)}y^{(0)}$, each of which has T components. The ith-last merge step is represented by $y^{(i)}$ in the following way:

$$y_j^{(i)} = \begin{cases} +1, & \text{if tape number } j \text{ is an input to the merge;} \\ 0, & \text{if tape number } j \text{ is not used in the merge;} \\ -1, & \text{if tape number } j \text{ gets the output of the merge.} \end{cases} \tag{2}$$

Thus, exactly one component of $y^{(i)}$ is -1, and the other components are 0's and 1's. The final vector $y^{(0)}$ is special; it is a unit vector, having 1 in position j if the final sorted output appears on unit j, and 0 elsewhere. These definitions imply that the vector sum

$$v^{(i)} = y^{(i)} + y^{(i-1)} + \cdots + y^{(0)} \tag{3}$$

represents the distribution of runs on tape just before the ith-last merge step, with $v_j^{(i)}$ runs on tape j. In particular, $v^{(m)}$ tells how many runs the initial distribution pass places on each tape.

The three merge patterns described in tabular form earlier in this section have the following vector representations:

Balanced ($T = 4$, $S = 8$)

$$
\begin{aligned}
v^{(7)} &= (\ 4,\ \ 4,\ \ 0,\ \ 0) \\
y^{(7)} &= (+1,\ +1,\ -1,\ \ 0) \\
y^{(6)} &= (+1,\ +1,\ \ 0,\ -1) \\
y^{(5)} &= (+1,\ +1,\ -1,\ \ 0) \\
y^{(4)} &= (+1,\ +1,\ \ 0,\ -1) \\
y^{(3)} &= (-1,\ \ 0,\ +1,\ +1) \\
y^{(2)} &= (\ 0,\ -1,\ +1,\ +1) \\
y^{(1)} &= (+1,\ +1,\ -1,\ \ 0) \\
y^{(0)} &= (\ 0,\ \ 0,\ \ 1,\ \ 0)
\end{aligned}
$$

Cascade ($T = 4$, $S = 14$)

$$
\begin{aligned}
v^{(10)} &= (\ 6,\ \ 5,\ \ 3,\ \ 0) \\
y^{(10)} &= (+1,\ +1,\ +1,\ -1) \\
y^{(9)} &= (+1,\ +1,\ +1,\ -1) \\
y^{(8)} &= (+1,\ +1,\ +1,\ -1) \\
y^{(7)} &= (+1,\ +1,\ -1,\ \ 0) \\
y^{(6)} &= (+1,\ +1,\ -1,\ \ 0) \\
y^{(5)} &= (+1,\ -1,\ \ 0,\ \ 0) \\
y^{(4)} &= (-1,\ +1,\ +1,\ +1) \\
y^{(3)} &= (\ 0,\ -1,\ +1,\ +1) \\
y^{(2)} &= (\ 0,\ \ 0,\ -1,\ +1) \\
y^{(1)} &= (+1,\ +1,\ +1,\ -1) \\
y^{(0)} &= (\ 0,\ \ 0,\ \ 0,\ \ 1)
\end{aligned}
$$

Polyphase ($T = 3$, $S = 13$)

$$
\begin{aligned}
v^{(12)} &= (\ 5,\ \ 8,\ \ 0) \\
y^{(12)} &= (+1,\ +1,\ -1) \\
y^{(11)} &= (+1,\ +1,\ -1) \\
y^{(10)} &= (+1,\ +1,\ -1) \\
y^{(9)} &= (+1,\ +1,\ -1) \\
y^{(8)} &= (+1,\ +1,\ -1) \\
y^{(7)} &= (-1,\ +1,\ +1) \\
y^{(6)} &= (-1,\ +1,\ +1) \\
y^{(5)} &= (-1,\ +1,\ +1) \\
y^{(4)} &= (+1,\ -1,\ +1) \\
y^{(3)} &= (+1,\ -1,\ +1) \\
y^{(2)} &= (+1,\ +1,\ -1) \\
y^{(1)} &= (-1,\ +1,\ +1) \\
y^{(0)} &= (\ 1,\ \ 0,\ \ 0)
\end{aligned}
$$

It may seem awkward to number these vectors backwards, with $y^{(m)}$ coming first and $y^{(0)}$ last, but this peculiar viewpoint turns out to be advantageous for developing the theory. One good way to search for an optimal method is to start with the sorted output and to imagine "unmerging" it to various tapes, then unmerging these, etc., considering the successive distributions $v^{(0)}$, $v^{(1)}$, $v^{(2)}, \ldots$ in the reverse order from which they actually occur during the sorting process. In fact that is essentially the approach we have taken already in our analysis of polyphase and cascade merging.

Every merge pattern obviously has a vector representation. Conversely, it is easy to see that the sequence of vectors $y^{(m)} \ldots y^{(1)}\, y^{(0)}$ corresponds to an actual merge pattern if and only if the following three conditions are satisfied:

i) $y^{(0)}$ is a unit vector.

ii) $y^{(i)}$ has exactly one component equal to -1, all other components equal to 0 or $+1$, for $m \geq i \geq 1$.

iii) All components of $y^{(i)} + \cdots + y^{(1)} + y^{(0)}$ are nonnegative, for $m \geq i \geq 1$.

The tree representation of a merge pattern gives another picture of the same information. We construct a tree with one external "leaf" node for each initial run, and one internal node for each run that is merged, in such a way that the descendants of each internal node are the runs from which it was fabricated. Each internal node is labeled with the step number on which the corresponding run was formed, numbering steps backwards as in the vector representation; furthermore, the line just above each node is labeled with the name of the tape on which that run appears. For example, the three merge patterns above have the tree representations depicted in Fig. 76, if we call the tapes A, B, C, D instead of T1, T2, T3, T4.

This representation displays many of the relevant properties of the merge pattern in convenient form; for example, if the run on level 0 of the tree (the

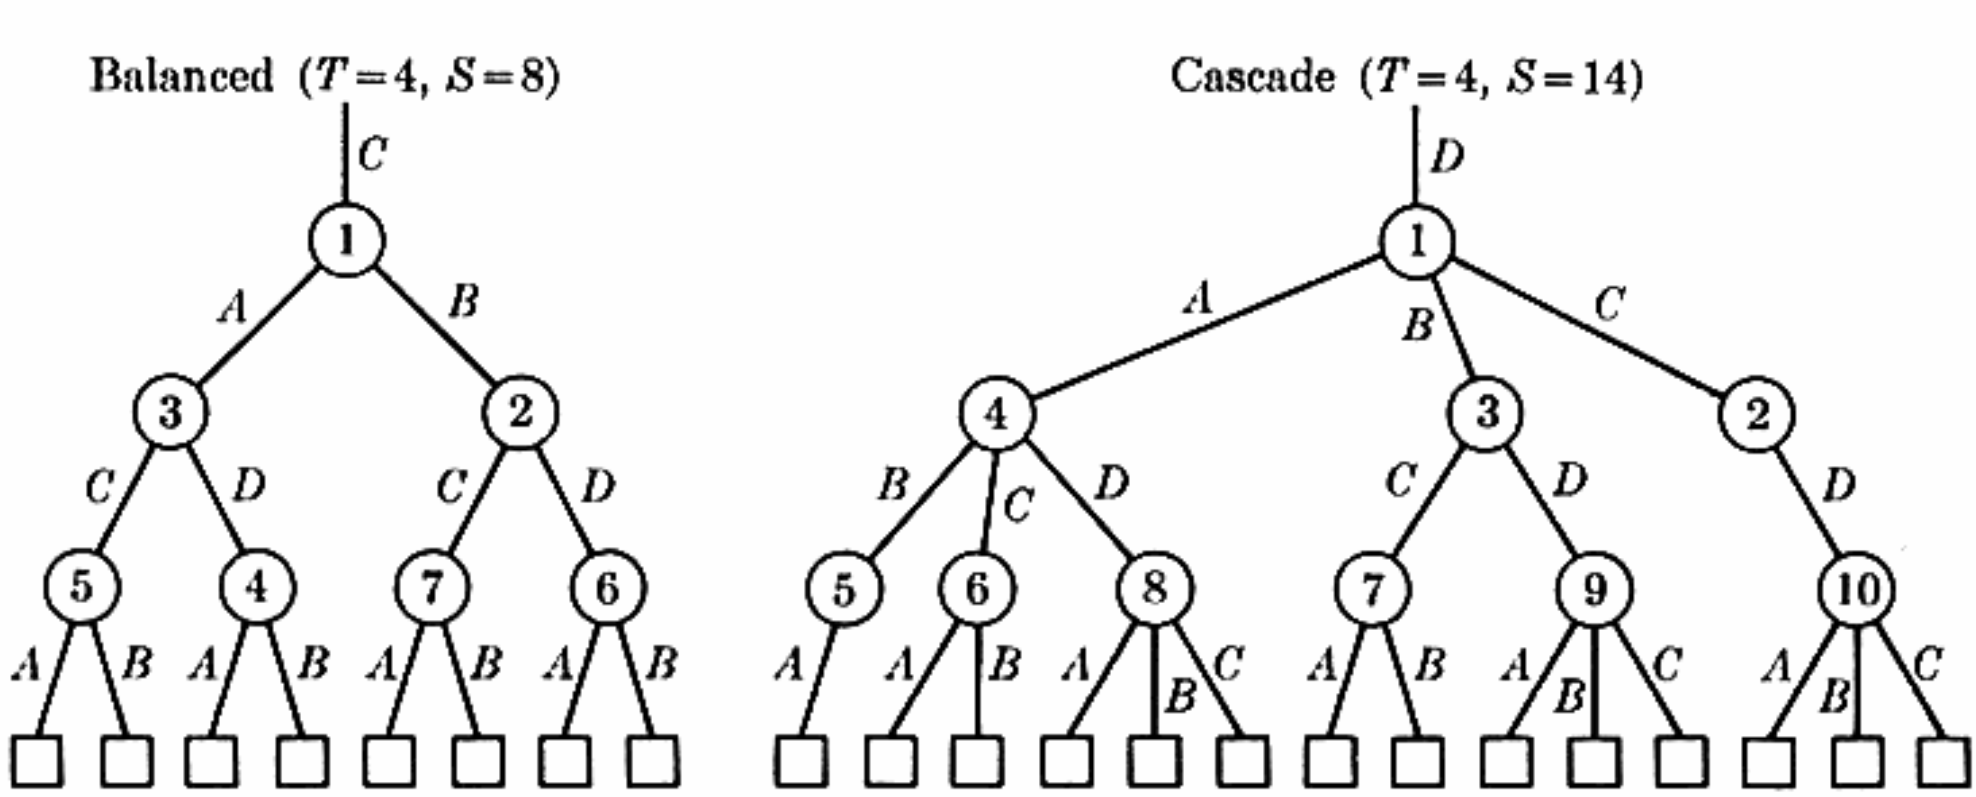

Fig. 76. Tree representations of three merge patterns.

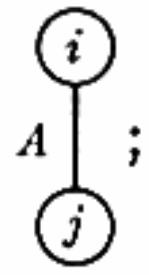
root) is to be ascending, then the runs on level 1 must be descending, those on level 2 must be ascending, etc.; an initial run is ascending if and only if the corresponding external node is on an even-numbered level. Furthermore the total number of initial runs processed during the merging (not including the initial distribution) is exactly equal to the *external path length* of the tree, since each initial run on level k is processed exactly k times.

Every merge pattern has a tree representation, but not every tree defines a merge pattern. A tree whose internal nodes have been labeled with the numbers 1 through m, and whose lines have been labeled with tape names, represents a valid read-backwards merge pattern if and only if

a) No two lines adjacent to the same internal node have the same tape name;

b) If $i > j$, and if A is a tape name, the tree does not contain the configuration



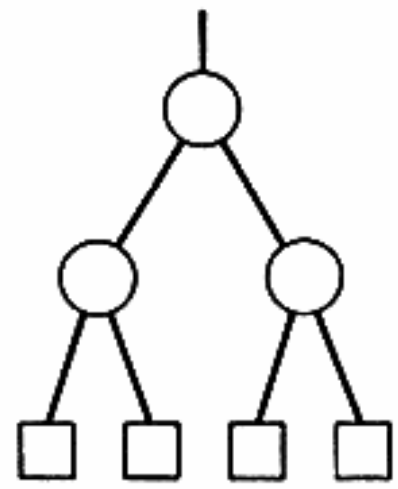
;

c) If $i < j < k < l$, and if A is a tape name, the tree does not contain

both  and  or both  and  . (4)

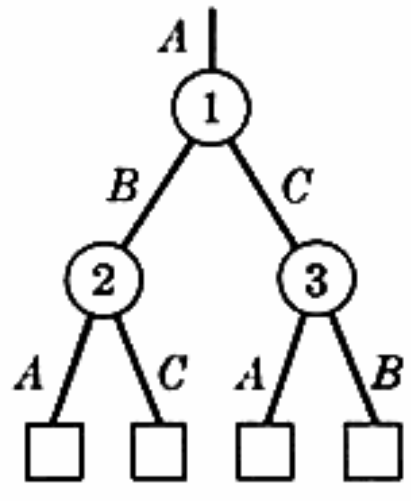
Condition (a) is self-evident, since the input and output tapes in a merge must be distinct; similarly, (b) is obvious. The "no crossover" condition (c) mirrors the last-in-first-out restriction which characterizes read-backwards operations on tape: A run formed at step k must be removed before a run formed previously on that same tape; hence the configurations in (4) are impossible. It is not difficult to verify that any labeled tree satisfying conditions (a), (b), (c) does indeed correspond to a read-backwards merge pattern.

If there are T tape units, condition (a) implies that the degree of each internal node is $T - 1$ or less. It is not always possible to attach suitable labels to all such trees; for example, when $T = 3$ there is no merge pattern whose tree has the shape



(5)

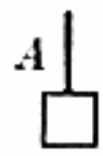
This shape would lead to an optimal merge pattern if we could attach step numbers and tape names in a suitable way, since it is the only way to achieve the minimum external path length in a tree having four external nodes. But there is essentially only one way to do the labeling according to conditions (a) and (b), because of the symmetries of the diagram, namely,



(6)

and this violates condition (c). A shape which *can* be labeled, according to the above conditions, using T or less tape names, is called a *T-lifo* tree.

Another way to characterize all labeled trees that can arise from merge patterns is to consider how all such trees can be "grown." Start with some tape name, say A, and with the seedling tree

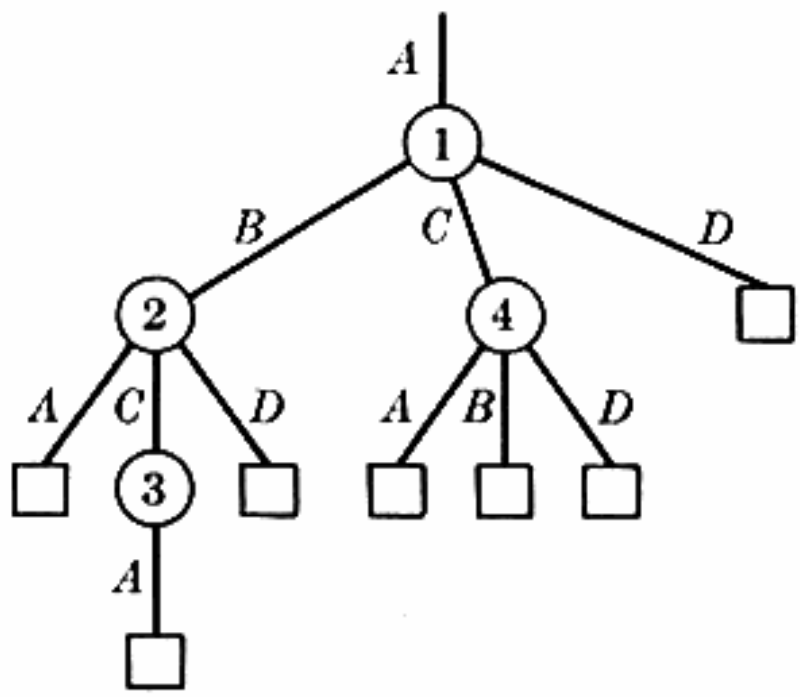


Step number i in the tree's growth consists of choosing distinct tape names $B, B_1, B_2, \ldots, B_k$, and changing the *most recently formed* external node corresponding to B

from 
to 
(7)

This "last formed, first grown on" rule explains exactly how the tree representation can be constructed directly from the vector representation.

The determination of strictly optimum T-tape merge patterns, i.e. of trees which have the exact minimum path length over all T-lifo trees with a given number of external nodes, seems to be quite difficult. For example, the following nonobvious pattern turns out to be an optimum way to merge seven initial runs on four tapes, reading backwards:



(8)

A one-way merge is actually necessary to achieve the optimum! (See exercise 8.) On the other hand, it is not so difficult to give constructions that are *asymptotically* optimal, for any fixed T.

Let $K_T(n)$ be the minimum external path length achievable in a T-lifo tree with n external nodes. From the theory developed in Section 2.3.4.5, it is not difficult to prove that

$$K_T(n) \geq nq - \lfloor ((T-1)^q - n)/(T-2) \rfloor, \qquad q = \lceil \log_{T-1} n \rceil, \tag{9}$$

since this is the minimum external path length of *any* tree with n external nodes and all nodes of degree $< T$. At the present time comparatively few values of $K_T(n)$ are known exactly. Here are some upper bounds which are probably exact:

$n =$	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
$K_3(n) \leq$	0	2	5	9	12	16	21	25	30	34	39	45	50	56	61
$K_4(n) \leq$	0	2	3	6	8	11	14	17	20	24	27	31	33	37	40

(10)

Karp has discovered that *any* tree whose internal nodes have degrees $< T$ is *almost* T-lifo, in the sense that it can be made T-lifo by changing some of the external nodes to one-way merges. In fact, the construction of a suitable labeling is fairly simple. Let A be a particular tape name, and proceed as follows:

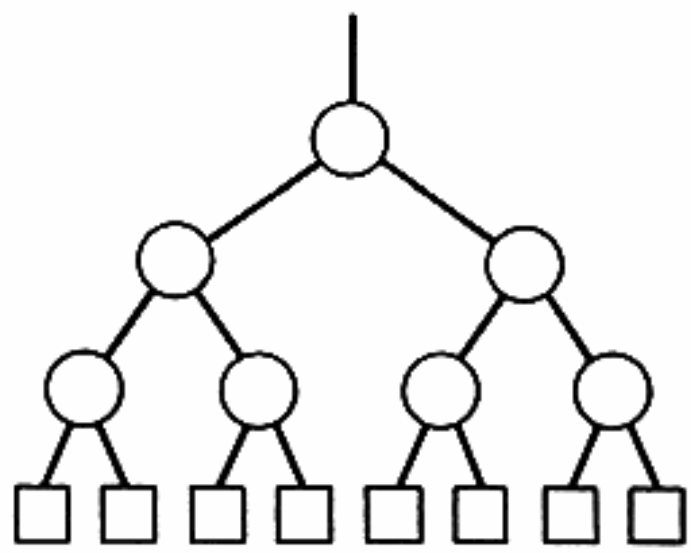
Step 1. Attach tape names to the lines of the tree diagram, in any manner consistent with condition (a) above, provided that the special name A is used only in the leftmost line of a branch.

Step 2. Replace each external node of the form

whenever $B \neq A$.

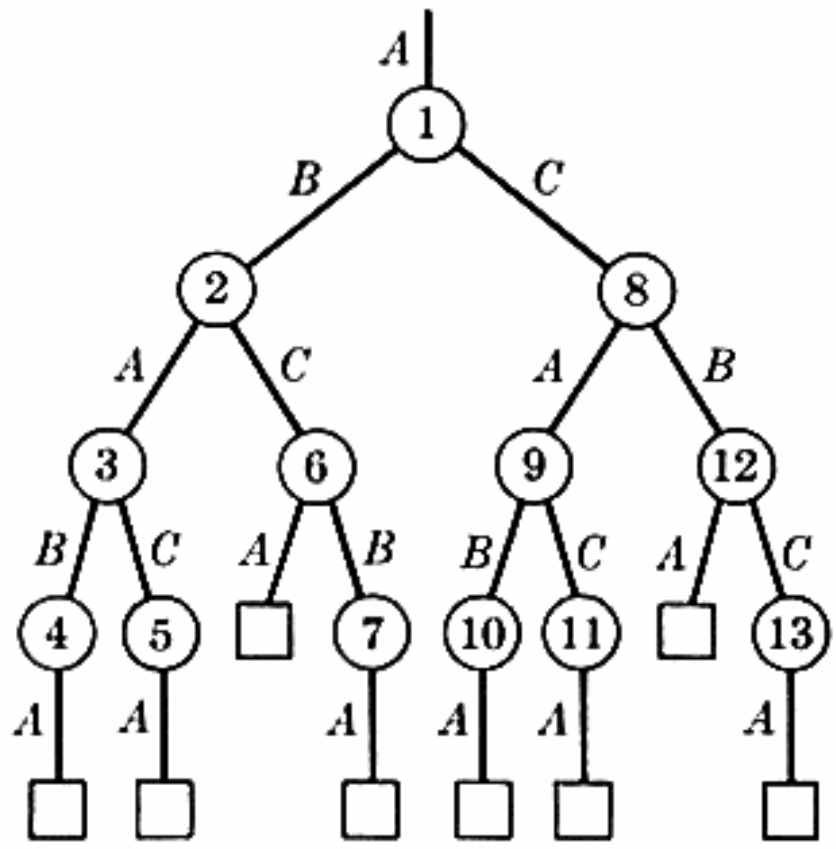
Step 3. Number the internal nodes of the tree in *preorder*. The result will be a labeling satisfying conditions (a), (b), (c).

For example, if we start with the tree



(11)

and three tapes, this procedure might assign labels as follows:



(12)

It is not difficult to verify that Karp's construction satisfies the "last formed, first grown on" discipline, because of the nature of preorder (see exercise 12).

Note that the result of this construction is a merge pattern for which all of the initial runs appear on tape A. This suggests the following distribution and sorting scheme which we may call the *preorder merge:*

P1. Distribute initial runs onto tape A until the input is exhausted. Let S be the total number of initial runs.

P2. Carry out the above construction, using a minimum-path-length $(T - 1)$-ary tree with S external nodes, obtaining a T-lifo tree whose external path length is within S of the lower bound in (9).

P3. Merge the runs according to this pattern. ▮

This scheme will produce its output on any desired tape. But *it has one serious flaw*—does the reader see what will go wrong? The problem is that the merge pattern requires some of the runs initially on tape A to be ascending, and some to be descending, depending on whether the corresponding external node appears on an odd or an even level. This problem can be resolved without knowing S in advance, by copying runs which should be descending onto an auxiliary tape or tapes, just before they are needed. Then the total amount of processing, in terms of initial run lengths, comes to

$$S \log_{T-1} S + O(S). \tag{13}$$

Thus the preorder merge is definitely better than polyphase or cascade, as $S \to \infty$; indeed, it is asymptotically *optimum*, since (9) shows that $S \log_{T-1} S + O(S)$ is the best we could ever hope to achieve on T tapes. On the other hand, for the comparatively small values of S which usually arise in practice, the preorder merge is rather inefficient; polyphase or cascade methods are simpler and faster, when S is reasonably small. Perhaps it will be possible to invent a simple distribution-and-merge scheme that is competitive with polyphase and cascade for small S, and which is asymptotically optimum for large S.

The second set of exercises below shows how Karp has formulated the question of *read-forward* merging in a similar way. The theory turns out to be

rather more complicated in this case, although some very interesting results have been discovered.

EXERCISES—First Set

1. [*17*] It is often convenient, during read-forward merging, to mark the end of each run on tape by including an artificial "sentinel" record whose key is $+\infty$. How should this practice be modified, when reading backwards?

2. [*20*] Will the columns of an array like (1) always be nondecreasing, or is there a chance that we will have to "subtract" runs from some tape as we go from one level to the next?

▶ **3.** [*20*] Prove that the polyphase distribution method described in connection with (1) will always produce an A run on tape T1 when sorting is complete, if T1 originally starts with $ADA\cdots$ and T2 through T5 start with $DAD\cdots$.

4. [*22*] Is it a good idea to do read-backward polyphase merging after distributing all runs in *ascending* order, imagining all the "D" positions to be initially filled with dummies?

▶ **5.** [*23*] What formulas for the strings of merge numbers replace (8), (9), (10), and (11) of Section 5.4.2, when read-backward polyphase merging is used? Show the merge numbers for the fifth level distribution on six tapes, by drawing a diagram like Fig. 71(a).

6. [*07*] What is the vector representation of the merge pattern whose tree representation is (8)?

7. [*16*] Draw the tree representation for the read-backwards merge pattern defined by the following sequence of vectors:

$$
\begin{aligned}
v^{(33)} &= (\ 20,\ \ 9,\ \ 5) & y^{(22)} &= (+1,-1,+1) & y^{(10)} &= (+1,+1,-1)\\
y^{(33)} &= (+1,-1,+1) & y^{(21)} &= (-1,+1,+1) & y^{(9)} &= (+1,-1,+1)\\
y^{(32)} &= (+1,+1,-1) & y^{(20)} &= (+1,+1,-1) & y^{(8)} &= (+1,+1,-1)\\
y^{(31)} &= (+1,+1,-1) & y^{(19)} &= (-1,+1,+1) & y^{(7)} &= (+1,+1,-1)\\
y^{(30)} &= (+1,+1,-1) & y^{(18)} &= (+1,+1,-1) & y^{(6)} &= (+1,+1,-1)\\
y^{(29)} &= (+1,-1,+1) & y^{(17)} &= (+1,+1,-1) & y^{(5)} &= (-1,+1,+1)\\
y^{(28)} &= (-1,+1,+1) & y^{(16)} &= (+1,+1,-1) & y^{(4)} &= (+1,-1,+1)\\
y^{(27)} &= (+1,-1,+1) & y^{(15)} &= (+1,+1,-1) & y^{(3)} &= (-1,+1,+1)\\
y^{(26)} &= (+1,-1,+1) & y^{(14)} &= (+1,-1,+1) & y^{(2)} &= (+1,-1,+1)\\
y^{(25)} &= (+1,+1,-1) & y^{(13)} &= (+1,-1,+1) & y^{(1)} &= (-1,+1,+1)\\
y^{(24)} &= (+1,-1,+1) & y^{(12)} &= (-1,+1,+1) & y^{(0)} &= (\ 1,\ \ 0,\ \ 0)\\
y^{(23)} &= (+1,-1,+1) & y^{(11)} &= (+1,+1,-1)
\end{aligned}
$$

8. [*23*] Prove that (8) is an optimum way to merge, reading backwards, when $S = 7$ and $T = 4$, and that all methods which avoid one-way merging are inferior.

9. [*M22*] Prove the lower bound (9).

10. [*41*] Prepare a table of the exact values of $K_T(n)$, using a computer.

▸**11.** [*20*] True or false: Any read-backwards merge pattern that uses nothing but $(T-1)$-way merging must always have the runs alternating $ADAD\cdots$ on each tape; it will not work if two adjacent runs appear in the same order.

12. [*22*] Prove that Karp's preorder construction always yields a labeled tree satisfying conditions (a), (b), and (c).

13. [*16*] Make (12) more efficient, by removing as many of the one-way merges as possible so that preorder still gives a valid labeling of the internal nodes.

14. [*40*] Devise an algorithm which carries out the preorder merge without explicitly representing the tree in steps P2 and P3, using only $O(\log S)$ words of memory to control the merging pattern.

15. [*M39*] Karp's preorder construction in the text yields trees with one-way merges at several terminal nodes. Prove that when $T = 3$ it is possible to contruct asymptotically optimal 3-lifo trees in which two-way merging is used throughout.

In other words, let $\hat{K}_T(n)$ be the minimum external path length over all T-lifo trees with n external nodes, such that every internal node has degree $T-1$. Prove that $\hat{K}_3(n) = n\log_2 n + O(n)$.

16. [*M46*] In the notation of exercise 15, is $\hat{K}_T(n) = n\log_{T-1} n + O(n)$ for *all* $T \geq 3$, when $n \equiv 1$ (modulo $T-1$)?

▸**17.** [*28*] (Richard D. Pratt.) To achieve ascending order in a read-backward cascade merge, we could insist on an *even* number of merging passes; this suggests a technique of initial distribution which is somewhat different from Algorithm 5.4.3C. (a) Change 5.4.3–1 so that it shows only the perfect distributions which require an even number of merging passes. (b) Design an initial distribution scheme which interpolates between these perfect distributions. (Thus, if the number of initial runs falls between perfect distributions, it is desirable to merge some, but not all, of the runs twice, in order to reach a perfect distribution.)

18. [*46*] Suppose that T tape units are available, for some $T \geq 3$, and that T1 contains N records while the remaining tapes are empty. Is it possible to reverse the order of the records on T1 in less than $O(N \log N)$ steps, *without* reading backwards? (The operation is, of course, trivial if backwards reading is allowed.) Cf. exercise 5.2.5–14 for a class of such algorithms that *do* require order $N \log N$ steps.

EXERCISES—Second Set

The following exercises develop the theory of tape merging on read-forward tapes; in this case each tape acts as a queue instead of as a stack. A merge pattern can be represented as a sequence of vectors $y^{(m)} \ldots y^{(1)}y^{(0)}$ exactly as in the text, but when we convert the vector representation to a tree representation we change "last formed, first grown on" to "*first* formed, first grown on." Thus the invalid configurations (4) would be changed to

both  and  or both  and  . (4′)

A tree which can be labeled so as to represent a read-forward merge on T tapes is called T-fifo, analogous to the term "T-lifo" in the read-backwards case.

When tapes can be read backwards, they make very good stacks. But unfortunately they don't make very good general purpose queues. If we randomly write and read, in a first-in-first-out manner, we waste a lot of time moving from one part of the tape to another. Even worse, we will soon run off the end of the tape! We run into the same problem as the queue overrunning memory in 2.2.2–(4) and (5), but the solution in 2.2.2–(6) and (7) doesn't apply to tapes since they aren't circular loops. Therefore we shall call a tree *strongly T-fifo* if it can be labeled so that the corresponding merge pattern makes each tape follow the special queue discipline "write, rewind, read all, rewind; write, rewind, read all, rewind; etc."

▶ **19.** [*22*] (R. M. Karp.) Find a binary tree which is not 3-fifo.

▶ **20.** [*22*] Formulate the condition "strongly T-fifo" in terms of a fairly simple rule about invalid configurations of tape labels, analogous to (4′).

21. [*18*] Draw the tree representation for the read-forwards merge pattern defined by the vectors in exercise 7. Is this tree strongly 3-fifo?

22. [*28*] (R. M. Karp.) Show that the tree representations for polyphase and cascade merging, with perfect distributions, are exactly the same for both the read-backwards and the read-forwards case, except for the numbers which label the internal nodes. Find a larger class of vector representations of merging patterns for which this is true.

23. [*24*] (R. M. Karp.) Let us say that a segment $y^{(q)} \ldots y^{(r)}$ of a merge pattern is a *stage* if no output tape is subsequently used as an input tape, i.e. if there do not exist i, j, k with $q \geq i > k \geq r$ and $y_j^{(i)} = -1$ and $y_j^{(k)} = +1$. The purpose of this exercise is to prove that *cascade merge minimizes the number of stages*, over all merge patterns having the same number of tapes and initial runs.

It is convenient to define some notation. Let us write $v \rightarrow w$ if v and w are T-vectors such that there is a merge pattern which reduces w to v in its first stage. (Thus there is a merge pattern $y^{(m)} \ldots y^{(0)}$ such that $y^{(m)} \ldots y^{(l+1)}$ is a stage, $w = y^{(m)} + \cdots + y^{(0)}$, and $v = y^{(l)} + \cdots + y^{(0)}$.) Let us write $v \preceq w$ if v and w are T-vectors such that the sum of the largest k elements of v is $\leq$ the sum of the largest k elements of w, for $1 \leq k \leq T$. Thus, for example, $(2, 1, 2, 2, 2, 1) \preceq (1, 2, 3, 0, 3, 1)$, since $2 \leq 3$, $2+2 \leq 3+3, \ldots, 2+2+2+2+1+1 \leq 3+3+2+1+1+0$. Finally, if $v = (v_1, \ldots, v_T)$, let $C(v) = (s_T, s_{T-2}, s_{T-3}, \ldots, s_1, 0)$, where s_k is the sum of the largest k elements of v.

(a) Prove that $v \rightarrow C(v)$. (b) Prove that $v \preceq w$ implies $C(v) \preceq C(w)$. (c) Assuming the result of exercise 24, prove that cascade merge minimizes the number of stages.

24. [*M35*] In the notation of exercise 23, prove that $v \rightarrow w$ implies $w \preceq C(v)$.

25. [*M36*] (R. M. Karp.) Let us say that a segment $y^{(q)} \ldots y^{(r)}$ of a merge pattern is a *phase* if no tape is used both for input and for output, i.e., if there do not exist i, j, k with $q \geq i$, $k \geq r$ and $y_j^{(i)} = +1$ and $y_j^{(k)} = -1$. The purpose of this exercise is to investigate merge patterns that minimize the number of phases. We shall write $v \Rightarrow w$ if w can be reduced to v in one phase (cf. the similar notation introduced in exercise 23), and we let $D_k(v) = (s_k + t_{k+1}, s_k + t_{k+2}, \ldots, s_k + t_T, 0, \ldots, 0)$, where t_j denotes the jth largest element of v and $s_k = t_1 + \cdots + t_k$. (a) Prove that $v \Rightarrow D_k(v)$ for $1 \leq k < T$. (b) Prove that $v \preceq w$ implies $D_k(v) \preceq D_k(w)$, for $1 \leq k < T$. (c) Prove that $v \Rightarrow w$ implies $w \preceq D_k(v)$, for some k, $1 \leq k < T$. (d) Consequently,

a merge pattern which sorts the maximum number of initial runs on T tapes in q phases can be represented by a sequence of integers $k_1\, k_2 \ldots k_q$, such that the initial distribution is $D_{k_q}(\ldots(D_{k_2}(D_{k_1}(u)))\ldots)$, where $u = (1, 0, \ldots, 0)$. This minimum-phase strategy has a strongly T-fifo representation, and it also belongs to the class of patterns in exercise 22. When $T = 3$ it is the *polyphase* merge, and for $T = 4, 5, 6, 7$ it is a variation of the *balanced* merge.

26. [*M46*] (R. M. Karp.) Is the optimum sequence $k_1\, k_2 \ldots k_q$ mentioned in exercise 25 always equal to $1\lceil T/2\rceil\lfloor T/2\rfloor\lceil T/2\rceil\lfloor T/2\rfloor\ldots$, for all $T \geq 4$ and all sufficiently large q?

5.4.5. The Oscillating Sort

A somewhat different approach to merge sorting was introduced by Sheldon Sobel in *JACM* **9** (1962), 372–375. Instead of starting with a distribution pass where all the initial runs are dispersed to tapes, he proposed an algorithm which oscillates back and forth between distribution and merging, so that much of the sorting takes place before the input has been completely examined.

Suppose, for example, that there are five tapes available for merging. Sobel's method would sort 16 initial runs as follows:

	Operation	T1	T2	T3	T4	T5	"Cost"
Phase 1.	Distribute	A_1	A_1	A_1	A_1	—	4
Phase 2.	Merge	—	—	—	—	D_4	4
Phase 3.	Distribute	—	A_1	A_1	A_1	D_4A_1	4
Phase 4.	Merge	D_4	—	—	—	D_4	4
Phase 5.	Distribute	D_4A_1	—	A_1	A_1	D_4A_1	4
Phase 6.	Merge	D_4	D_4	—	—	D_4	4
Phase 7.	Distribute	D_4A_1	D_4A_1	—	A_1	D_4A_1	4
Phase 8.	Merge	D_4	D_4	D_4	—	D_4	4
Phase 9.	Merge	—	—	—	A_{16}	—	16

Here as in Section 5.4.4 we use A_r and D_r to stand respectively for ascending and descending runs of relative length r. The method begins by writing an initial run onto each of four tapes, and merges them (reading backwards) onto the fifth tape. Distribution resumes again, this time cyclically shifted one place to the right with respect to the tapes, and a second merge produces another run D_4. When four D_4's have been formed in this way, an additional merge creates A_{16}. We could go on to create three more A_{16}'s, merging them into a D_{64}, and so on until the input is exhausted. It isn't necessary to know the length of the input in advance.

When the number of initial runs, S, is 4^m, it is not difficult to see that this method processes each record exactly $m + 1$ times (once during the distribution and m times during a merge). When S is between 4^{m-1} and 4^m, we could assume that dummy runs are present, bringing S up to 4^m; hence the total sorting time

would essentially amount to $\lceil \log_4 S \rceil + 1$ passes over all the data. This is just what would be achieved by a balanced sort on *eight* tapes; in general, oscillating sort with T work tapes is equivalent to balanced merging with $2(T - 1)$ tapes, since it makes $\lceil \log_{T-1} S \rceil + 1$ passes over the data. When S is a power of $T - 1$, this is the best *any* T-tape method could possibly do, since it achieves the lower bound in Eq. 5.4.4–9. On the other hand when S is $(T - 1)^{m-1} + 1$, just one higher than a power of $T - 1$, the method wastes nearly a whole pass.

Exercise 2 shows how to eliminate part of this penalty for non-perfect-powers S, by using a special ending routine. A further refinement was discovered in 1966 by Dennis L. Bencher, who called his procedure the "criss-cross merge" [see H. Wedekind, *Datenorganisation* (Berlin: W. de Gruyter, 1970), 164–166; and *U.S. Patent 3540000* (November 10, 1970)]. The main idea is to delay merging until more knowledge of S has been gained. We shall discuss a slightly modified form of Bencher's original scheme.

This improved oscillating sort proceeds as follows:

	Operation	T1	T2	T3	T4	T5	"Cost"
Phase 1.	Distribute	—	A_1	A_1	A_1	A_1	4
Phase 2.	Distribute	—	A_1	A_1A_1	A_1A_1	A_1A_1	3
Phase 3.	Merge	D_4	—	A_1	A_1	A_1	4
Phase 4.	Distribute	D_4A_1	—	A_1	A_1A_1	A_1A_1	3
Phase 5.	Merge	D_4	D_4	—	A_1	A_1	4
Phase 6.	Distribute	D_4A_1	D_4A_1	—	A_1	A_1A_1	3
Phase 7.	Merge	D_4	D_4	D_4	—	A_1	4
Phase 8.	Distribute	D_4A_1	D_4A_1	D_4A_1	—	A_1	3
Phase 9.	Merge	D_4	D_4	D_4	D_4	–	4

We do not merge the D_4's into an A_{16} at this point (unless the input happens to be exhausted); only after building up to

Phase 15.	Merge	D_4D_4	D_4D_4	D_4D_4	D_4	—	4

will we get

Phase 16.	Merge	D_4	D_4	D_4	—	A_{16}	16.

The second A_{16} will occur after three more D_4's have been made,

Phase 22.	Merge	D_4D_4	D_4D_4	D_4	—	$A_{16}D_4$	4
Phase 23.	Merge	D_4	D_4	—	A_{16}	A_{16}	16

and so on (cf. phases 1–5). The advantage of Bencher's scheme can be seen for example if there are only five initial runs: Oscillating sort as modified in exercise 2 would do a four-way merge (in Phase 2) followed by a two-way merge, for a total cost of $4 + 4 + 1 + 5 = 14$, while Bencher's scheme would do a two-way merge (in Phase 3) followed by a four-way merge, for a total cost of

$4 + 1 + 2 + 5 = 12$. (Both methods also involve a small additional cost, namely one unit of rewind before the final merge.)

A precise description of Bencher's method appears in Algorithm B below. Unfortunately it seems to be a procedure which is harder to understand than to code; it is much easier to explain the technique to a computer than to a computer scientist! This is partly because it is a recursive method that has been expressed in iterative form and then "optimized" somewhat; the reader may find it necessary to trace through the operation of this algorithm several times before he really discovers what is going on.

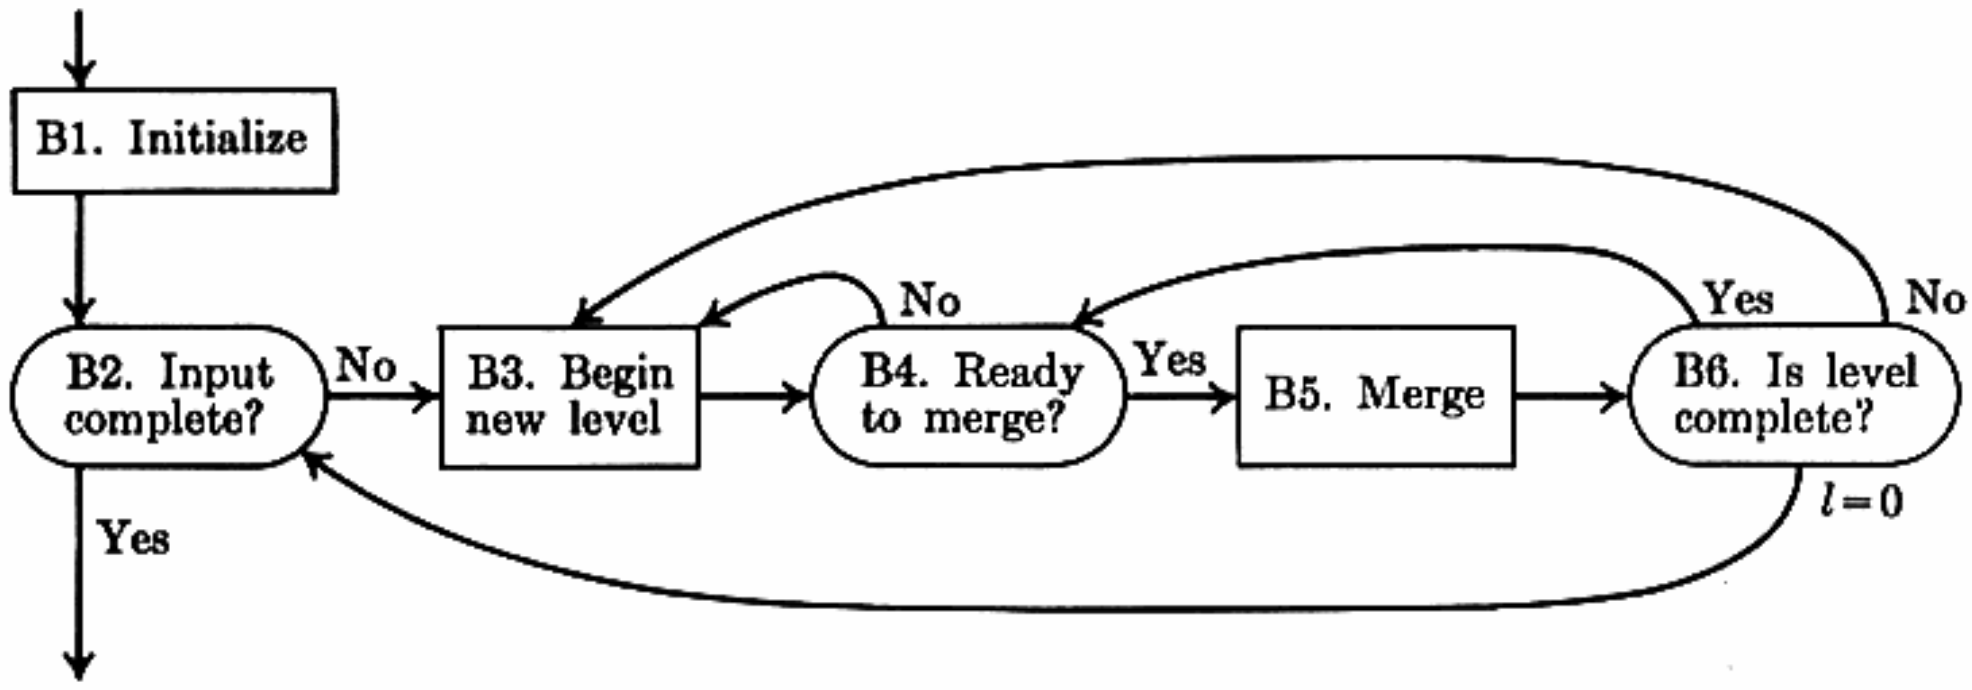


Fig. 77. Oscillating sort, with a "criss-cross" distribution.

Algorithm B (*Oscillating sort with "criss-cross" distribution*). This algorithm takes initial runs and disperses them to tapes, occasionally interrupting the distribution process in order to merge some of the tape contents. The algorithm uses P-way merging, assuming that $T = P + 1 \geq 3$ tape units are available (*not* counting the unit which may be necessary to hold the input data). The tape units must allow reading in both forward and backward directions, and they are designated by the numbers $0, 1, \ldots, P$. The following tables are maintained:

$\texttt{D}[j]$, $0 \leq j \leq P$ — Number of dummy runs assumed to be present at the end of tape j.

$\texttt{A}[l, j]$, $0 \leq l \leq L$, $0 \leq j \leq P$ — Here L is a number which is large enough that at most P^{L+1} initial runs will be input. When $\texttt{A}[l, j] = k \geq 0$, a run of nominal length P^k is present on tape j, corresponding to "level l" of the algorithm's operation. This run is ascending if k is even, descending if k is odd. When $\texttt{A}[l, j] = -1$, level l does not use tape j.

The statement "Write an initial run on tape j" is an abbreviation for the following operations:

> Set $\texttt{A}[l, j] \leftarrow 0$. If the input is exhausted, increase $\texttt{D}[j]$ by 1; otherwise write an initial run (in ascending order) onto tape j.

The statement "Merge to tape j" is an abbreviation for the following operations:

If $\texttt{D}[i] > 0$ for all $i \neq j$, decrease $\texttt{D}[i]$ by 1 for all $i \neq j$ and increase $\texttt{D}[j]$ by 1. Otherwise merge one run to tape j, from all tapes $i \neq j$ such that $\texttt{D}[i] = 0$, and decrease $\texttt{D}[i]$ by 1 for all other $i \neq j$.

B1. [Initialize.] Set $\texttt{D}[j] \leftarrow 0$ for $0 \leq j \leq P$. Then write an initial run on tape j, for $1 \leq j \leq P$. Set $\texttt{A}[0, 0] \leftarrow -1$, $l \leftarrow 0$, $q \leftarrow 0$.

B2. [Input complete?] (At this point tape q is empty and the other tapes contain at most one run each.) If there is more input, go on to step B3. But if the input is exhausted, rewind all tapes $j \neq q$ such that $\texttt{A}[0, j]$ is even; then merge to tape q, reading forward on tapes just rewound, and reading backward on the other tapes. This completes the sort, with the output in ascending order on tape q.

B3. [Begin new level.] Set $l \leftarrow l + 1$, $r \leftarrow q$, $s \leftarrow 0$, and $q \leftarrow (q + 1) \bmod T$. Write an initial run on tape $(q + j) \bmod T$, for $1 \leq j \leq T - 2$. (Thus an initial run is written onto each tape except tapes q and r.) Set $\texttt{A}[l, q] \leftarrow -1$ and $\texttt{A}[l, r] \leftarrow -1$.

B4. [Ready to merge?] If $\texttt{A}[l - 1, q] \neq s$, go back to step B3.

B5. [Merge.] (At this point $\texttt{A}[l - 1, q] = \texttt{A}[l, j] = s$ for all $j \neq q$, $j \neq r$.) Merge to tape r. (See the definition of this operation above.) Then set $s \leftarrow s + 1$, $l \leftarrow l - 1$, $\texttt{A}[l, r] \leftarrow s$, and $\texttt{A}[l, q] \leftarrow -1$. Set $r \leftarrow (2q - r) \bmod T$. (In general, we have $r = (q - 1) \bmod T$ when s is even, $r = (q + 1) \bmod T$ when s is odd.)

B6. [Is level complete?] If $l = 0$, go to B2. Otherwise if $\texttt{A}[l, j] = s$ for all $j \neq q$ and $j \neq r$, go to B4. Otherwise return to B3. ∎

We can use a "recursion induction" style of proof to show that this algorithm is valid, just as we have done for Algorithm 2.3.1T. Suppose that we begin at step B3 with $l = l_0$, $q = q_0$, $s_+ = \texttt{A}[l_0, (q_0 + 1) \bmod T]$, and $s_- = \texttt{A}[l_0, (q_0 - 1) \bmod T]$; and assume furthermore that either $s_+ = 0$ or $s_- = 1$ or $s_+ = 2$ or $s_- = 3$ or $\cdots$. It is possible to verify by induction that the algorithm will eventually get to step B5 without changing rows 0 through l_0 of A, and with $l = l_0 + 1$, $q = q_0 \pm 1$, $r = q_0$, and $s = s_+$ or s_-, where we choose the $+$ sign if $s_+ = 0$ or ($s_+ = 2$ and $s_- \neq 1$) or ($s_+ = 4$ and $s_- \neq 1, 3$) or $\cdots$, and we choose the $-$ sign if ($s_- = 1$ and $s_+ \neq 0$) or ($s_- = 3$ and $s_+ \neq 0, 2$) or $\cdots$. The proof sketched here is not very elegant, but the algorithm has been stated in a form more suited to implementation than to verification.

Figure 78 shows the efficiency of Algorithm B, in terms of the average number of times each record is merged as a function of the number S of initial runs, assuming that the initial runs are approximately equal in length. (Corresponding graphs for polyphase and cascade sort have appeared in Figs. 70 and 74.) A slight improvement, mentioned in exercise 3, has been used in preparing this chart.

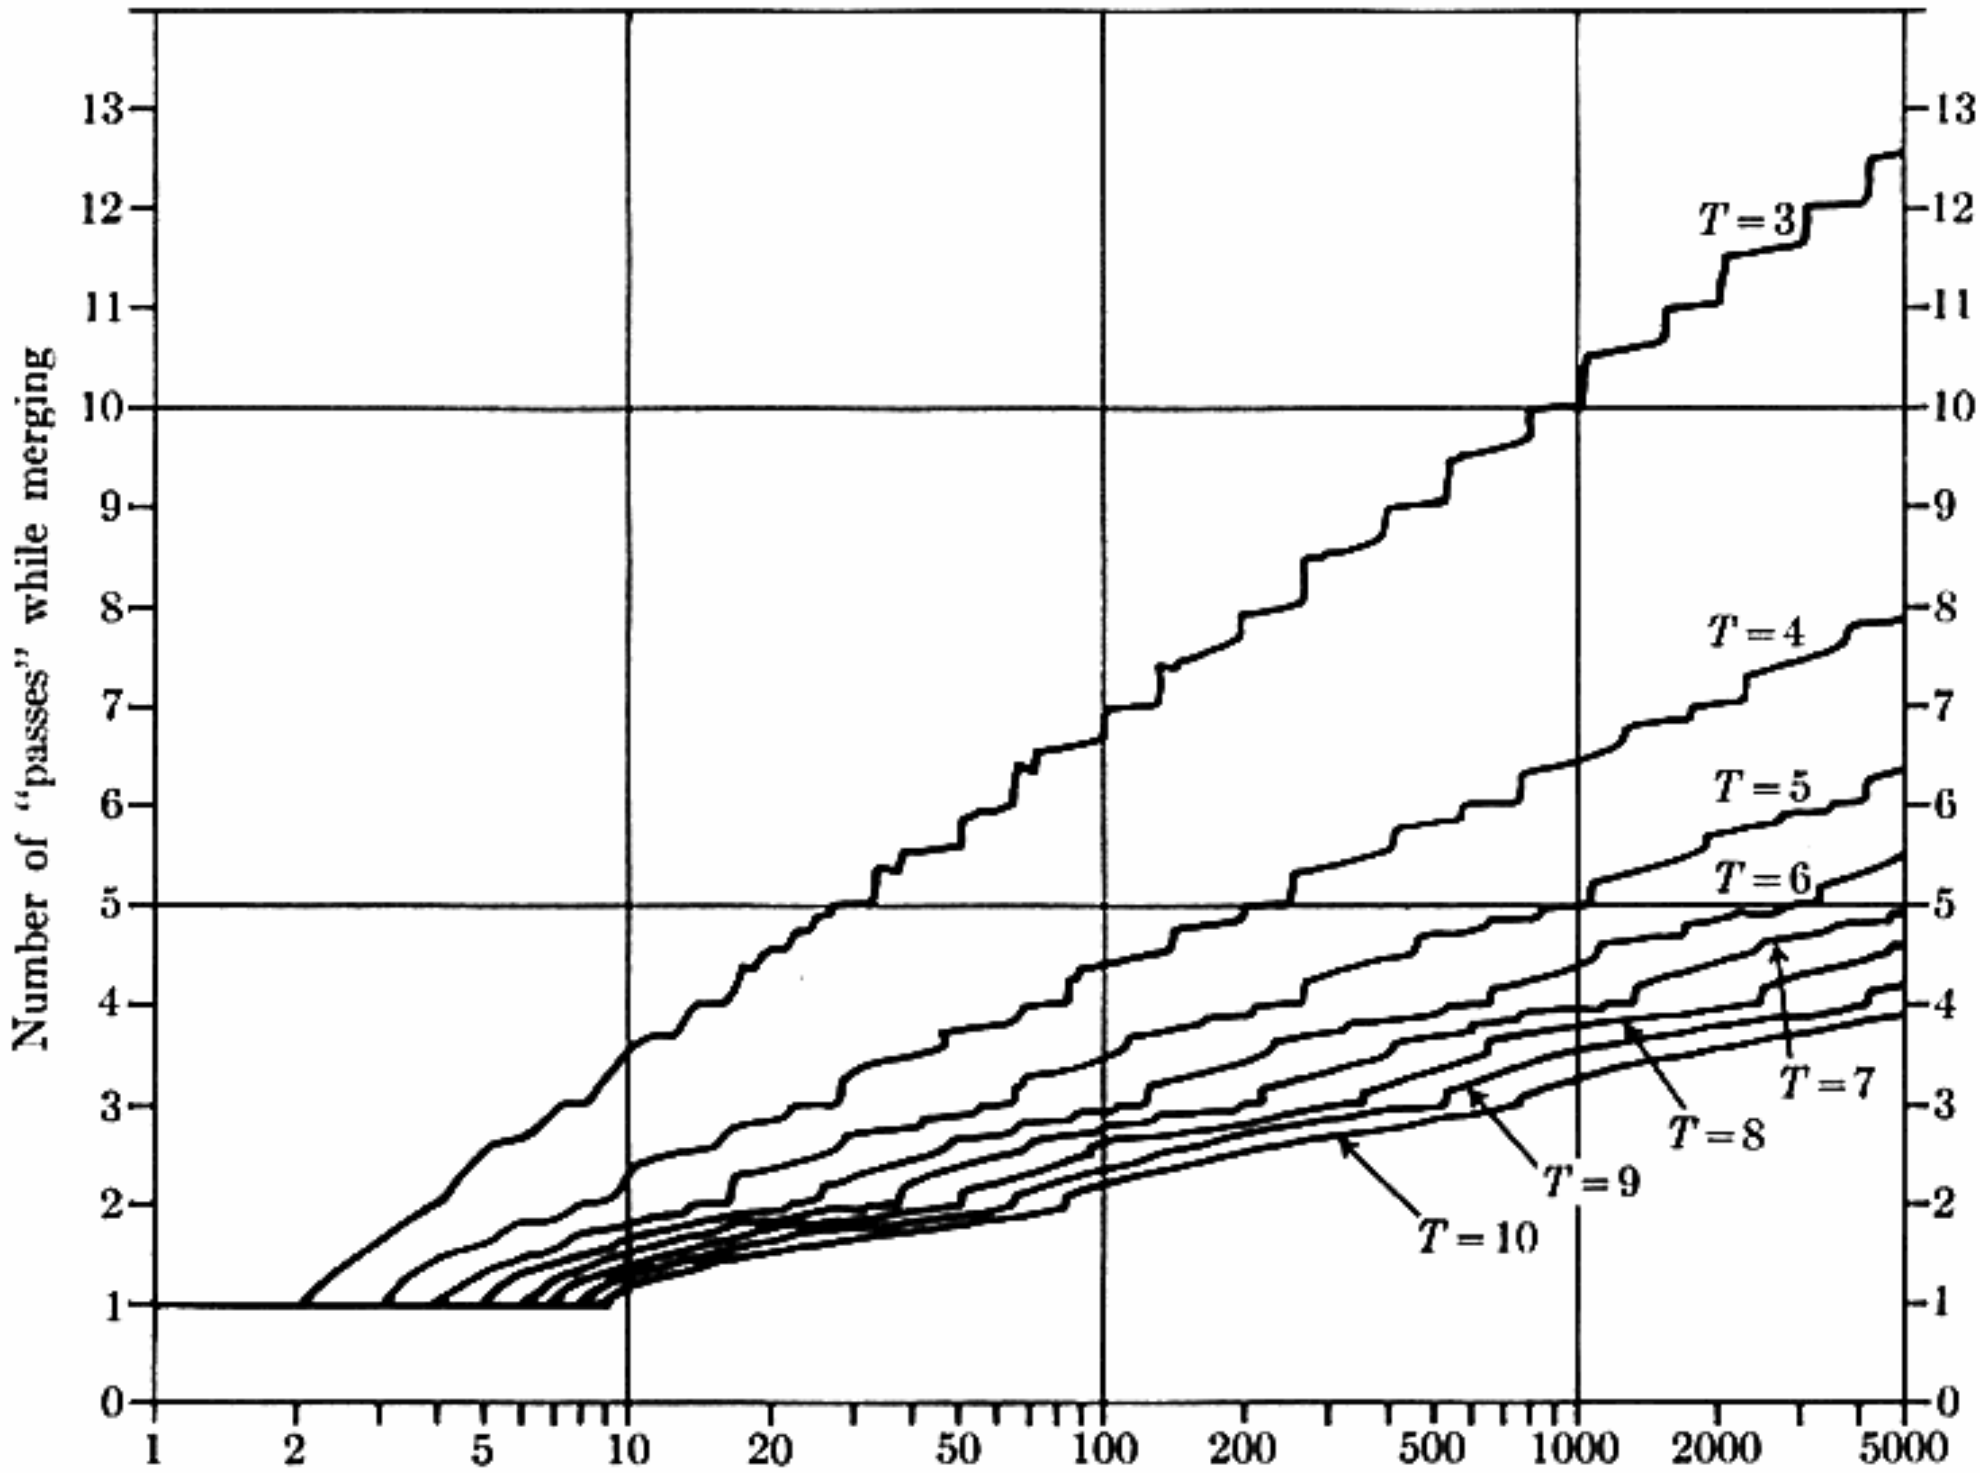

Fig. 78. Efficiency of oscillating sort, using the technique of Algorithm B and exercise 3.

Reading forwards. The oscillating sort pattern appears to require a read-backwards capability, since we need to store long runs somewhere as we merge newly-input short runs. However, M. A. Goetz [*Proc. AFIPS Spring Jt. Comp. Conf.* **25** (1964), 599–607] has discovered a way to perform an oscillating sort using only forward reading and simple rewinding. His method is radically different from the other schemes we have seen in this chapter, because

a) Data is sometimes written at the front of the tape, with the understanding that the existing data in the *middle* of the tape is not destroyed.

b) All initial strings have a fixed maximum length.

Condition (a) violates the "first-in-first-out" property we have assumed to be characteristic of forward reading, but it can be implemented reliably if a sufficient amount of blank tape is left between runs and if "parity errors" are ignored at appropriate times. Condition (b) tends to be somewhat incompatible with an efficient use of replacement selection.

Goetz's read-forward oscillating sort has the somewhat dubious distinction of being one of the first algorithms to be patented as an algorithm instead of as a physical device [*U.S. Patent 3380029* (April 23, 1968)]; unless successfully contested, this means it is illegal to use the algorithm in a program without

permission of the patentee. Bencher's read-backwards oscillating sort technique was patented by IBM several years later. [Thus, we have reached the end of the era when the joy of discovering a new algorithm was satisfaction enough! Since programming is strongly analogous to the fabrication of a machine, and since computer programs are now worth money, patented algorithms are inevitable. Of course the specter of people keeping new techniques completely secret is far worse than the public appearance of algorithms which are proprietary for a limited time.]

The central idea in Goetz's method is to arrange things so that each tape begins with a run of relative length 1, followed by one of relative length P, then P^2, etc. For example, when $T = 5$ the sort begins as follows, using "." to indicate the current position of the read-write head on each tape:

	Operation	T1	T2	T3	T4	T5	"Cost"	Remarks
Phase 1.	Distribute	$.A_1$	$.A_1$	$.A_1$	$.A_1$	$A_1.$	5	[T5 not rewound]
Phase 2.	Merge	$\aleph_1.$	$\aleph_1.$	$\aleph_1.$	$\aleph_1.$	$A_1\,A_4.$	4	[Now rewind all]
Phase 3.	Distribute	$.A_1$	$.A_1$	$.A_1$	$A_1.$	$.A_1\,A_4$	4	[T4 not rewound]
Phase 4.	Merge	$\aleph_1.$	$\aleph_1.$	$\aleph_1.$	$A_1\,A_4.$	$\aleph_1.A_4$	4	[Now rewind all]
Phase 5.	Distribute	$.A_1$	$.A_1$	$A_1.$	$.A_1\,A_4$	$.A_1\,A_4$	4	[T3 not rewound]
Phase 6.	Merge	$\aleph_1.$	$\aleph_1.$	$A_1\,A_4.$	$\aleph_1.A_4$	$\aleph_1.A_4$	4	[Now rewind all]
Phase 7.	Distribute	$.A_1$	$A_1.$	$.A_1\,A_4$	$.A_1\,A_4$	$.A_1\,A_4$	4	[T2 not rewound]
Phase 8.	Merge	$\aleph_1.$	$A_1\,A_4.$	$\aleph_1.A_4$	$\aleph_1.A_4$	$\aleph_1.A_4$	4	[Now rewind all]
Phase 9.	Distribute	$A_1.$	$.A_1\,A_4$	$.A_1\,A_4$	$.A_1\,A_4$	$.A_1\,A_4$	4	[T1 not rewound]
Phase 10.	Merge	$A_1A_4.$	$\aleph_1.A_4$	$\aleph_1.A_4$	$\aleph_1.A_4$	$\aleph_1.A_4$	4	[No rewinding]
Phase 11.	Merge	$A_1A_4A_{16}.$	$\aleph_1\,\aleph_4.$	$\aleph_1\,\aleph_4.$	$\aleph_1\,\aleph_4.$	$\aleph_1\,\aleph_4.$	16	[Now rewind all]

And so on. During Phase 1, T1 was rewinding while T2 was receiving its input, then T2 was rewinding while T3 was receiving input, etc. Eventually, when the input is exhausted, dummy runs will start to appear, and it sometimes becomes necessary to imagine that they have been written explicitly on the tape at full length. For example, if $S = 18$, the A_1's on T4 and T5 would be dummies during Phase 9; we would have to skip forward on T4 and T5 while merging from T2 and T3 to T1 during Phase 10, because we have to get to the A_4's on T4 and T5 in preparation for Phase 11. On the other hand, the dummy A_1 on T1 need not appear explicitly. Thus the "endgame" is a bit tricky.

A further example of this method appears in the next section.

EXERCISES

1. [*22*] The text illustrates Sobel's original oscillating sort for $T = 5$ and $S = 16$. Give a precise specification of an algorithm which generalizes the procedure, sorting $S = P^L$ initial runs on $T = P + 1 \geq 3$ tapes. Strive for an algorithm which can be described very simply.

2. [*24*] If $S = 6$ in Sobel's original method, we could pretend that $S = 16$ and that 11 dummy runs were present. Then Phase 3 in the text's example would put dummy runs A_0 on T4 and T5; Phase 4 would merge the A_1's on T2 and T3 into a D_2 on T1; Phases 5–8 would do nothing; and Phase 9 would produce A_6 on T4. It

would be better to rewind T2 and T3 just after Phase 3, then to produce A_6 immediately on T4 by three-way merging.

Show how to modify the algorithm of exercise 1, so that an improved ending like this is obtained when S is not a perfect power of P.

▶ **3.** [*24*] Prepare a chart showing the behavior of Algorithm B when $T = 3$, assuming that there are nine initial runs. Show that the procedure is obviously inefficient in one place, and prescribe corrections to Algorithm B which will remedy the situation.

4. [*21*] Step B3 sets both A[l, q] and A[l, r] to -1. Show that one of these two operations is always superfluous, since the corresponding A table entry is never looked at.

5. [*M25*] Let S be the number of initial runs present in the input to Algorithm B. Which values of S require *no rewinding* in step B2?

5.4.6. Practical Considerations for Tape Merging

Here comes the nitty-gritty: Now that we have discussed the various families of merge patterns, it is time to see how they actually apply to real configurations of computers and magnetic tapes, and to compare them in a meaningful way. Our study of internal sorting showed that we can't adequately judge the efficiency of a sorting method merely by counting the number of comparisons it performs; similarly we can't properly evaluate an external sorting method by simply knowing the number of passes it makes over the data.

In this section we shall discuss the characteristics of typical tape units, and the way they affect initial distribution and merging. In particular we shall study some schemes for buffer allocation, and the corresponding effects on running time. We also shall consider briefly the construction of *sort generator* programs.

How tape works. There is considerable variation in the characteristics of tape units provided by different manufacturers. For convenience, we shall define a hypothetical MIXT tape unit, which is reasonably typical of the equipment being manufactured at the time this book was written. By studying how to design a sorting algorithm for MIXT tapes, it will be easier to understand how to deal with other particular tape units.

MIXT reads and writes 800 characters per inch of tape, at a rate of 75 inches per second. This means that one character is read or written every $\frac{1}{60}$ ms, i.e. $16\frac{2}{3}$ microseconds, when the tape is active. [Actual tape units which are currently being sold have densities ranging from 200 to 1600 characters per inch, and tape speeds ranging from $37\frac{1}{2}$ to 150 inches per second, so their effective speed varies from $\frac{1}{8}$ to 4 times as fast as MIXT. In practice, much sorting is done in commercial environments on relatively small and inexpensive equipment which is slower than that considered here. On the other hand, tape units may soon change drastically, making the present assumptions obsolete. Our main concern here is not to obtain particular answers; it is to learn how to combine theory and practice in a reasonable way.]

One of the important considerations to keep in mind is that individual tapes aren't infinitely long. Each reel contains 2400 feet of tape or less, hence

there is room for at most 23,000,000 or so characters per reel of MIXT tape; and it takes about 23000000/3600000 $\approx$ 6.4 minutes to read them all. If larger files must be sorted, it is generally best to sort one reelfull at a time, and then to merge the individual sorted reels, in order to avoid excess tape handling. This means that the number of initial runs, S, actually present in the merge patterns we have been studying is never extremely large. We will never find $S > 5000$, even with a very small internal memory which produces initial runs only 5000 characters long. Consequently the formulas which give asymptotic efficiency of the algorithms as $S \to \infty$ are primarily of academic interest.

Data appears on tape in *blocks* (Fig. 79), and each read/write instruction transmits a single block. Blocks are often called "records," but we shall avoid this terminology because it conflicts with the fact that we are sorting a file of "records" in another sense. On many of the early sorting programs written during the 1950's, this distinction was unnecessary, since one record was written per block; but we shall see that it is usually advantageous to have quite a few records in every block on the tape.

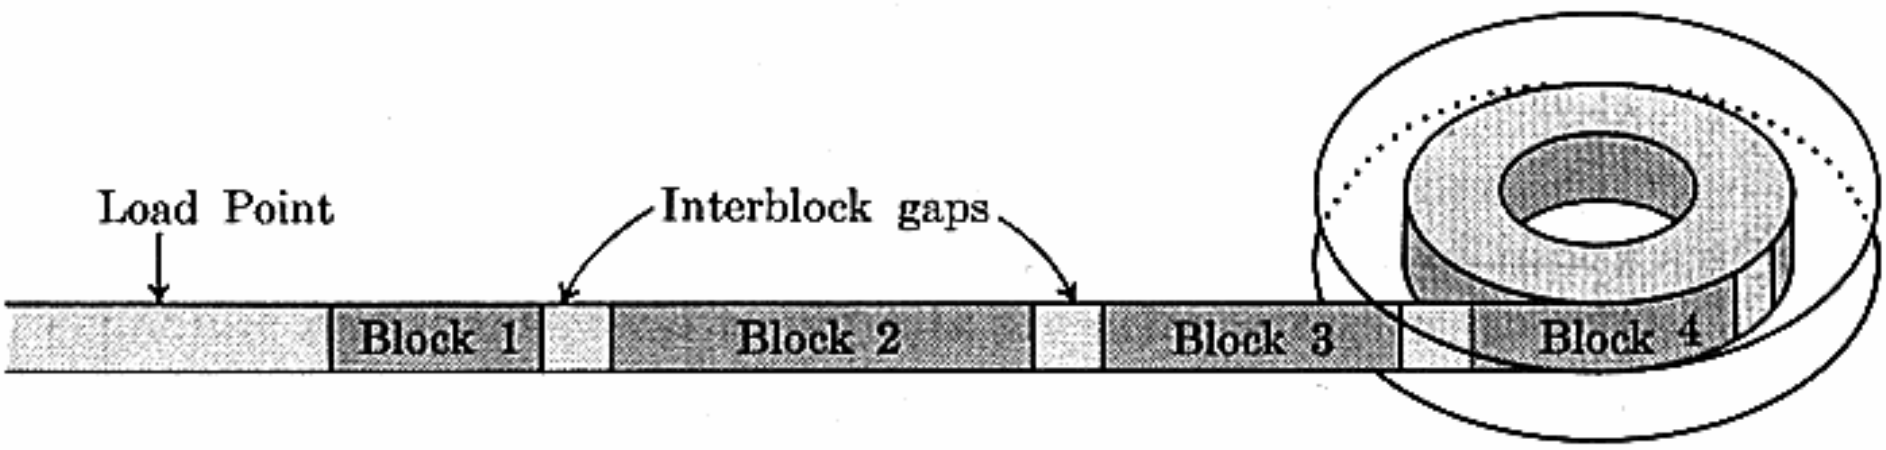

Fig. 79. Magnetic tape with variable-size blocks.

An *interblock gap*, 480 character positions long, appears between adjacent blocks, in order to allow the tape to stop and to start between individual read or write commands. The effect of interblock gaps is to decrease the number of characters per reel of tape, depending on the number of characters per block (see Fig. 80); and the average number of characters transmitted per second decreases in the same way, since tape moves at a fairly constant speed.

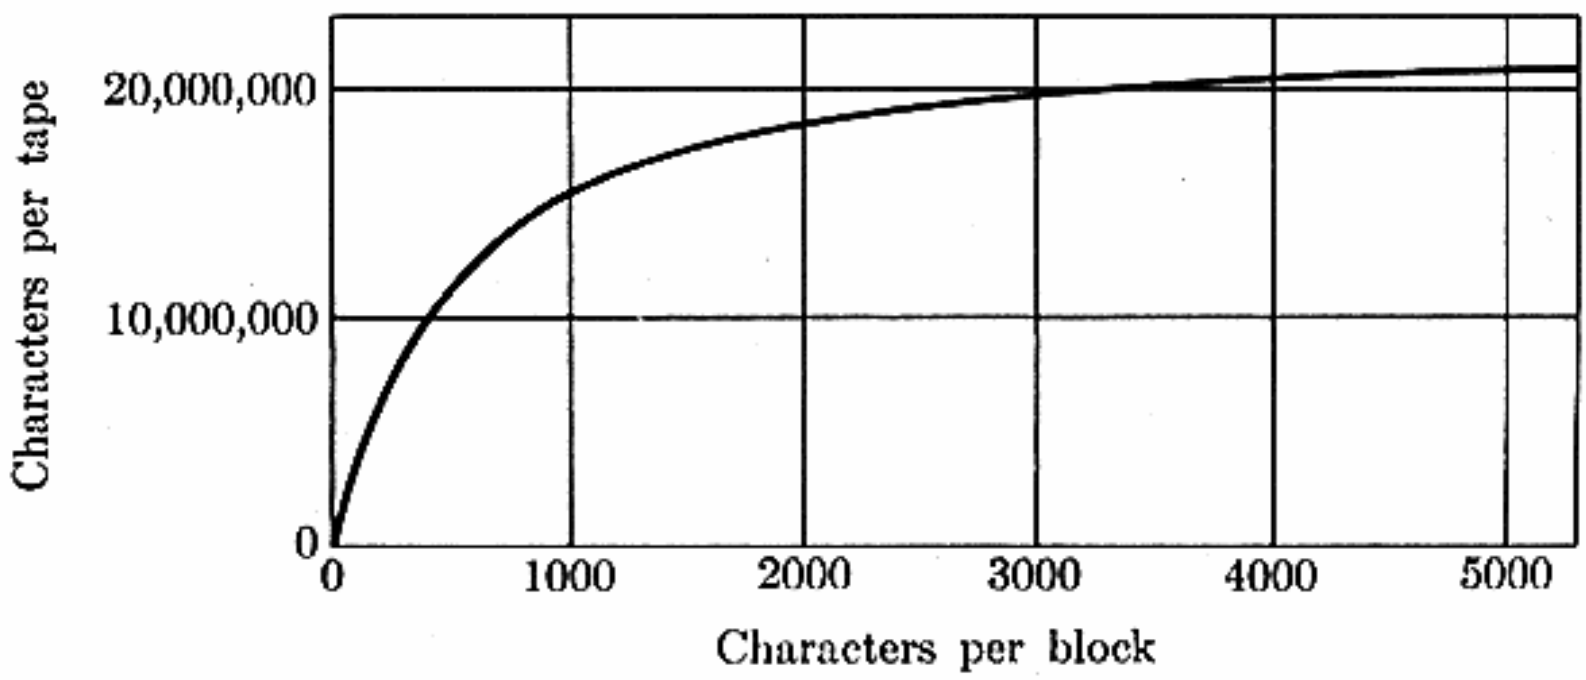

Fig. 80. The number of characters per reel of MIXT tape, as a function of the block size.

Many "old fashioned" computers have fixed block sizes which are rather small. For example, MIX as defined in Chapter 1 always reads and writes 100-word blocks; since this represents about 500 characters per block, and 480 characters per gap, almost half the tape is wasted! Most machines now allow the block size to be variable, and so we shall discuss the choice of appropriate block sizes below.

At the end of a read or write operation, the tape unit "coasts" at full speed over the first 66 characters (or so) of the gap. If the next operation for the same tape is initiated during this time, the tape motion continues without interruption. But if the next operation doesn't come soon enough, the tape will stop and it will also require some time to accelerate to full speed on the next operation. The combined stop-start time delay is 5 ms, 2 for the stop and 3 for the start (see Fig. 81). Thus if we just miss the chance to have continuous full-speed reading, the effect on running time is essentially the same as if there were 780 characters instead of 480 in the interblock gap.

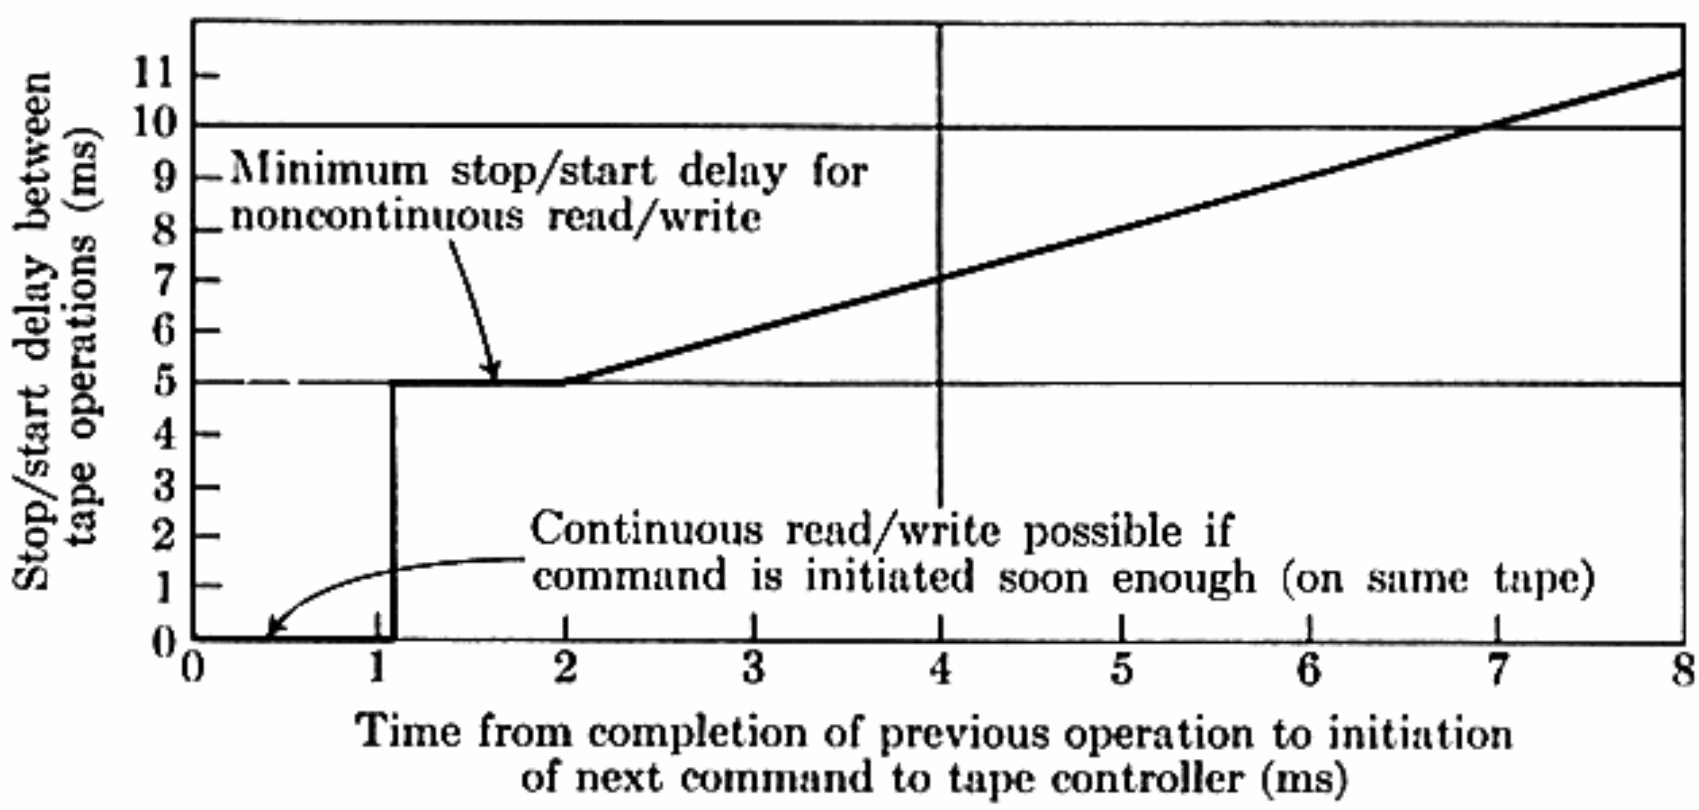

Fig. 81. How to compute the stop/start delay time. (This gets added to the time used for reading or writing the blocks and the gaps.)

Now let us consider the operation of *rewinding*. Unfortunately, it is generally difficult to characterize the exact time needed to rewind over a given number n of characters. On some machines there is a "high-speed rewind" which applies only when n is greater than 5 million or so; for smaller values of n, rewinding goes at normal read/write speed. On other machines there is a special motor which is used on all rewind operations; it gradually accelerates the tape reel to a certain number of revolutions per minute, then puts on the brakes when it is time to stop, and the actual tape speed varies with the fullness of the reel. For simplicity, we shall assume that MIXT requires max (30, $n/150$) ms to rewind over n character positions (including gaps), roughly two-fifths as long as it took to write them. This is a reasonably good approximation to the behavior of many actual tape units, where the ratio of read/write time to rewind time is generally between 2 and 3, but it does not adequately model the

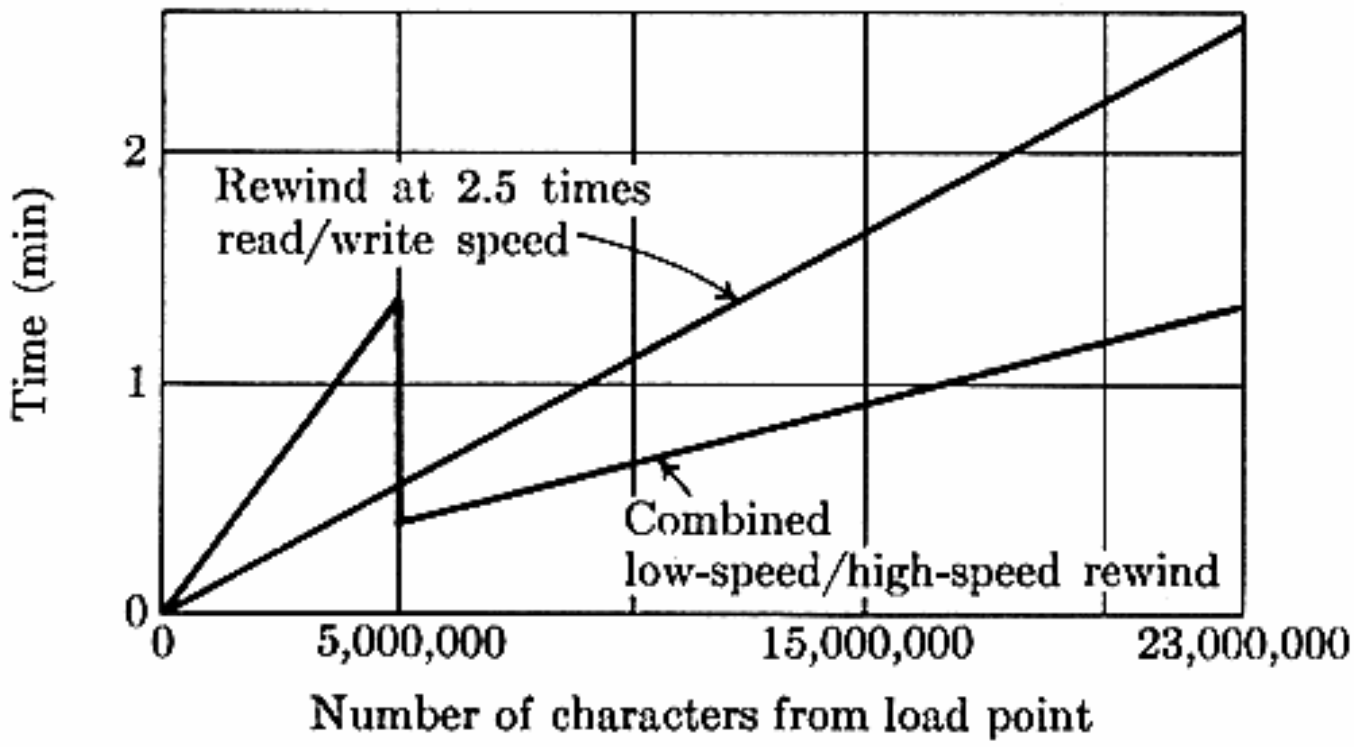

Fig. 82. Approximate running time for two commonly used rewind techniques.

effect of combined low-speed and high-speed rewind which is present on many other machines. (See Fig. 82.)

Initial loading and/or rewinding will position a tape at "load point", and an extra 110 ms are necessary for any read or write operation initiated at load point. When the tape is not at load point, it may be read backwards; an extra 32 ms is added to the time of any backward operation following a forward operation or any forward operation following a backward one.

Finally we must consider the allowable simultaneity of input and output. For economic reasons, several tape units are often attached to a *tape controller*, which is able to deal with only one or two of its units at a time because there are a limited number of data paths between it and the computer. Sometimes controllers are not capable of dealing with more than one unit at a time, but they are often able to read on one unit while writing on another. Somewhat rarer are controllers which can read on two units simultaneously; and the author has never seen a controller that can write on two units at once. Rewinding is a special case: 30 ms after a `MIXT` rewind has been initiated, the tape unit is "detached" from its controller, which becomes free to access other units. In this way a very large number of tape units could be rewinding simultaneously.

Nearly all machines allow input and output to proceed concurrently with computing, although many computers run 20 to 40 percent more slowly when input/output is in progress due to "cycle sharing."

Merging revisited. Let us now look again at the process of P-way merging, with an emphasis on input and output activities, assuming that $P + 1$ tape units are being used for the input files and the output file. Our goal is to overlap the input/output operations as much as possible with each other and with the computations of the program, so that the overall merging time is minimized.

It is instructive to consider the following special case, in which serious restrictions are placed on the amount of simultaneity possible. Suppose that

a) At most one tape may be written on at any one time.
b) At most one tape may be read from at any one time.

c) Reading, writing, and computing may take place simultaneously only when the read and write operations have been initiated simultaneously.

It turns out that a system of $2P$ input buffers and 2 output buffers is sufficient to keep the tape moving at essentially its maximum speed, even though these three restrictions are imposed, unless the computer is unusually slow. Note that (a) is not really a restriction, since there is only one output tape. Furthermore the amount of input is equal to the amount of output, so there is only one tape being read, on the average, at any given time; if condition (b) is not satisfied, there will necessarily be periods when no input at all is occurring. Thus we can minimize the merging time if we keep the output tape busy.

An important technique called prediction or *forecasting* leads to the desired effect. While we are doing a P-way merge, we generally have P "current input buffers," which are being used as the source of data; some of them are more full than others, depending on how much of their data has already been scanned. If all of them become empty at about the same time, we will need to do a lot of reading before we can proceed further, unless we have foreseen this eventuality in advance. Fortunately it is always possible to tell which buffer will empty first, by simply looking at the *last* record in each buffer. The buffer whose last record has the smallest key will always be the first one empty, regardless of the values of any other keys; so we always know which file should be the source of our next input command. The following algorithm spells out this principle in detail.

Algorithm F (*Forecasting with floating buffers*). This algorithm controls the buffering during a P-way merge of long input files, for $P \geq 2$. Assume that the input tapes and files are numbered $1, 2, \ldots, P$. The algorithm uses $2P$ input buffers `I`$[1], \ldots,$ `I`$[2P]$; two output buffers `O`$[0]$ and `O`$[1]$; and the following auxiliary tables:

`A`$[j]$, $1 \leq j \leq 2P$: 0 if `I`$[j]$ is available for input, 1 otherwise;

`B`$[i]$, $1 \leq i \leq P$: The buffer containing the last block read so far from file i;

`C`$[i]$, $1 \leq i \leq P$: The buffer currently being used for the input from file i;

`L`$[i]$, $1 \leq i \leq P$: The last key read so far from file i;

`S`$[j]$, $1 \leq j \leq 2P$: The buffer to use when `I`$[j]$ becomes empty.

The algorithm described here does not terminate; an appropriate way to "shut it off" is discussed below.

F1. [Initialize.] Read the first block from tape i into buffer `I`$[i]$, set `A`$[i] \leftarrow 1$, `A`$[P + i] \leftarrow 0$, `B`$[i] \leftarrow i$, `C`$[i] \leftarrow i$, and set `L`$[i]$ to the key of the final record in `I`$[i]$, for $1 \leq i \leq P$. Then find m such that `L`$[m] = \min \{$`L`$[1], \ldots,$ `L`$[P]\}$; and set $t \leftarrow 0$, $k \leftarrow P + 1$. Begin to read from tape m into buffer `I`$[k]$.

F2. [Merge.] Merge records from buffers `I`$[$`C`$[1]], \ldots,$ `I`$[$`C`$[P]]$ to `O`$[t]$, until `O`$[t]$ is full. If during this process an input buffer, say `I`$[$`C`$[i]]$, becomes empty and `O`$[t]$ is not yet full, set `A`$[$`C`$[i]] \leftarrow 0$, `C`$[i] \leftarrow$ `S`$[$`C`$[i]]$, and continue to merge.

F3. [I/O complete.] Wait until the previous read (or read/write) operation is

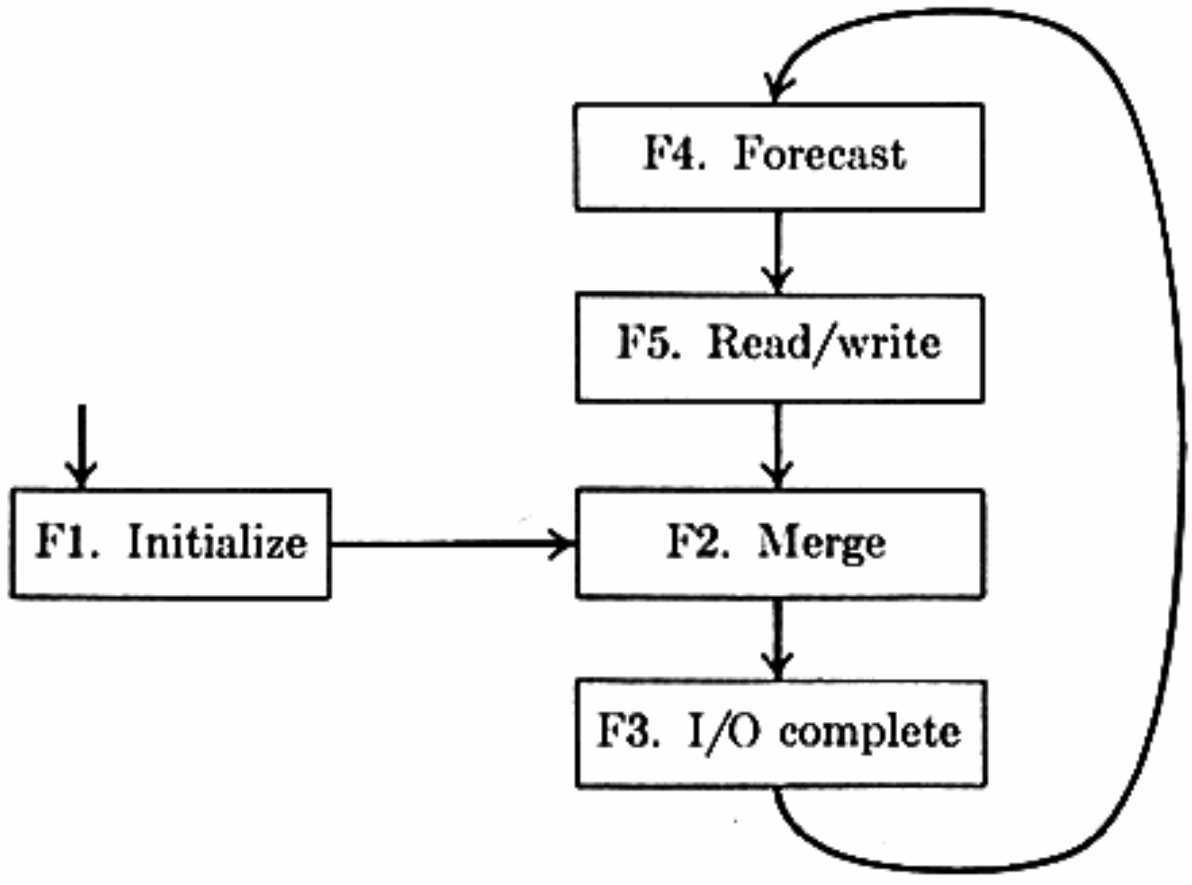

Fig. 83. Forecasting with floating buffers.

complete. Then set A[k] ← 1, S[B[m]] ← k, B[m] ← k, and set L[m] to the key of the final record in I[k].

F4. [Forecast.] Find m such that L[m] = min {L[1], . . . , L[P]}, and find k such that A[k] = 0.

F5. [Read/write.] Begin to read from tape m into buffer I[k], and to write from buffer O[t] onto the output tape. Then set $t \leftarrow 1 - t$ and return to F2. ▮

The example in Fig. 84 shows how forecasting works, when $P = 2$, assuming that each block on tape contains only two records. The input buffer contents are illustrated each time we get to the beginning of step F2. Algorithm F essentially forms P *queues of buffers*, with C[i] pointing to the front and B[i]

Fig. 84. Buffer queuing, according to Algorithm F.

to the rear of the ith queue, and with S[j] pointing to the successor of buffer I[j]; these pointers are shown as arrows in Fig. 84. Line 1 illustrates the state of affairs after initialization: There is one buffer for each input file, and another block is being read from File 1 (since 03 < 05). Line 2 shows the status of things after the first block has been merged: we are outputting a block containing "01 02", and inputting the next block from File 2 (since 05 < 09). Note that in line 3, three of the four input buffers are essentially committed to File 2, since we are reading from that file and we already have a full buffer and a partly full buffer in its queue. This "floating buffer" arrangement is an important feature of Algorithm F, since we would be unable to proceed in line 4 if we had chosen File 1 instead of File 2 for the input on line 3.

In order to prove that Algorithm F is valid, we must show two things:

i) There is always an input buffer available (i.e., we can always find a k in step F4).

ii) If an input buffer is exhausted while merging, its successor is already present in memory (i.e., S[C[i]] is meaningful in step F2).

Suppose (i) is false, so that all buffers are unavailable at some point when we reach step F4. Each time we get to that step, the total amount of unprocessed data among all the buffers is exactly P bufferloads, i.e. just enough data to fill P buffers if it were relocated, since we are inputting and outputting data at the same rate. Some of the buffers are only partially full; but at most one buffer for each file is partially full, so at most P buffers are partly full. By hypothesis all $2P$ of the buffers are unavailable, so at least P of them must be completely full. This can happen only if P are full and P are empty, otherwise we would have too much data. But at most one buffer can be unavailable and empty at any one time; hence (i) cannot be false.

Suppose (ii) is false, so that we have no unprocessed records in memory, for some file, but the current output buffer is not yet full. By the principle of forecasting, we must have no more than one block of data for all the other files, since we do not read in a block for a file unless that block will be needed before the buffers on any other file are exhausted. Therefore the total number of unprocessed records amounts to at most $P - 1$ blocks; adding the unfilled output buffer leads to less than P bufferloads of data in memory, a contradiction.

This argument establishes the validity of Algorithm F; and it also indicates the possibility of pathological circumstances under which the algorithm just barely avoids disaster. An important subtlety that we have not mentioned, regarding the possibility of equal keys, is discussed in exercise 5.

One way to terminate Algorithm F gracefully is to set L[p] to ∞ in step F3 if the block just read is the last of a run. (It is customary to indicate the end of a run in some special way.) After all of the data on all of the files has been read, we will eventually find all of the L's equal to ∞ in step F4; then it is usually possible to begin reading the first blocks of the next run on each file, beginning initialization of the next merge phase as the final $P + 1$ blocks are output.

Thus we can keep the output tape going at essentially full speed, without reading more than one tape at a time. An exception to this rule occurs in step F1, where it would be beneficial to read several tapes at once in order to get things going in the beginning; but step F1 can usually be arranged to overlap with the preceding part of the computation.

The idea of looking at the last record in each block, to predict which buffer will empty first, was discovered in 1953 by F. E. Holberton. The technique was first published by E. H. Friend [*JACM* **3** (1956), 144–145, 165]. His rather complicated algorithm used $3P$ input buffers, with three dedicated to each input file; Algorithm F improves the situation by making use of "floating buffers," allowing any single file to claim as many as $P + 1$ input buffers at once, yet never needing more than $2P$ in all.

A discussion of merging with less than $2P$ input buffers appears at the end of this section. Some computers have a "scatter read—gather write" capability, which allows input/output from nonconsecutive cells in memory; the implications of such a feature are beyond the scope of this book.

Comparative behavior of merge patterns. Let us now use what we know about tapes and merging, to compare the effectiveness of the various merge patterns that we have studied in Sections 5.4.2 through 5.4.5. It is very instructive to work out the details of each method as applied to a particular "unbiased" example. Consider therefore the problem of sorting a file whose records each contain 100 characters, when there are 100,000 character positions of memory available for data storage (exclusive of the program and its auxiliary variables, and the comparatively small amount of space needed for links in a selection tree). The input appears in random order on tape, in blocks of 5000 characters each, and the output is to appear in the same format. There are five "scratch tapes" to work with, in addition to the unit containing the input tape.

The total number of records to be sorted is 100,000, but this information is not known in advance to the sorting algorithm.

Chart A (located between pages 340 and 341) summarizes the actions which transpire when ten different merging schemes are applied to this data. The best way to look at this important illustration is to imagine that you are actually watching the sort take place: scan each line slowly from left to right, pretending that you can actually see six tapes reading, writing, rewinding, and/or reading backward, as indicated on the diagram. During a P-way merge the input tapes will be moving only $1/P$ times as often as the output tape. Note that when the original input tape has been completely read (and rewound "with lock"), Chart A assumes that a skilled computer operator dismounts it and replaces it with a scratch tape, in just 30 seconds. In examples 2, 3, and 4 this is "critical path time" when the computer is idly waiting for the operator to finish; but in the remaining examples, the dismount-reload operation is overlapped by other processing.

Example 1. Read-forward balanced merge. Let's review the specifications of the problem: The records are 100 characters long, there is enough internal

memory to hold 1000 records at a time, and each block on the input tape contains 5000 characters (50 records). There are 100,000 records (= 10,000,000 characters = 2000 blocks) in all.

We are free to choose the block size for intermediate files. A six-tape balanced merge uses three-way merging, so the technique of Algorithm F calls for 8 buffers; we may therefore use blocks containing 1000/8 = 125 records (= 12500 characters) each.

The initial distribution pass can make use of replacement selection (Section 5.4.1), and in order to keep the tapes running smoothly we may use two input buffers of 50 records each, plus two output buffers of 125 records each. This leaves room for 650 records in the replacement selection tree. Most of the initial runs will therefore be about 1300 records long (10 or 11 blocks); it turns out that 78 initial runs are produced in Chart A, the last one being rather short.

The first merge pass indicated shows nine runs merged to tape 4, instead of alternating between tapes 4, 5, and 6. This makes it possible to do useful work while the computer operator is loading a scratch tape onto unit 6; since the total number S of runs is known once the initial distribution has been completed, the algorithm knows that $\lceil S/9 \rceil$ runs should be merged to tape 4, then $\lceil (S-3)/9 \rceil$ to tape 5, then $\lceil (S-6)/9 \rceil$ to tape 6.

The entire sorting procedure for this example can be summarized in the following way, using the notation introduced in Section 5.4.2:

1^{26}	1^{26}	1^{26}	—	—	—
—	—	—	3^9	3^9	3^8
9^3	9^3	$9^2 6^1$	—	—	—
—	—	—	27^1	27^1	24^1
78^1	—	—	—	—	—

Example 2. Read-forward polyphase merge. The second example in Chart A carries out the polyphase merge, according to Algorithm 5.4.2D. In this case we do five-way merging, so the memory is split into 12 buffers of 83 records each. During the initial replacement selection we have two 50-record input buffers and two 83-record output buffers, leaving 734 records in the tree; so the initial runs this time are about 1468 records long (17 or 18 blocks). The situation illustrated shows that $S = 70$ initial runs were obtained, the last two actually being only four blocks and one block long, respectively. The merge pattern can be summarized thus:

$0^{13}1^{18}$	$0^{13}1^{17}$	$0^{13}1^{15}$	$0^{12}1^{12}$	$0^8 1^8$	—
1^{15}	1^{14}	1^{12}	1^8	—	$0^8 1^4 2^1 5^3$
1^7	1^6	1^4	—	4^8	$1^4 2^1 5^3$
1^3	1^2	—	8^4	4^4	$2^1 5^3$
1^1	—	$16^1 19^1$	8^2	4^2	5^2
—	34^1	19^1	8^1	4^1	5^1
70^1	—	—	—	—	—

Curiously, polyphase actually took about 25 seconds *longer* than the far less sophisticated balanced merge! There are two main reasons for this:

1) Balanced merge was particularly lucky in this case, since $S = 78$ is so close to a perfect power of 3. If 82 initial runs had been produced, the balanced merge would have taken an extra pass.

2) Polyphase merge wasted 30 seconds while the input tape was being changed, and a total of more than 5 minutes went by while it was waiting for rewind operations to be completed. By contrast the balanced merge needed comparatively little rewind time. In the second phase of the polyphase merge, 13 seconds were saved because the 8 dummy runs on tape 6 could be assumed present even while that tape was rewinding; but no other rewind overlap occurred. Therefore polyphase lost out even though it required significantly less read/write time.

Example 3. Read-forward cascade merge. This case is analogous to the preceding, but using Algorithm 5.4.3C. The merging may be summarized thus:

1^{14}	1^{15}	1^{12}	1^{14}	1^{15}	—
1^{5}	1^{9}	—	1^{14}	1^{15}	$1^{3}2^{3}3^{6}$
$5^{1}6^{3}$	5^{3}	$5^{3}6^{2}$	—	1^{1}	2^{2}
—	12^{1}	6^{1}	18^{1}	18^{1}	16^{1}
70^{1}	—	—	—	—	—

(Remember to watch each of these examples in action, by scanning Chart A.)

Example 4. Tape-splitting polyphase merge. This procedure, described at the end of Section 5.4.2, allows most of the rewind time to be overlapped. It uses four-way merging, so we divide the memory into ten 100-record buffers; there are 700 records in the replacement selection tree, so it turns out that 72 initial runs are formed. The last run, again, is very short. A distribution scheme analogous to Algorithm 5.4.2D has been used, followed by a simple but somewhat ad hoc method of placing dummy runs:

1^{21}	1^{19}	1^{15}	1^{8}	—	$0^{2}1^{9}$
$0^{2}1^{17}$	$0^{2}1^{15}$	$0^{2}1^{11}$	$0^{2}1^{4}$	—	$0^{2}1^{9}4^{4}$
1^{13}	1^{11}	1^{7}	—	$0^{2}4^{4}$	$0^{2}1^{9}4^{4}$
1^{10}	1^{8}	1^{4}	—	$0^{2}4^{4}3^{2}4^{1}$	$1^{8}4^{4}$
1^{6}	1^{4}	—	4^{4}	$0^{2}4^{4}3^{2}4^{1}$	$1^{4}4^{4}$
1^{5}	1^{3}	—	$4^{4}3^{1}$	$0^{1}4^{4}3^{2}4^{1}$	$1^{3}4^{4}$
1^{2}	—	$3^{1}7^{2}$	$4^{4}3^{1}$	$4^{2}3^{2}4^{1}$	4^{4}
1^{1}	—	$3^{1}7^{2}13^{1}$	$4^{3}3^{1}$	$4^{1}3^{2}4^{1}$	4^{3}
—	13^{1}	$3^{1}7^{2}13^{1}$	$4^{2}3^{1}$	$3^{2}4^{1}$	4^{2}
—	$13^{1}14^{1}$	$7^{2}13^{1}$	$4^{1}3^{1}$	$3^{1}4^{1}$	4^{1}
18^{1}	$13^{1}14^{1}$	$7^{1}13^{1}$	3^{1}	4^{1}	—
18^{1}	14^{1}	13^{1}	—	—	27^{1}
—	—	—	72^{1}	—	—

This turns out to give the best running time of all the examples in Chart A that do not read backward. Since S will never get to be very large, it would be possible to develop a more complicated algorithm which places dummy runs in an even better way (cf. Eq. 5.4.2–26).

Example 5. Cascade merge with rewind overlap. This procedure runs almost as fast as the previous example, although the algorithm governing it is much simpler. We simply use the cascade sort method as in Algorithm 5.4.3C for the initial distribution, but with $T = 5$ instead of $T = 6$. Then each phase of each "cascade" staggers the tapes so that we ordinarily don't write on a tape until after it has had a chance to be rewound. The pattern, very briefly, is

1^{21}	1^{22}	1^{19}	1^{10}	—	—
1^{4}	1^{7}	—	—	$1^{2}2^{2}3^{5}$	4^{10}
7^{2}	—	8^{3}	$7^{2}8^{2}$	—	4^{1}
—	26^{1}	—	8^{1}	22^{1}	16^{1}
72^{1}	—	—	—	—	—

Example 6. Read-backward balanced merge. This is like example 1 but with all the rewinding eliminated:

A_1^{26}	A_1^{26}	A_1^{26}	—	—	—
—	—	—	D_3^{9}	D_3^{9}	D_3^{8}
A_9^{3}	A_9^{3}	$A_9^{2}A_6^{1}$	—	—	—
—	—	—	D_{24}^{1}	D_{27}^{1}	D_{27}^{1}
A_{78}^{1}	—	—	—	—	—

Since there was comparatively little rewinding in example 1, this scheme is not a great deal better than the read-forward case. In fact, it turns out to be slightly slower than tape-splitting polyphase, in spite of the fortunate value $S = 78$.

Example 7. Read-backward polyphase merge. In this example only five of the six tapes are used, in order to eliminate the time for rewinding and changing the input tape. Thus, only four-way merging is used, and the buffer allocation is like that in examples 4 and 5. A distribution like Algorithm 5.4.2D is used, but with alternating directions of runs, and with tape 1 fixed as the final output tape. First an ascending run is written on tape 1; then descending runs on tapes 2, 3, 4; then ascending runs on 2, 3, 4; then descending on 1, 2, 3; etc. Each time we switch direction, replacement selection usually produces a shorter run, so it turns out that 77 initial runs are formed instead of the 72 in examples 4 and 5.

This procedure results in a distribution of (22, 21, 19, 15) runs, and the next perfect distribution is (29, 56, 52, 44). Exercise 5.4.4–5 shows how to generate strings of merge numbers which can be used to place dummy runs in

an "optimum" way; such a procedure is feasible in practice because the finiteness of a tape reel ensures that S is never too large. Therefore the example in Chart A has been constructed using such a method for dummy run placement (see exercise 7). This turns out to be the fastest of all the examples illustrated.

Example 8. Read-backward cascade merge. As in example 7, only five tapes are used here. This procedure follows Algorithm 5.4.3C, using rewind and forward read to avoid one-way merging (since rewinding is more than twice as fast as reading on MIXT units). Distribution is therefore the same as in example 6. The pattern may be summarized briefly as follows, using ↓ to denote rewinding:

A_1^{21}	A_1^{22}	A_1^{19}	A_1^{10}	—
$A_1^4\downarrow$	$A_1^7\downarrow$	—	$D_1^2D_2^2D_3^5$	D_4^{10}
$A_8A_7^2$	A_5^2	A_9^4	—	$D_4^1\downarrow$
—	D_{17}	$A_9\downarrow$	D_{25}	D_{21}
A_{72}	—	—	—	—

Example 9. Read-backward oscillating sort. Oscillating sort with $T = 5$ (Algorithm 5.4.5B) can use buffer allocation as in examples 4, 5, 7, and 8, since it does four-way merging. However, replacement selection does not behave in the same way, since a run of length 700 (not 1400 or so) is output just before entering each merge phase, in order to clear the internal memory. Consequently 85 runs are produced in this example, instead of 72. Some of the key steps in the process are

—	A_1	A_1A_1	A_1A_1	A_1A_1
D_4	—	A_1	A_1	A_1
. . . . .				
D_4D_4	D_4D_4	D_4D_4	D_4	—
D_4	D_4	D_4	—	A_{16}
. . . . .				
D_4	$A_{16}D_4D_4$	$A_{16}D_4$	$A_{16}D_4A_1$	A_{16}
D_4	$A_{16}D_4D_4$	$A_{16}D_4D_1$	$A_{16}D_4$	A_{16}
—	$A_{16}D_4$	$A_{16}D_4$	A_{16}	$A_{16}A_{13}$
—	$A_{16}D_4$	A_{16}	$A_{16}A_4$	$A_{16}A_{13}$
—	A_{16}	$A_{16}A_4$	$A_{16}A_4$	$A_{16}A_{13}$
D_{37}	—	$A_{16}\downarrow$	$A_{16}\downarrow$	$A_{16}\downarrow$
—	A_{85}	—	—	—

Example 10. Read-forward oscillating sort. In the final example, replacement selection is not used because all initial runs must be the same length. There-

fore full core loads of 1000 records are internally sorted whenever an initial run is required; this makes $S = 100$. Some key steps in the process are

A_1	A_1	A_1	A_1	A_1
—	—	—	—	A_1A_4
. . . . .				
A_1	A_1	A_1	A_1	A_1A_4
—	—	—	A_1A_4	$\not{A}_1A_4$
—	—	—	A_1A_4	A_1A_4
. . . . .				
A_1	A_1A_4	A_1A_4	A_1A_4	A_1A_4
A_1A_4	$\not{A}_1A_4$	$\not{A}_1A_4$	$\not{A}_1A_4$	$\not{A}_1A_4$
$A_1A_4A_{16}$	—	—	—	—
. . . . .				
—	A_1A_4	A_1A_4	A_1A_4	$A_1A_4A_{16}A_{64}$
A_4	$\not{A}_1A_4$	$\not{A}_1A_4$	$\not{A}_1A_4$	$\not{A}_1A_4A_{16}A_{64}$
A_4A_{16}	—	—	—	$\not{A}_1\not{A}_4A_{16}A_{64}$
$\not{A}_4A_{16}$	A_4	—	—	$\not{A}_1\not{A}_4A_{16}A_{64}$
—	—	—	A_{36}	$\not{A}_1\not{A}_4\not{A}_{16}A_{64}$
A_{100}	—	—	—	—

This routine turned out to be slowest of all, partly because it did not use replacement selection, but mostly because of its rather awkward ending (a two-way merge).

Estimating the running time. Let's see now how to figure out the approximate execution time of a sorting method using MIXT tapes. Could we have predicted the outcomes shown in Chart A without carrying out a detailed simulation?

One way that has traditionally been used to compare different merge patterns is to superimpose graphs such as we have seen in Figs. 70, 74, and 78. These graphs show the effective number of passes over the data, as a function of the number of initial runs, assuming that each initial run has approximately the same length. (See Fig. 85.) But this is *not* a very realistic comparison, because we have seen that different methods lead to different numbers of initial runs; furthermore there is a different "overhead time" caused by the relative frequency of interblock gaps, and the rewind time also has significant effects. All of these machine-dependent features make it impossible to prepare charts which make a valid comparison of the methods on a machine-independent basis. On the other hand, Fig. 85 does show us that, except for balanced merge, the effective number of passes can be reasonably well approximated by smooth curves of the form $\alpha \ln S + \beta$. Therefore we can make a fairly good comparison

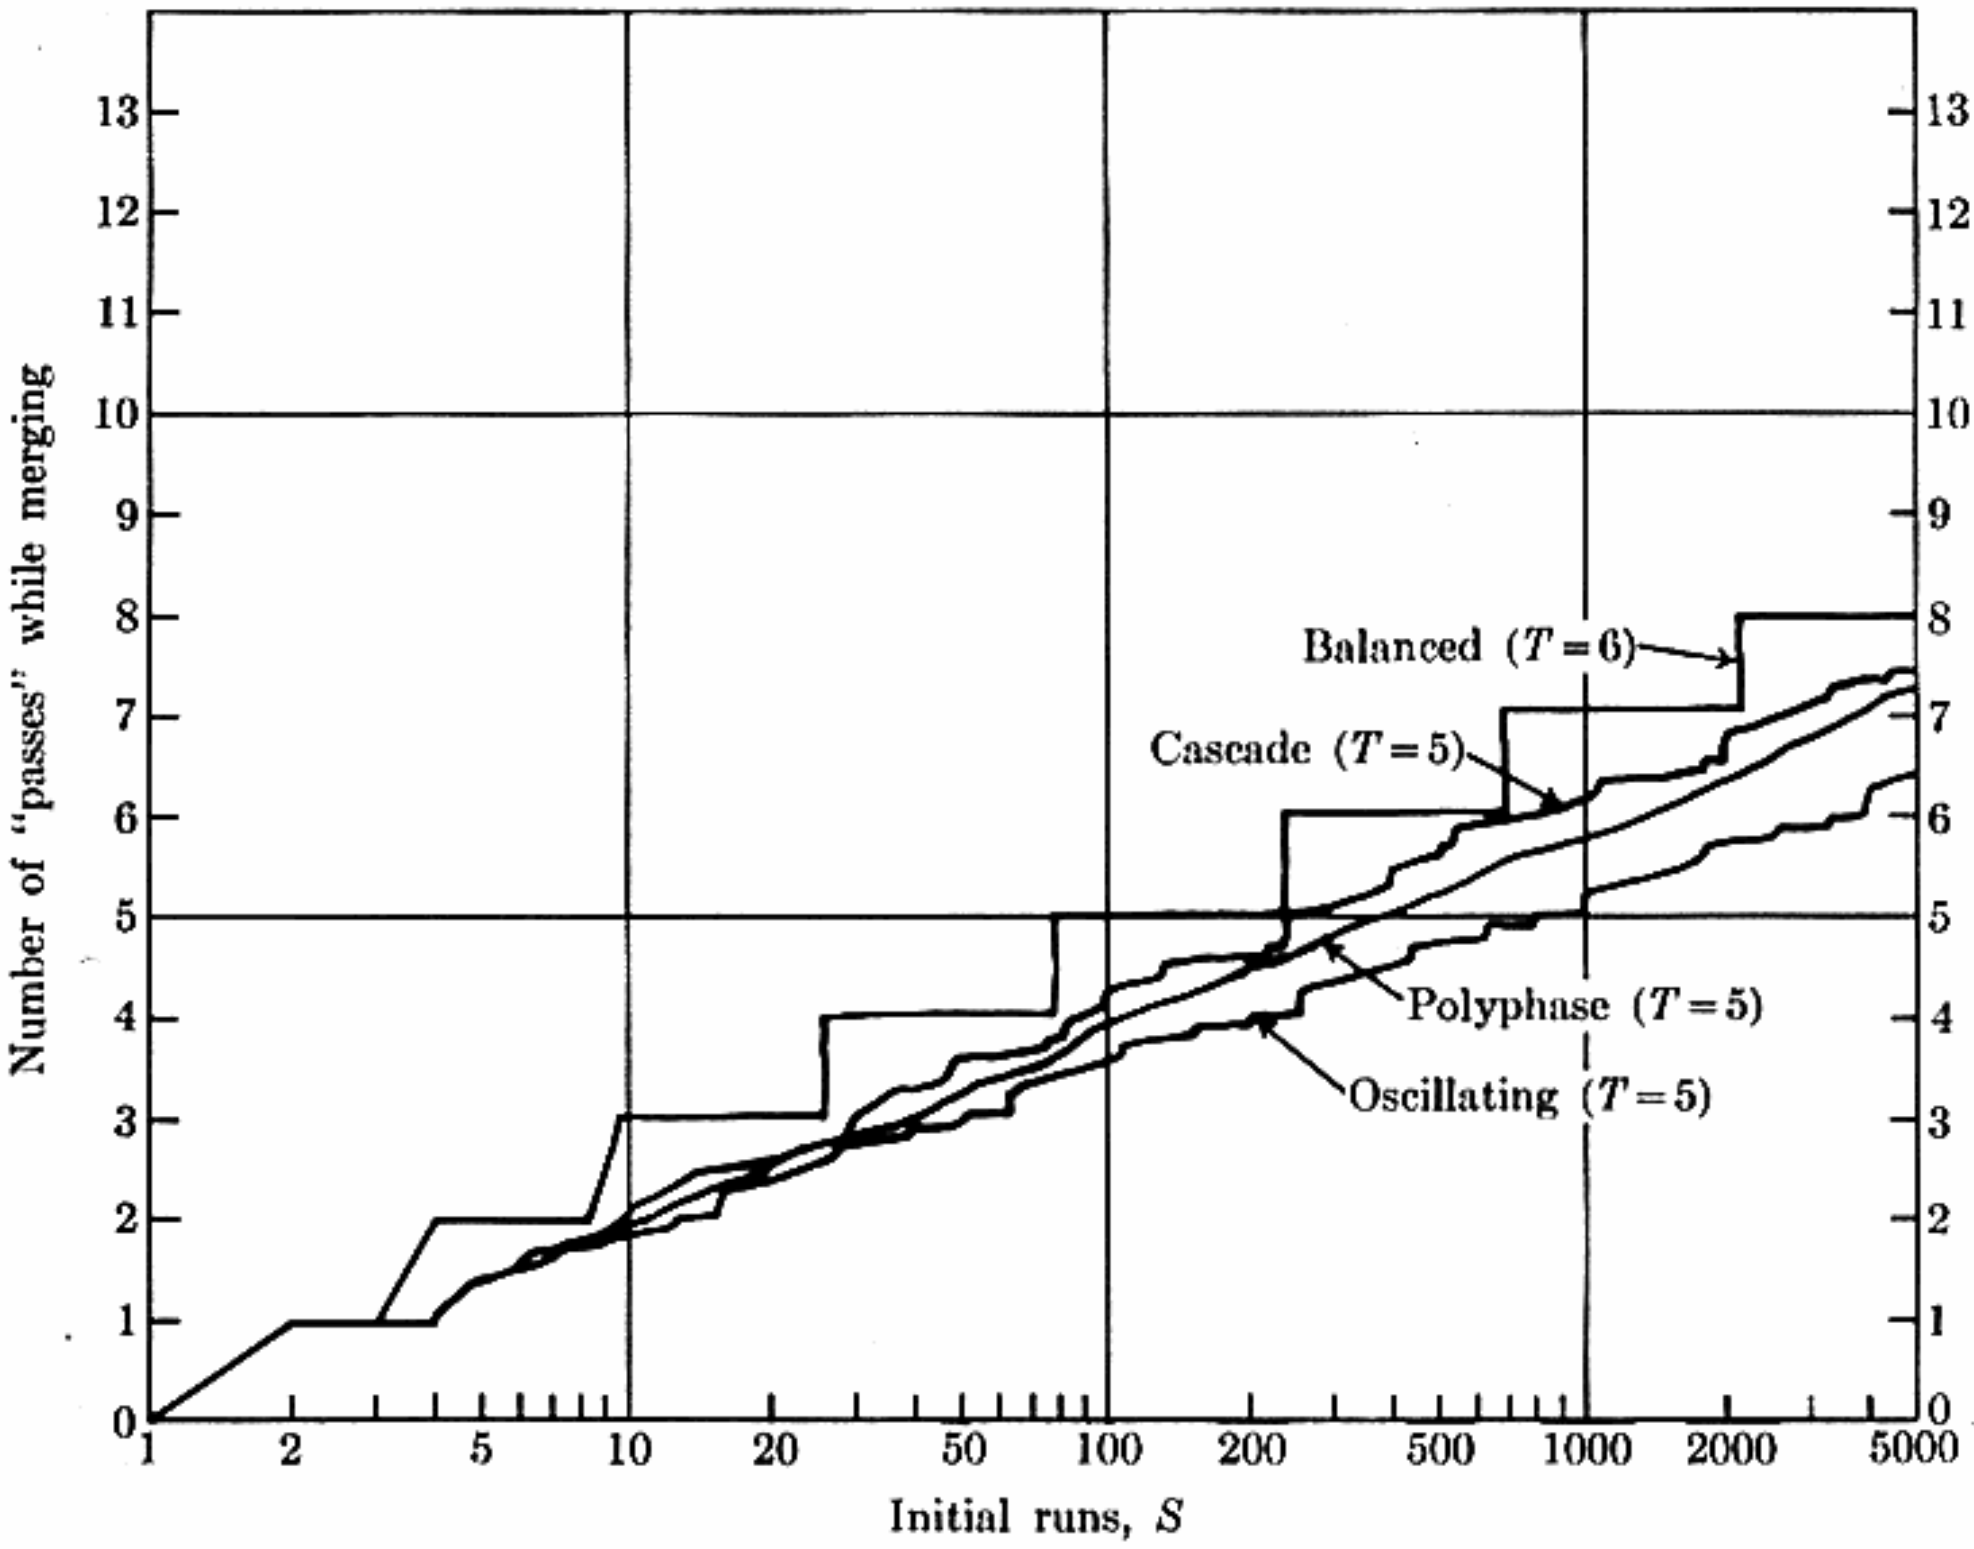

Fig. 85. A somewhat misleading way to compare merge patterns.

of the methods in any particular situation, by studying formulas that approximate the running time. Our goal, of course, is to find formulas that are simple yet sufficiently realistic.

Let us now attempt to develop such formulas, in terms of the following parameters:

N = number of records to be sorted,
C = number of characters per record,
M = number of character positions available in the internal memory (assumed to be a multiple of C),
τ = number of seconds to read or write one character,
$\rho\tau$ = number of seconds to rewind over one character,
$\sigma\tau$ = number of seconds for stop-start time delay,
γ = number of characters per interblock gap,
δ = number of seconds for operator to dismount and replace input tape,
B_i = number of characters per block in the unsorted input,
B_o = number of characters per block in the sorted output.

For MIXT we have $\tau = 1/60000$, $\rho = 2/5$, $\sigma = 300$, $\gamma = 480$. The example application treated above has $N = 100000$, $C = 100$, $M = 100000$, $B_i = B_o = 5000$, $\delta = 30$. These parameters are usually the machine and data characteristics that affect sorting time most critically (although rewind time is often given by a more complicated expression than a simple ratio ρ). Given the above parameters and a merge pattern, we shall compute further quantities such as

$P =$ maximum order of merge in the pattern,

$P' =$ number of records in replacement selection tree,

$S =$ number of initial runs,

$\pi = \alpha \ln S + \beta =$ approximate average number of times each character is read and written, not counting the initial distribution or the final merge,

$\pi' = \alpha' \ln S + \beta' =$ approximate average number of times rewinding over each character during intermediate merge phases,

$B =$ number of characters per block in the intermediate merge phases,

$\omega_i, \omega, \omega_o =$ "overhead ratio," the effective time required to read or write a character (due to gaps and stop/start) divided by the hardware time τ.

The examples of Chart A have chosen block and buffer sizes according to the formula

$$B = \left\lfloor \frac{M}{C(2P+2)} \right\rfloor C, \tag{1}$$

so that the blocks can be as large as possible consistent with the buffering scheme of Algorithm F. (In order to avoid trouble during the final pass, P should be small enough that (1) makes $B \geq B_o$.) The size of the tree during replacement selection is then

$$P' = (M - 2B_i - 2B)/C. \tag{2}$$

For random data the number of initial runs S can be estimated as

$$S \approx \left\lceil \frac{N}{2P'} + \frac{7}{6} \right\rceil, \tag{3}$$

using the results of Section 5.4.1. Assuming that $B_i < B$ and that the input tape can be run at full speed during the distribution (see below), it takes about $NC\omega_i\tau$ seconds to distribute the initial runs, where

$$\omega_i = (B_i + \gamma)/B_i. \tag{4}$$

While merging, the buffering scheme allows simultaneous reading, writing, and computing, but the frequent switching between input tapes means that we must add the stop/start time penalty; therefore we set

$$\omega = (B + \gamma + \sigma)/B, \tag{5}$$

and the merge time is approximately

$$(\pi + \rho\pi')NC\omega\tau. \tag{6}$$

This formula penalizes rewind slightly, since ω includes stop/start time, but other considerations (such as rewind interlock and the penalty for reading from load point) usually compensate for this. The final merge pass, assuming that $B_o \leq B$, is constrained by the overhead ratio

$$\omega_o = (B_o + \gamma)/B_o. \tag{7}$$

We may estimate the running time of the final merge and rewind as

$$NC(1 + \rho)\omega_o\tau;$$

in practice it might take somewhat longer due to the presence of unequal block lengths (input and output are not synchronized as in Algorithm F), but the running time will be pretty much the same for all merge patterns.

Before going into more specific formulas for individual patterns, let us try to justify two of the assumptions made above.

a) *Can replacement selection keep up with the input tape?* In the examples of Chart A it probably can, since it takes about ten iterations of the inner loop of Algorithm 5.4.1R to select the next record, and we have $C\omega_i\tau >$ 1667 microseconds in which to do this. With careful programming of the replacement selection loop, this can be done on many (but not all) machines. Note that the situation is somewhat less critical while merging: the computation time per record is almost always less than the tape time per record during a P-way merge, since P isn't very large.

b) *Should we really choose B to be the maximum possible buffer size, as in* (1)? A large buffer size cuts down the overhead ratio ω in (5); but it also increases the number of initial runs S, since P' is decreased. It is not immediately clear which factor is more important. Considering the merging time as a function of $x = CP'$, we can express it in the form

$$\left(\theta_1 \ln\left(\frac{N}{x} + \frac{7}{6}\right) + \theta_2\right)\left(\frac{\theta_3 - x}{\theta_4 - x}\right) \tag{8}$$

for some appropriate constants θ_1, θ_2, θ_3, θ_4, with $\theta_3 > \theta_4$. Differentiating with respect to x shows that there is some N_0 such that for all $N \geq N_0$ it does not pay to increase x at the expense of buffer size. In the sorting

application of Chart A, for example, N_0 turns out to be roughly 10000; when sorting more than 10000 records the large buffer size is superior.

Note however that with balanced merge the number of passes jumps sharply when S passes a power of P. If an approximation to N is known in advance, the buffer size should be chosen so that S will most likely be slightly less than a power of P. For example, the buffer size for the first line of Chart A was 12500; since $S = 78$, this was very satisfactory, but if S had turned out to be 82 it would have been much better to decrease the buffer size a little.

Formulas for the ten examples. Returning to Chart A, let us try to give formulas which approximate the running time in each of the ten methods. In most cases the basic formula

$$NC\omega_i\tau + (\pi + \rho\pi')NC\omega\tau + (1 + \rho)NC\omega_o\tau \tag{9}$$

will be a sufficiently good approximation to the overall sorting time, once we have specified the number of intermediate merge passes $\pi = \alpha \ln S + \beta$ and the number of intermediate rewind passes $\pi' = \alpha' \ln S + \beta'$. Sometimes it is necessary to add a further correction to (9); details for each method can be worked out as follows:

Example 1. Read-forward balanced merge. The formulas $\pi = \lceil \ln S/\ln P \rceil - 1$, $\pi' = \lceil \ln S/\ln P \rceil/P$ may be used for P-way merging on $2P$ tapes.

Example 2. Read-forward polyphase merge. We may take $\pi' \approx \pi$, since every phase is usually followed by a rewind of about the same length as the previous merge. From Table 5.4.2–1 we get the values $\alpha = 0.795$, $\beta = 0.864 - 2$, in the case of six tapes. (This "-2" is due to the fact that the table entry includes the initial and final passes as well as the intermediate ones.) The time for rewinding the input tape after the initial distribution, namely $\rho NC\omega_i\tau + \delta$, should be added to (9).

Example 3. Read-forward cascade merge. Table 5.4.3–1 gives the values $\alpha = 0.773$, $\beta = 0.808 - 2$. Rewind time is comparatively difficult to estimate; perhaps setting $\pi' \approx \pi$ is accurate enough. As in example 2, we need to add the initial rewind time to (9).

Example 4. Tape-splitting polyphase merge. Table 5.4.2–5 gives $\alpha = 0.752$, $\beta = 1.024 - 2$. The rewind time is almost overlapped except after the initialization ($\rho NC\omega_i\tau + \delta$) and two phases near the end ($2\rho NC\omega\tau$ times 36 percent). We may also subtract 0.18 from β since the first half phase is overlapped by the initial rewind.

Example 5. Cascade merge with rewind overlap. Here we use Table 5.4.3–1 for $T = 5$, to get $\alpha = 0.897$, $\beta = 0.800 - 2$. Nearly all of the unoverlapped rewind occurs just after the initial distribution and just after each two-way merge. After a perfect initial distribution, the longest tape contains about $1/g$ of the data, where g is the "growth ratio." After each two-way merge the amount of rewind in the six-tape case is $d_k\, d_{n-k}$ (cf. exercise 5.4.3–5), and it can be shown that in the T-tape case the amount of rewind after two-way merges is approximately

$$(2/(2T - 1))(1 - \cos(4\pi/(2T - 1)))$$

of the file. In our case ($T = 5$) this is $\frac{2}{9}(1 - \cos 80°) \approx 0.183$ of the file, and the number of times it occurs is $0.946 \ln S + 0.796 - 2$.

Example 6. Read-backward balanced merge. This is like example 1, except that

most of the rewinding is eliminated. The change in direction from forward to backward causes some delays, but they are not significant. There is a 50–50 chance that rewinding before the final pass will be necessary, so we may take $\pi' = 1/(2P)$.

Example 7. Read-backward polyphase merge. Since replacement selection in this case produces runs that change direction about every P times, we must replace (3) by another formula for S. A reasonably good approximation (cf. exercise 5.4.1–24) is $S = \lceil N(3 + 1/P)/6P' \rceil + 1$. All rewind time is eliminated, and Table 5.4.2–1 gives $\alpha = 0.863, \beta = 0.921 - 2$.

Example 8. Read-backward cascade merge. From Table 5.4.3–1 we have $\alpha = 0.897$, $\beta = 0.800 - 2$. The rewind time can be estimated as twice the difference "passes with copying" minus "passes without copying" in that table, plus $1/(2P)$ in case the final merge must be preceded by rewinding to get ascending order.

Example 9. Read-backward oscillating sort. In this case replacement selection has to be started and stopped many times; bursts of $P - 1$ to $2P - 1$ runs are distributed at a time, averaging P in length; the average length of runs therefore turns out to be approximately $P'(2P - 4/3)/P$, and we may estimate $S = \lceil N/((2 - 4/(3P))P') \rceil + 1$. A little time is used to switch from merging to distribution and vice-versa; this is approximately the time to read in P' records from the input tape, namely $P'C\omega_i\tau$, and it occurs about S/P times. Rewind time and merging time may be estimated as in example 6.

Example 10. Read-forward oscillating sort. This method is not easy to analyze, because the final "cleanup" phases performed after the input is exhausted are not as efficient as the earlier phases. Ignoring this troublesome aspect, and simply calling it one extra pass, we can estimate the merging time by setting $\alpha = 1/\ln P$, $\beta = 0$, and $\pi' = \pi/P$. The distribution of runs is somewhat different in this case, since replacement selection is not used; we set $P' = M/C$ and $S = \lceil N/P' \rceil$. With care it is possible to overlap computing, reading, and writing during the distribution, with an additional factor of about $(M + 2B)/M$ in the overhead. The "mode-switching" time mentioned in example 9 is not needed in the present case because it is overlapped by rewinding. So the estimated sorting time in this case is (9) plus $2BNC\omega_i\tau/M$.

Table 1

SUMMARY OF SORTING TIME ESTIMATES

Example	P	B	P'	S	ω	α	β	α'	β'	(9)	Additions to (9)	Estimated total	Actual total
1	3	12500	650	79	1.062	0.910	−1.000	0.303	0.000	1064		1064	1076
2	5	8300	734	70	1.094	0.795	−1.136	0.795	−1.136	1010	$\rho NC\omega_i\tau + \delta$	1113	1103
3	5	8300	734	70	1.094	0.773	−1.192	0.773	−1.192	972	$\rho NC\omega_i\tau + \delta$	1075	1127
4	4	10000	700	73	1.078	0.752	−0.994	0.000	0.720	844	$\rho NC\omega_i\tau + \delta$	947	966

Table 1 shows that the estimates are not too bad in these examples, although in a few cases there is a discrepancy of 50 seconds or so. The formulas in examples 2 and 3 indicate that cascade merge should be preferable to poly-

phase on six tapes, yet in practice polyphase was better! The reason is that graphs like Fig. 85 (which shows the five-tape case) are more nearly straight lines for the polyphase algorithm; cascade is superior to polyphase on six tapes for $14 \le S \le 15$ and $43 \le S \le 55$, near the "perfect" cascade numbers 15 and 55, but the polyphase distribution of Algorithm 5.4.2D is equal or better for all other $S \le 100$. Cascade will win over polyphase as $S \to \infty$, but S doesn't actually approach ∞! The underestimate in example 9 is due to similar circumstances; polyphase was superior to oscillating even though the asymptotic theory tells us that oscillating will be best for large S.

Some miscellaneous remarks. It is now appropriate to make a few more or less random observations about tape merging:

1) The above formulas show that the sorting is essentially a function of N times C, not of N and C independently. Except for a few relatively minor considerations (such as the fact that B was taken to be a multiple of C), our formulas say that it takes about as long to sort one million records of 10 characters each as to sort 100 thousand records of 100 characters each. Actually there may be a difference, not revealed in our formulas, because of the space used by link fields during replacement selection. In any event the size of the *key* makes hardly any difference, unless keys get so long and complicated that internal computation cannot keep up with the tapes.

With long records and short keys it is tempting to "detach" the keys, sort them first, and then somehow rearrange the records as a whole. But this idea doesn't seem to work out, it merely postpones the agony, because the final rearrangement procedure takes about as long as a conventional merge sort would take.

2) We have seen that it takes from 15 to 19 minutes to sort 100,000 100-character records under the above assumptions. How long would it take to sort them on a card sorter? This question is of practical interest because card sorters are cheaper than computers. Assuming that each record can be squeezed onto an 80-column card, and that the alphabetic key occupies six columns, requiring an average of $1\frac{2}{3}$ passes to sort on each column, we must run each card through the machine about 10 times. At 1000 cards per minute that would take 1000 minutes, which is almost 17 hours. (During this time there is a fairly good chance that some cards will get inadvertently shuffled or jammed in the machine.)

3) When writing a sort routine that is to be used repeatedly, it is wise to estimate its running time very carefully and to compare the theory with actual observed performance. Since the theory of sorting has been fairly well developed, this procedure has been known to turn up bugs in the input/output hardware or software on existing systems; the service was slower than it should have been, yet nobody had noticed it until the sorting routine ran too slowly!

4) Some computer systems have two "banks" of tape units, attached to separate "channels" in such a way that simultaneous reading and writing is

permitted only on tapes from opposite banks. Balanced merging is especially well suited to such configurations. Consider, for example, the case of six tapes with three in each bank, and suppose that we want to do polyphase merging with $T = 6$. During a five-way merge, two of the input tapes will be on the wrong bank, so roughly two-fifths of the input time cannot be overlapped with output. This adds approximately 40 percent to the sorting time, so that balanced merge turns out to be better than polyphase even in the read-backward case.

5) Our analaysis of replacement selection has been carried out for "random" files, but the files which actually arise in practice very often have a good deal of existing order. (In fact, sometimes people will sort a file that is already in order, just to be sure.) Therefore experience has shown that replacement selection is preferable to other kinds of internal sort, even more so than our formulas indicate. This advantage is slightly mitigated in the case of read-backward polyphase sorting, since a number of descending runs must be produced; indeed, R. L. Gilstad (who first published the polyphase merge) originally rejected the read-backward technique for that reason. But he noticed later that alternating directions will still pick up long ascending runs. Furthermore, read-backward polyphase is the only standard technique which likes descending input files as well as ascending ones.

6) Another advantage of replacement selection is that it allows simultaneous reading, writing, and computing. If we merely did the internal sort in an obvious way—filling the memory, sorting it, then writing it out as it becomes filled with the next load—the distribution pass would take about twice as long!

The only other internal sort we have discussed which appears to be amenable to simultaneous reading, writing, and computing is heapsort. (This idea has been used in preparing example 10 of Chart A.) Suppose for convenience that the internal memory holds 1000 records, and that each block on tape holds 100. We may proceed as follows, letting $B_1\, B_2 \ldots B_{10}$ stand for the contents of memory divided into ten 100-record blocks.

Step 0. Fill memory, and make the elements of $B_2 \ldots B_{10}$ satisfy the inequalities for a heap (with smallest element at the root).

Step 1. Make $B_1 \ldots B_{10}$ into a heap, then select out the least 100 records and move them to B_{10}.

Step 2. Write out B_{10}, while selecting the smallest 100 records of $B_1 \ldots B_9$ and moving them to B_9.

Step 3. Read into B_{10}, and write out B_9, while selecting the smallest 100 records of $B_1 \ldots B_8$ and moving them to B_8.

⋮

Step 9. Read into B_4, and write out B_3, while selecting the smallest 100 records of $B_1\, B_2$ and moving them to B_2 and while making the heap inequalities valid in $B_5 \ldots B_{10}$.

Step 10. Read into B_3, and write out B_2, while sorting B_1 and while making the heap inequalities valid in $B_4 \ldots B_{10}$.

Step 11. Read into B_2, and write out B_1, while making the heap inequalities valid in $B_3 \ldots B_{10}$.

Step 12. Read into B_1, while making the heap inequalities valid in $B_2 \ldots B_{10}$. Return to step 1. ▮

7) We have been assuming that the number N of records to be sorted is not known in advance. Actually in most computer applications it would be possible to keep track of the number of records in all files at all times, and we could assume that our computer system is capable of telling us the value of N. How much help would this be? Unfortunately, not very much! We have seen that replacement selection is very advantageous, but it leads to an unpredictable number of initial runs. In a balanced merge we could use information about N to set the buffer size B in such a way that S will probably be just less than a power of P; and in a polyphase distribution with optimum placement of dummy runs we could use information about N to decide what level to shoot for (cf. Table 5.4.2–2).

Alternatively, without using replacement selection we could apply the preorder merge, described at the close of Section 5.4.4, making it into an oscillating sort that distributes initial runs in the appropriate direction at the appropriate moment (instead of taking them from "tape A" as described there). This method is essentially *optimum* among all methods that do internal sorting without replacement selection, since it merges according to the best possible P-ary tree; but it actually runs more slowly than methods based on replacement selection.

8) Tape drives tend to be the least reliable part of a computer. Maintenance men typically have more calls to fix tape units than any other component of a machine, and computer operators must learn how to restart jobs after a tape failure. The author has never yet seen an installation with 10 or more tape units all simultaneously in good working condition! Therefore it is considered axiomatic that *the original input tape should never be destroyed until it is known that the entire sort has been satisfactorily completed.* The "operator dismount time" is annoying in some of the examples of Chart A, but it would be too risky to overwrite the input in view of the probability that something might go wrong during a long sort.

9) When changing from forward write to backward read, we can save some time by never writing the last bufferload onto tape; it will just be read back in again anyway! Chart A shows that this trick actually saves comparatively little time, except in the oscillating sort where directions are reversed frequently.

10) If we have a large number of tape units available, it is not always best to use as many of them as possible in order to get a "high order of merge." For example, a higher order of merge usually implies a smaller block size; and

the percentage difference between $\log_P S$ and $\log_{P+1} S$ is not very great when P is large. Consider also the poor computer operator who has to mount all those scratch tapes. On the other hand, exercise 12 describes an interesting way to make use of additional tape units, grouping them so as to overlap input/output time without increasing the order of merge.

11) On machines like MIX, which have fixed rather small block sizes, hardly any internal memory is needed while merging. Oscillating sort then becomes more attractive, because it becomes possible to maintain the replacement selection tree in memory while merging. In fact we can improve on oscillating sort in this case (as suggested by Colin J. Bell in 1962), merging a new initial run into the output every time we merge from the working tapes!

12) We have observed that multireel files should be sorted one reel at a time, in order to avoid excessive tape handling. This is sometimes called a "reel time" application. Actually a balanced merge on six tapes can sort *three* reelfulls, up until the time of the final merge, if it has been programmed carefully.

In order to merge a fairly large number of individually sorted reels, a minimum-path-length merging tree will be fastest (cf. Section 5.4.4). This construction was first made by E. H. Friend [*JACM* **3** (1956), 166–167]; then W. H. Burge [*Information and Control* **1** (1958), 181–197] pointed out that an optimum way to merge runs of given (possibly unequal) lengths is obtained by constructing a tree with minimum *weighted* path length, using the run lengths as weights (cf. Sections 2.3.4.5 and 5.4.9), if we ignore tape handling time. But multireel files should probably be kept on a disk or other large memory instead of tape.

13) Our discussions have blithely assumed that we have direct control over the input/output instructions for tape units, and that no complicated system interface keeps us from using tape as efficiently as the tape designers intended. These idealistic assumptions give us insights into the tape merging problem, and may give some insights into the proper design of operating systems, but we should realize that multiprogramming and multiprocessing can make the situation considerably more complicated.

14) The issues we have studied in this section were first discussed in print by E. H. Friend [*JACM* **3** (1956), 134–168], W. Zoberbier [*Elektron. Datenverarb.* **5** (1960), 28–44], and M. A. Goetz [*Digital Computer User's Handbook* (New York: McGraw-Hill, 1967) 1.292–1.320].

Summary. We can sum up what we have learned about comparing different merge patterns in the following way:

Theorem A. *It is difficult to decide which merge pattern is best in a given situation.* ∎

The examples we have seen in Chart A show how 100,000 randomly ordered 100-character records (or 1 million 10-character records) might be sorted using

six tapes under realistic assumptions. This much data fills about half of a tape, and it can be sorted in about 15 to 19 minutes; however, there is considerable variation in available tape equipment, and running times for such a job may vary between about four minutes and about two hours on different machines. About 3 minutes of the time in our examples were used for initial distribution of runs and internal sorting; about $4\frac{1}{2}$ minutes were used for the final merge and rewinding the output tape; and about $7\frac{1}{2}$ to $11\frac{1}{2}$ minutes were spent in intermediate stages of merging.

Given six tapes that cannot read backward, the best sorting method under our assumptions was the "tape-splitting polyphase merge" (example 4); and for tapes that do allow backward reading, the best method turned out to be read-backward polyphase with a complicated placement of dummy runs (example 7). Oscillating sort (example 9) was a close second. In both cases the cascade merge provided a simpler alternative which was only slightly slower (examples 5 and 8). In the read-forward case, a straightforward balanced merge (example 1) was surprisingly effective, partly by luck in this particular example but partly also because it spends comparatively little time rewinding.

The situation would change somewhat if we had a different number of available tapes.

Sort generators. Given the wide variability of data and equipment characteristics, it is almost impossible to write a single external sorting program that is satisfactory in very many applications. And it is also rather difficult to prepare a program that really handles tapes efficiently. Therefore the preparation of sorting software is a particularly challenging job. A *sort generator* is a program that produces machine code specially tailored to particular sorting applications, based on parameters which describe the data format and the hardware configuration. Such a program is often tied to high-level languages such as COBOL or PL/I, or it might be written as a set of macros to be used with a macroassembler.

One of the features normally provided by a sort generator is the ability to insert "own coding," special instructions to be incorporated into the first and last passes of the sorting routine. First-pass own coding is usually used to edit the input records, often shrinking them or slightly expanding them into a form which is easier to sort. For example, suppose that the input records are to be sorted on a nine-character key which represents a date in month-day-year format:

```
JUL041776  OCT311517  NOV051605  JUL141789  NOV201917
```

On the first pass the three-letter month code can be looked up in a table, and the month codes can be replaced by numbers with the most significant fields at the left:

```
17760704  15171031  16051105  17890714  19171120
```

This decreases the record length and makes subsequent comparisons much

simpler. (An even more compact code could also be substituted.) Last-pass own coding can be used to restore the original format, and/or to make other desired changes to the file, and/or to compute some function of the output records. The merging algorithms we have studied are organized in such a way that it is easy to distinguish the last pass from other merge phases. Note that when own coding is present there must be at least two passes over the file even if it is initially in order. Own coding which changes the record size can make it difficult for the oscillating sort to overlap some of its input/output operations.

Sort generators also take care of system details like tape label conventions, and they often provide for "hash totals" or other checks to make sure that none of the data has been lost or altered. Sometimes there are provisions for stopping the sort at convenient places and resuming later. The fanciest generators allow records to have dynamically varying lengths [cf. D. J. Waks, *CACM* **6** (1963), 267–272].

***Merging with fewer buffers.** We have seen that $2P + 2$ buffers are sufficient to keep tapes moving rapidly during a P-way merge. Let us conclude this section by making a mathematical analysis of the merging time when *less* than $2P + 2$ buffers are present.

Two output buffers are clearly desirable, since we can be writing from one while forming the next block of output in the other. Therefore we may ignore the output question entirely, and concentrate only on the input.

Suppose there are $P + Q$ input buffers, where $1 \le Q \le P$. We shall use the following approximate model of the situation, as suggested by L. J. Woodrum [*IBM Systems J.* **9** (1970), 118–144]: It takes one unit of time to read a block of tape. During this time there is a probability p_0 that no input buffers have been emptied, p_1 that one has been emptied, $p_{\ge 2}$ that two or more have been, etc. When completing a tape read we are in one of $Q + 1$ states:

State 0. Q buffers are empty; we begin to read a block into one of them from the appropriate file, using the forecasting technique explained earlier in this section. After one unit of time we go to state 1 with probability p_0, otherwise we remain in state 0.

State 1. $Q - 1$ buffers are empty; we begin to read into one of them, forecasting the appropriate file. After one unit of time we go to state 2 with probability p_0, to state 1 with probability p_1, and to state 0 with probability $p_{\ge 2}$.

⋮

State $Q - 1$. One buffer is empty; we begin to read into it, forecasting the appropriate file. After one unit of time we go to state Q with probability p_0, to state $Q - 1$ with probability $p_1, \ldots,$ to state 1 with probability p_{Q-1}, and to state 0 with probability $p_{\ge Q}$.

State Q. All buffers are filled. Tape reading stops for an average of μ units of time and then we go to state 1.

We start in state 0. This model of the situation corresponds to a *Markov process* (cf. exercise 2.3.4.2–26), which can be analyzed via generating functions in the following interesting way: Let z be an arbitrary parameter, and assume that each time we have a chance to read from tape we make a decision to do so with probability z, but we decide to terminate the algorithm with probability $1 - z$. Now let $g_Q(z) = \sum_{n\ge 0} a_n^{(Q)} z^n (1 - z)$ be the average number of times that state Q occurs in such a process; it follows that $a_n^{(Q)}$ is the average number of times state Q occurs when exactly n blocks have been read. Then $n + a_n\mu$ is the average total time for input + computation. If we had perfect overlap, as in the $(2P + 2)$-buffer algorithm, the total time would be only n units, so $a_n\mu$ represents the "reading hangup" time.

Let A_{ij} be the probability that we go from state i to state j in this process, for $0 \le i, j \le Q + 1$, where $Q + 1$ is a new "stopped" state. For example, the A-matrix takes the following forms for small Q:

$$Q = 1: \quad \begin{pmatrix} p_{\ge 1}z & p_0 z & 1 - z \\ 1 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix},$$

$$Q = 2: \quad \begin{pmatrix} p_{\ge 1}z & p_0 z & 0 & 1 - z \\ p_{\ge 2}z & p_1 z & p_0 z & 1 - z \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix},$$

$$Q = 3: \quad \begin{pmatrix} p_{\ge 1}z & p_0 z & 0 & 0 & 1 - z \\ p_{\ge 2}z & p_1 z & p_0 z & 0 & 1 - z \\ p_{\ge 3}z & p_2 z & p_1 z & p_0 z & 1 - z \\ 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \end{pmatrix}.$$

Exercise 2.3.4.2–26b tells us that $g_Q(z) = \text{cofactor}_{Q0}(I - A)/\det(I - A)$. Thus for example when $Q = 1$ we have

$$g_1(z) = \det\begin{pmatrix} 0 & -p_0 z & z - 1 \\ 1 & 0 & 0 \\ 0 & 0 & 1 \end{pmatrix} \Big/ \det\begin{pmatrix} 1 - p_{\ge 1}z & -p_0 z & z - 1 \\ -1 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix}$$

$$= \frac{p_0 z}{1 - p_1 z - p_0 z} = \frac{p_0 z}{1 - z} = \sum_{n\ge 0} n p_0 z^n (1 - z),$$

so $a_n^{(1)} = np_0$. This of course was obvious *a priori*, since the problem is very simple when $Q = 1$. A similar calculation when $Q = 2$ (see exercise 14) gives the less obvious formula

$$a_n^{(2)} = \frac{p_0^2 n}{1 - p_1} - \frac{p_0^2 (1 - p_1^n)}{(1 - p_1)^2}. \tag{10}$$

In general we can show that $a_n^{(Q)}$ has the form $\alpha^{(Q)}n + O(1)$ as $n \to \infty$, where the constant $\alpha^{(Q)}$ is not terribly difficult to calculate. (See exercise 15.) It turns out that $\alpha^{(3)} = p_0^3/((1 - p_1)^2 - p_0p_2)$.

The nature of merging makes it fairly reasonable to assume that $\mu = 1/P$ and that we have a binomial distribution

$$p_k = \binom{P}{k}\left(\frac{1}{P}\right)^k\left(\frac{P-1}{P}\right)^{P-k}.$$

For example, when $P = 5$ we have $p_0 = .32768$, $p_1 = .4096$, $p_2 = .2048$, $p_3 = .0512$, $p_4 = .0064$, and $p_5 = .00032$; hence $\alpha^{(1)} = 0.328$, $\alpha^{(2)} = 0.182$, and $\alpha^{(3)} = 0.127$. In other words, if we use $5 + 3$ input buffers instead of $5 + 5$, we can expect an additional "reading hangup" time of about $0.127/5 \approx$ 2.5 percent.

Of course this model is only a very rough approximation; we know that when $Q = P$ there is no hangup time at all, but the model says there is. The extra reading hangup time for smaller Q just about counterbalances the savings in overhead gained by having larger blocks, so the simple $Q = P$ scheme seems to be vindicated.

EXERCISES

1. [*13*] Give a formula for the exact number of characters per tape, when every block on the tape contains n characters. Assume that the tape could hold exactly 23000000 characters if there were no interblock gaps.

2. [*15*] Explain why the first buffer for File 2, in line 6 of Fig. 84, is completely blank.

3. [*20*] Would Algorithm F work properly if there were only $2P - 1$ input buffers instead of $2P$? If so, prove it; if not, give an example where it fails.

4. [*20*] How can Algorithm F be changed so that it works also when $P = 1$?

▶ **5.** [*21*] When equal keys are present on different files, it is necessary to be very careful in the forecasting process. Explain why, and show how to avoid difficulty by defining the merging and forecasting operations of Algorithm F more precisely.

6. [*22*] What changes should be made to Algorithm 5.4.3C, in order to convert it into an algorithm for cascade merge *with rewind overlap*, on $T + 1$ tapes?

▶ **7.** [*26*] The initial distribution in example 7 of Chart A produces

$$(A_1D_1)^{11} \qquad D_1(A_1D_1)^{10} \qquad D_1(A_1D_1)^{9} \qquad D_1(A_1D_1)^{7}$$

on tapes 1–4, where $(A_1D_1)^7$ means $A_1D_1A_1D_1A_1D_1A_1D_1A_1D_1A_1D_1A_1D_1$. Show how to insert additional A_0's and D_0's in a "best possible" way (in the sense that the overall number of initial runs processed while merging is minimized), bringing the distribution up to

$$A(DA)^{14} \qquad (DA)^{28} \qquad (DA)^{26} \qquad (DA)^{22}.$$

Hint: To preserve parity it is necessary to insert many of the A_0's and D_0's as adjacent

pairs. The merge numbers for each initial run may be computed as in exercise 5.4.4–5; some simplification occurs since adjacent runs always have adjacent merge numbers.

8. [*20*] Chart A shows that most of the schemes for initial distribution of runs (with the exception of the initial distribution for the cascade merge) tend to put consecutive runs onto different tapes. If consecutive runs went onto the same tape we could save the stop/start time; would it therefore be a good idea to modify the distribution algorithms so that they switch tapes less often?

▸ **9.** [*22*] Estimate how long the read-backward polyphase algorithm would have taken in Chart A, if we had used all $T = 6$ tapes for sorting, instead of $T = 5$ as in example 7. Was it wise to avoid using the input tape?

10. [*M23*] Use the analyses in Sections 5.4.2 and 5.4.3 to show that the length of each rewind during a standard six-tape polyphase or cascade merge is rarely more than about 54 percent of the file (except for the initial and final rewinds, which cover the entire file).

11. [*23*] By modifying the appropriate entries in Table 1, estimate how long the first nine examples of Chart A would have taken if we had a combined low speed/high speed rewind. Assume that $\rho = 1$ when the tape is less than about one-fourth full, and that the rewind time for fuller tapes is approximately five seconds plus the time which would be obtained for $\rho = \frac{1}{5}$. Change example 8 so that it uses cascade merge *with* copying, since rewinding and reading forward is slower than copying in this case. [*Hint:* Use the result of exercise 10.]

12. [*40*] Consider partitioning six tapes into three pairs of tapes, with each pair playing the role of a single tape in a polyphase merge with $T = 3$. One tape of each pair will contain blocks 1, 3, 5, . . . and the other tape will contain blocks 2, 4, 6, . . . ; in this way we can essentially have two input tapes and two output tapes active at all times while merging, effectively doubling the merging speed. (a) Find an appropriate way to extend Algorithm F to this situation. How many buffers should there be? (b) Estimate the total running time which would be obtained if this method were used to sort 100,000 100-character records, considering both the read-forward and read-backward cases.

13. [*20*] Can a five-tape oscillating sort, as defined in Algorithm 5.4.5B, be used to sort four reelfulls of input data, up until the time of the final merge?

14. [*M19*] Derive (10).

15. [*HM29*] Prove that $g_Q(z) = h_Q(z)/(1 - z)$, where $h_Q(z)$ is a rational function of z having no singularities inside the unit circle; hence $a_n^{(Q)} = h_Q(1)n + O(1)$ as $n \to \infty$. In particular, show that

$$h_3(1) = \det\begin{pmatrix} 0 & -p_0 & 0 & 0 \\ 0 & 1-p_1 & -p_0 & 0 \\ 0 & -p_2 & 1-p_1 & -p_0 \\ 1 & 0 & 0 & 0 \end{pmatrix} \Big/ \det\begin{pmatrix} 1 & -p_0 & 0 & 0 \\ 1 & 1-p_1 & -p_0 & 0 \\ 1 & -p_2 & 1-p_1 & -p_0 \\ 0 & 0 & -1 & 1 \end{pmatrix}.$$

16. [*M46*] Analyze merging with $P + Q$ input buffers more carefully than is done in the text, using a more accurate model.

17. [*41*] Carry out detailed studies of the problem of sorting 100,000 100-character records, drawing charts such as those in Chart A, assuming that 3, 4, or 5 tapes are available.

*5.4.7. External Radix Sorting

The previous sections have discussed the process of tape sorting by merging; but there is another way to sort with tapes, based on the radix sorting principle used in mechanical card sorters (cf. Section 5.2.5). This method is sometimes called distribution sorting, column sorting, pocket sorting, digital sorting, separation sorting, etc.; it turns out to be essentially the *opposite* of merging!

Suppose, for example, that we have four tapes and that there are only eight possible keys: 0, 1, 2, 3, 4, 5, 6, 7. If the input data is on tape T1, we can begin by transferring all even keys to T3, all odd keys to T4:

	T1	T2	T3	T4
Given	{0, 1, 2, 3, 4, 5, 6, 7}	—	—	—
Pass 1	—	—	{0, 2, 4, 6}	{1, 3, 5, 7}

Now we rewind, and read T3 and then T4, putting {0, 1, 4, 5} on T1 and {2, 3, 6, 7} on T2:

Pass 2	{0, 4} {1, 5}	{2, 6} {3, 7}	—	—

(The notation "{0, 4} {1, 5}" stands for a file which contains some records whose keys are all 0 or 4, followed by records whose keys are all 1 or 5. Note that T1 now contains those keys whose middle binary digit is 0.) After rewinding again and distributing 0, 1, 2, 3 to T3 and 4, 5, 6, 7 to T4, we have

Pass 3			{0} {1} {2} {3}	{4} {5} {6} {7}

Now we can finish up by copying T4 to the end of T3. In general, if the keys range from 0 to $2^k - 1$, we could sort the file in an analogous way using k passes, followed by a final "collection" phase which copies about half of the data from one tape to another. With six tapes we could use radix 3 representations in a similar way, to sort keys from 0 to $3^k - 1$ in k passes.

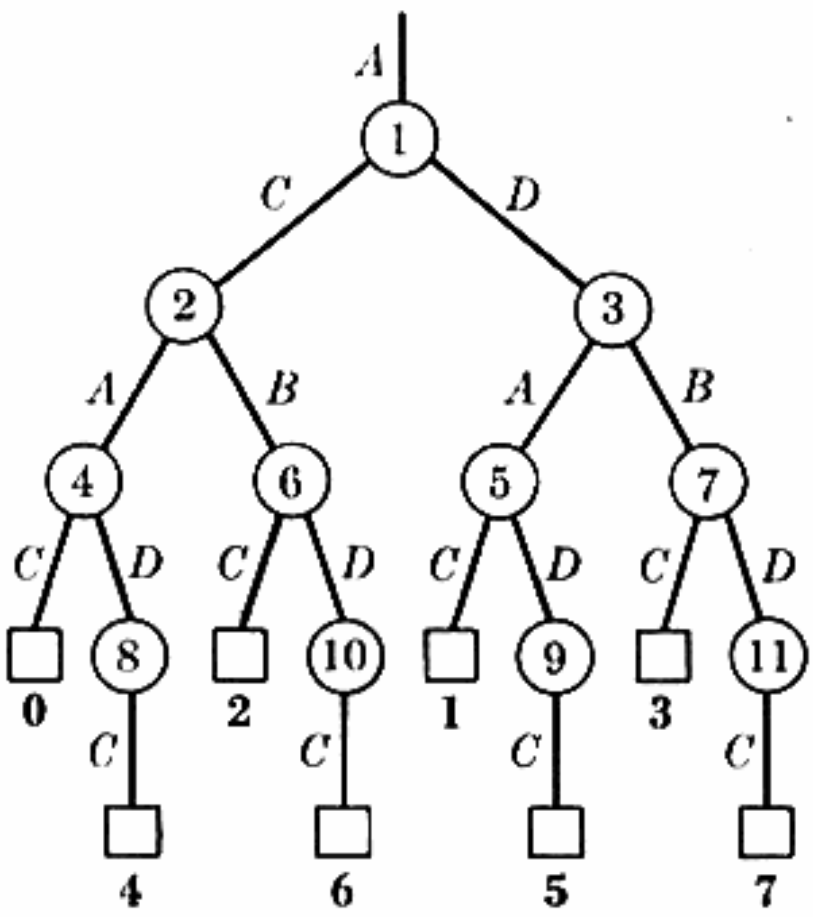
Partial-pass methods can also be used. For example, suppose that there are ten possible keys {0, 1, . . . , 9}, and consider the following procedure due to R. L. Ashenhurst [*Theory of Switching* 7 (Harvard Univ. Comp. Laboratory: May, 1954), I.1–I.76]:

	T1	T2	T3	T4	
Given	{0, 1, . . . , 9}	—	—	—	
Phase 1.	—	{0, 2, 4, 7}	{1, 5, 6}	{3, 8, 9}	1.0 pass
Phase 2.	{0}	—	{1, 5, 6} {2, 7}	{3, 8, 9} {4}	0.4 pass
Phase 3.	{0} {1} {2}	{6} {7}	—	{3, 8, 9} {4} {5}	0.5 pass
Phase 4.	{0} {1} {2} {3}	{6} {7} {8}	{9}	{4} {5}	0.3 pass
Collection	{0} {1} {2} {3} {4} . . . {9}				0.6 pass
					2.8 passes

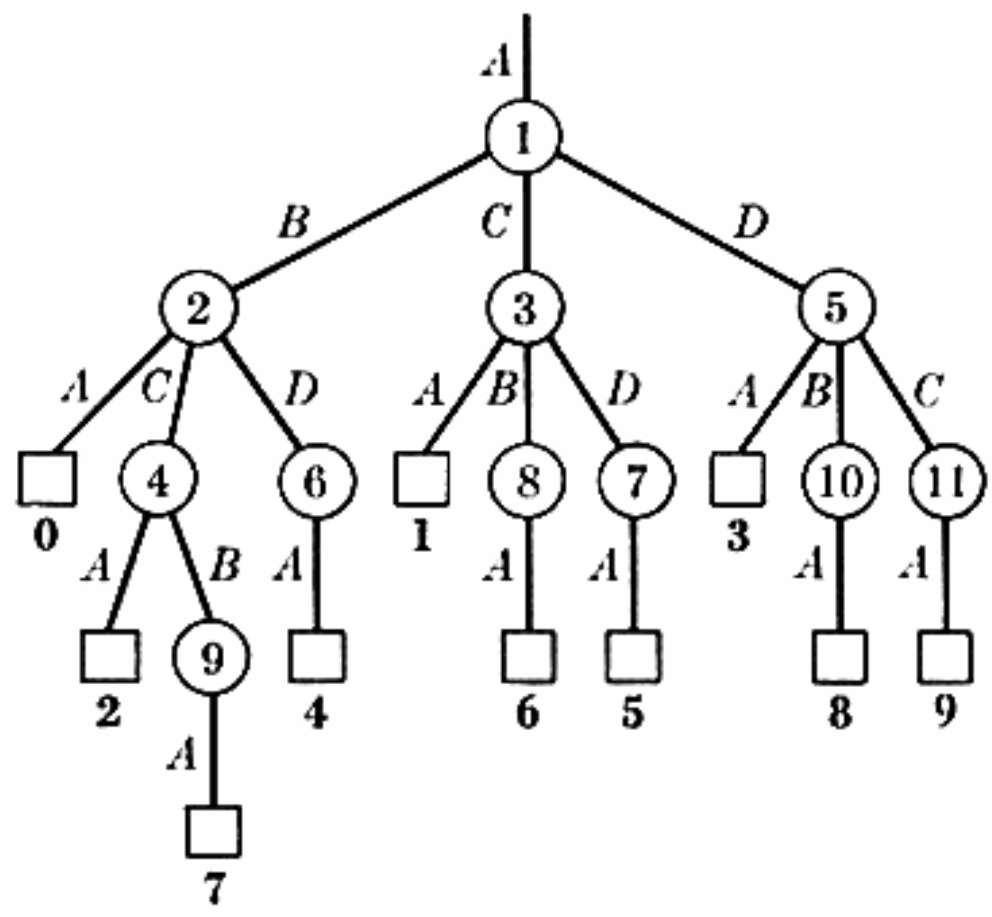
If each key value occurs about one-tenth of the time, the above procedure takes only 2.8 passes to sort ten keys, while the first example required 3.5 passes to sort only eight keys. Therefore we find that a clever distribution pattern can make a significant difference, for radix sorting as well as for merging.

The distribution patterns in the above examples can conveniently be represented as tree structures:

Example 1



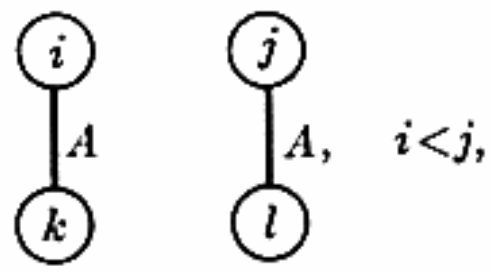
Example 2



The circular internal nodes of these trees are numbered 1, 2, 3, . . . , corresponding to steps 1, 2, 3, . . . of the process. Tape names A, B, C, D (instead of T1, T2, T3, T4) have been placed next to the lines of the trees, in order to show where the records go. Square external nodes represent portions of a file which contain only one key, and that key is shown in boldface type just below the node. The lines just above square nodes all carry the name of the output tape (C in the first example, A in the second).

Thus, step 3 of example 1 consists of reading from tape D and writing 1's and 5's on tape C, 3's and 7's on tape D. It is not difficult to see that the number of passes performed is equal to the *external path length* of the tree divided by the number of external nodes, if we assume that each key occurs equally often.

Because of the sequential nature of tape, and the first-in-first-out discipline of forwards reading, we can't simply use *any* labeled tree as the basis of a distribution pattern. In the tree of example 1, data gets written on tape A during step 2 and step 3; it is necessary to use the data written during step 2 before we use the data written during step 3. In general if we write onto a tape during steps i and j, where $i < j$, we must use the data written during step i first; when the tree contains two branches of the form



we must have $k < l$. Furthermore we cannot write anything onto tape A *between* steps k and l, because we must rewind between reading and writing.

The reader who has worked the exercises of Section 5.4.4 will now immediately perceive that the allowable trees for read-forward radix sorting on T tapes are precisely the "strongly T-fifo" trees which characterize read-forward *merge* sorting on T tapes! (See exercise 5.4.4–20.) The only difference is that all of the external nodes on the trees we are considering here have the same tape labels. We could remove this restriction by assuming a final "collection" phase which transfers all records to an output tape, or we could add that restriction to the rules for T-fifo trees by requiring that the initial distribution pass of a merge sort be explicitly represented in the corresponding merge tree.

In other words, *every merge pattern corresponds to a distribution pattern, and every distribution pattern corresponds to a merge pattern.* A moment's reflection shows why this is so: Consider running a merge sort backwards, "unmerging" the final output into subfiles which are unmerged into others, etc.; finally we will have unmerged the file into S runs. Such a pattern is possible with tapes if and only if the corresponding radix sort distribution pattern, for S keys, is possible. This duality between merging and distribution is almost perfect; it breaks down only in one respect, namely that the input tape must be saved at different times.

The eight-key example treated at the beginning of this section is clearly dual to a balanced merge on four tapes. The ten-key example with partial passes corresponds to the following ten-run merge pattern (if we suppress the copy phases, steps 6–11 in the tree):

	T1	T2	T3	T4
Initial distribution	1^4	1^3	1^1	1^2
Tree step 5	1^3	1^2	—	$1^2 3^1$
Tree step 4	1^2	1^1	2^1	$1^2 3^1$
Tree step 3	1^1	—	$2^1 3^1$	$1^1 3^1$
Tree step 2	—	4^1	3^1	3^1
Tree step 1	10^1	—	—	—

If we compare this to the radix sort, we see that the methods have essentially the same structure but are reversed in time, with the tape contents also reversed from back to front: $1^2 3^1$ (two runs each of length 1 followed by one of length 3) corresponds to $\{3, 8, 9\}\{4\}\{5\}$ (two subfiles each containing 1 key preceded by one subfile containing 3).

Going the other way, we can in principle construct a radix sort which is dual to polyphase merge, cascade merge, etc. For example, the 21-run polyphase merge on three tapes, illustrated at the beginning of Section 5.4.2, corresponds to the following interesting radix sort:

	T1	T2	T3
Given	{0, 1, . . . , 20}	—	—
Phase 1.	—	{0, 2, 4, 5, 7, 9, 10, 12, 13, 15, 17, 18, 20}	{1, 3, 6, 8, 11, 14, 16, 19}
Phase 2.	{0, 5, 10, 13, 18}	—	{1, 3, 6, 8, 11, 14, 16, 19} {2, 4, 7, 9, 12, 15, 17, 20}
Phase 3.	{0, 5, 10, 13, 18} {1, 6, 11, 14, 19} {2, 7, 12, 15, 20}	{3, 8, 16} {4, 9, 17}	—
Phase 4.	—	{3, 8, 16} {4, 9, 17} {5, 10, 18} {6, 11, 19} {7, 12, 20}	{0, 13} {1, 14} {2, 15}
Phase 5.	{8} {9} {10} {11} {12}	—	{0, 13} {1, 14} {2, 15} {3, 16} . . . {7, 20}
Phase 6.	{8} {9} {10} {11} {12} {13} . . . {20}	{0} {1} . . . {7}	—

The distribution rule used here to decide which keys go on which tapes at each step appears to be magic, but in fact it has a simple connection with the Fibonacci number system! (See exercise 2.)

Reading backward. Duality between radix sorting and merging applies also to algorithms that read tapes backward. We have defined "T-lifo trees" in Section 5.4.4, and it is easy to see that they correspond to radix sorts as well as to merge sorts.

A read backward radix sort was actually considered by John Mauchly already in 1946, in one of the first papers ever to be published about sorting (cf. Section 5.5); Mauchly essentially gave the following construction:

	T1	T2	T3	T4
Given	—	{0, 1, 2, . . . , 9}	—	—
Phase 1.	{4, 5}	—	{2, 3, 6, 7}	{0, 1, 8, 9}
Phase 2.	{4, 5} {2, 7}	{3, 6}	—	{0, 1, 8, 9}
Phase 3.	{4, 5} {2, 7} {0, 9}	{3, 6} {1, 8}	—	—
Phase 4.	{4, 5} {2, 7}	{3, 6} {1, 8}	{9}	{0}
. . . . .				
Phase 8.	—	—	{9} {8} {7} {6} {5}	{0} {1} {2} {3} {4}
Final collection	—	—	—	{0} {1} {2} {3} {4} {5} . . . {9}

This scheme is not the most efficient one possible, but it is interesting because it shows that partial pass methods were considered for radix sorting already in 1946, although they did not appear in the literature for merging until about 1960.

An efficient construction of read-backward distribution patterns has been suggested by A. Bayes [*CACM* **11** (1968), 491–493]: Given $P + 1$ tapes and S keys, divide the keys into P subfiles each containing $\lfloor S/P \rfloor$ or $\lceil S/P \rceil$ keys, and apply this procedure recursively to each subfile. When $S < 2P$, one subfile should consist of the smallest key alone, and it should be written onto the output file. (R. M. Karp's general preorder construction, which appears at the end of Section 5.4.4, includes this method as a special case.)

Backward reading makes merging a little more complicated because it reverses the order of runs. There is a corresponding effect on radix sorting: the outcome is stable or "anti-stable" depending on what level is reached in the tree. After a read-backward radix sort in which some of the external nodes are at odd levels and some are at even levels, the relative order of different

records with equal keys will be the *same* as the original order for some keys, but it will be the *opposite* of the original order for the other keys. (Cf. exercise 6.)

Oscillating merge sorts have their counterparts too, under duality. In an *oscillating radix sort* we continue to separate out the keys until reaching subfiles that have only one key or are small enough to be internally sorted; such subfiles are sorted and written onto the output tape, then the separation process is resumed. For example, if we have three work tapes and one output tape, and if the keys are binary numbers, we may start by putting keys of the form '0x' on tape T1, keys '1x' on T2. If T1 receives more than one memory load, we scan it again and put '00x' on T2 and '01x' on T3. Now if the '00x' subfile is short enough to be internally sorted, we do so and output the result, then continue by processing the '01x' subfile. Such a method was called a "cascading pseudo-radix sort" by E. H. Friend [*JACM* **3** (1956), 157–159]; it has been further developed by H. Nagler [*JACM* **6** (1959), 459–468], who gave it the colorful name "amphisbaenic sort," and by C. H. Gaudette [*IBM Tech. Disclosure Bull.* **12** (April, 1970), 1849–1853].

Does radix sorting beat merging? One important consequence of the duality principle is that *radix sorting is usually inferior to merge sorting*. This happens because the technique of replacement selection gives merge sorting a definite advantage; there is no apparent way to arrange radix sorts so that we can make use of internal sorts encompassing more than one memory load at a time. Indeed, the oscillating radix sort will often produce subfiles which are somewhat smaller than one memory load, so the distribution pattern corresponds to a tree with many more external nodes than would be present if merging and replacement selection were used. Consequently the external path length of the tree (i.e., the sorting time) is increased. (Cf. exercise 5.3.1–33.)

There are, however, some important applications for external radix sorting. Suppose for example that we have a file containing the names of all employees of a large corporation, in alphabetic order; the corporation has 10 divisions, and it is desired to sort the file by division, *retaining* the alphabetic order of the employees in each division. This is perfect situation in which to apply a stable radix sort, if the file is long, since the number of records which belong to each of the 10 divisions is likely to be more than the number of records which would be obtained in initial runs produced by replacement selection. In general, if the range of key values is so small that the collection of records having a given key would fill the internal memory more than twice, it is wise to use a radix sort technique.

We have seen in Section 5.2.5 that *internal* radix sorting is superior to merging, on certain high-speed computers, because the "inner loop" of the radix sort algorithm avoids complicated branching. If the external memory is especially fast, it may be impossible for such machines to merge data rapidly enough to keep up with the input/output equipment. Radix sorting may therefore turn out to be superior to merging in such a situation, especially if the keys are known to be uniformly distributed.

EXERCISES

1. [*20*] The general T-tape balanced merge with parameter P, $1 \leq P < T$, was defined near the beginning of Section 5.4. Show that this corresponds to a radix sort which uses a mixed radix system.

2. [*M28*] The text illustrates the three-tape polyphase radix sort for 21 keys. Generalize to the case of F_n keys; explain what keys appear on what tapes at the end of each phase. [*Hint:* Consider the Fibonacci number system, exercise 1.2.8–34.]

3. [*M40*] Extend the results of exercise 2 to the polyphase merge on four or more tapes. (Cf. exercise 5.4.2–10.)

4. [*M20*] Prove that Ashenhurst's distribution pattern is the best way to sort 10 keys on four tapes without reading backwards, in the sense that the associated tree has minimum external path length over all "strongly 4-fifo trees." (Thus, it is essentially the best method if we ignore rewind time.)

5. [*15*] Draw the 4-lifo tree corresponding to Mauchly's read-backwards radix sort for 10 keys.

▸ **6.** [*20*] A certain file contains two-digit keys 00, 01, . . . , 99. After performing Mauchly's radix sort on the unit's digit, we can repeat the same scheme on the ten's digits, interchanging the roles of tapes T2 and T4. In what order will the keys finally appear on T2?

7. [*21*] Does the duality principle apply also to multi-reel files?

Since we need three tapes to carry out a merge process without excessive tape motion, it is interesting to speculate about how we could perform a reasonable external sort using only two tapes.

One approach, suggested by H. B. Demuth in 1956, is sort of a combined replacement-selection and bubble sort. Assume that the input is on tape T1, and begin by reading $P + 1$ records into memory. Now output the record whose key is smallest, to tape T2, and replace it by the next input record. Continue outputting a record whose key is currently the smallest in memory, maintaining a selection tree or a priority queue of $P + 1$ elements. When the input is finally exhausted, the largest P keys of the file will be present in memory; output them is ascending order. Now rewind both tapes and repeat the process by reading from T2 and writing to T1; each such pass puts at least P more records into their proper place. A simple test can be built into the program which determines when the entire file is in sort. At most $\lceil (N - 1)/P \rceil$ passes will be necessary.

A few moment's reflection shows that each pass of this procedure is essentially equivalent to P consecutive passes of the bubble sort (Algorithm 5.2.2B)! If an element has P or more inversions, it will be smaller than everything in the tree when it is input, so it will be output immediately (thereby

losing P inversions). If an element has less than P inversions, it will go into the selection tree and will be output before all greater keys (thereby losing all its inversions). When $P = 1$, this is exactly what happens in the bubble sort, by Theorem 5.2.2I.

The total number of passes will therefore be $\lceil I/P \rceil$, where I is the maximum number of inversions of any element. By the theory developed in Section 5.2.2, the average value of I is $N - \sqrt{\pi N/2} + \frac{2}{3} + O(1/\sqrt{N})$.

If the file is not too much larger than the memory size, or if it is nearly in order to begin with, this order-P bubble sort will be fairly rapid; in fact, it might be advantageous to use it even when extra tape units are available, since it might not take as long as would be required for the computer operator to mount a third tape! On the other hand, it will run quite slowly on fairly long, randomly ordered files, since its running time is approximately proportional to N^2.

Let us consider how this method might be implemented for the 100,000-record example of Section 5.4.6. We need to choose P intelligently, in order to compensate for interblock gaps while doing simultaneous reading, writing, and computing. Since the example assumes that each record is 100 characters long and that 100,000 characters will fit into memory, we can make room for two input buffers and two output buffers of size B by setting

$$100(P + 1) + 4B = 100000. \tag{1}$$

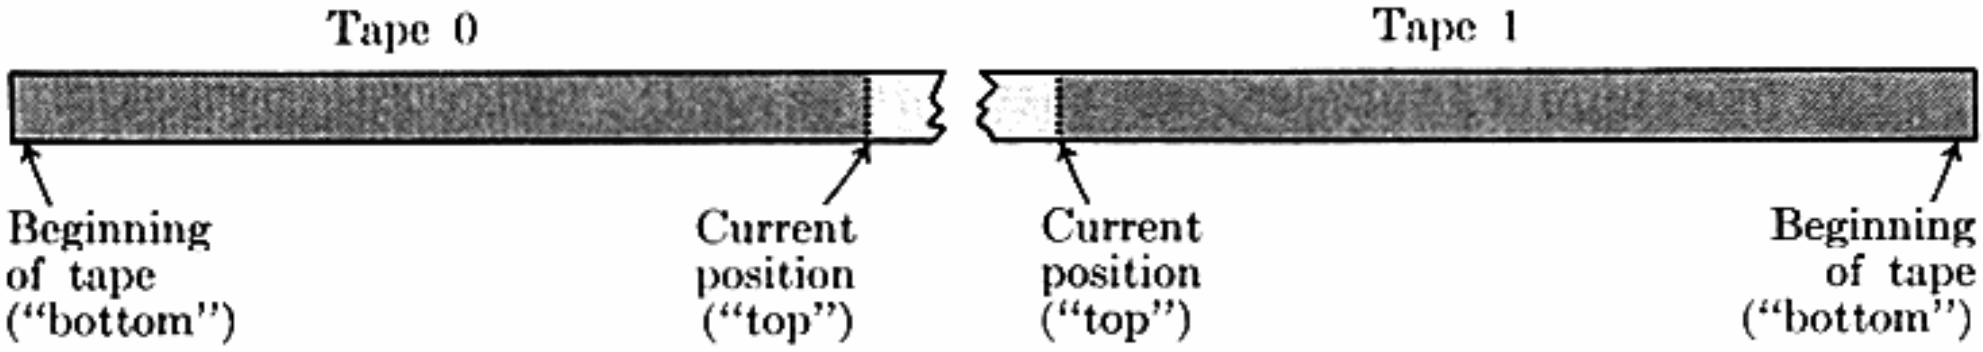
Using the notation of Section 5.4.6, the running time for each pass will be about

$$NC\omega\tau(1 + \rho), \qquad \omega = (B + \gamma)/B. \tag{2}$$

Since the number of passes is inversely proportional to P, we want to choose B to be a multiple of 100 which minimizes the quantity ω/P. Elementary calculus shows that this occurs when B is approximately $\sqrt{24975\gamma + \gamma^2} - \gamma$, so we take $B = 3000$, $P = 879$. Setting $N = 100000$ in the above formulas shows that the number of passes $\lceil I/P \rceil$ will be about 114, and the total estimated running time will be approximately 8.57 hours (assuming for convenience that the initial input and the final output also have $B = 3000$). This represents approximately 0.44 of a reelfull of data; a full reel would take about five times as long. Some improvements could be made if the algorithm were interrupted periodically, writing the records with largest keys onto an auxiliary tape which is dismounted, since such records are merely copied back and forth once they have been put into order.

Application of quicksort. Another internal sorting method which traverses the data in a nearly sequential manner is the partition exchange or quicksort procedure, Algorithm 5.2.2Q. Can we adapt it to two tapes? [N. B. Yoash, *CACM* **8** (1965), 649.]

It is not difficult to see how this can be done, using backward reading. Assume that the two tapes are numbered 0 and 1, and imagine that the file is laid out as follows:



Each tape serves as a stack; putting them together like this makes it possible to view the file as a linear list in which we can move the current position left or right by copying from one stack to the other. The following recursive subroutines define a suitable sorting procedure:

- SORT00 [Sort the top subfile on tape 0 and return it to tape 0].

If the subfile fits in the internal memory, sort it internally and return it to tape. Otherwise select one record R from the subfile, and let its key be K. Reading backward on tape 0, copy all records whose key is $> K$, forming a new subfile on the top of tape 1. Now read forward on tape 0, copying all records whose key is $= K$ onto tape 1. Then read backward again, copying all records whose key is $< K$ onto tape 1. Complete the sort by executing SORT10 on the $< K$ keys, then copying the $= K$ keys to tape 0, and finally executing SORT10 on the $> K$ keys.

- SORT01 [Sort the top subfile on tape 0 and write it on tape 1].

Same as SORT00, but the final "SORT10" is changed to "SORT11" followed by copying the $\leq K$ keys to tape 1.

- SORT10 [Sort the top subfile on tape 1 and write it on tape 0].

Same as SORT10, interchanging 0 with 1 and $<$ with $>$.

- SORT11 [Sort the top subfile on tape 1 and return it to tape 1].

Same as SORT00, interchanging 0 with 1 and $<$ with $>$.

The recursive nature of these subroutines can be handled without difficulty by storing appropriate control information on the tapes.

The running time for this algorithm can be estimated as follows, if we assume that the data are in random order, with negligible probability of equal keys. Let M be the number of records that fit into internal memory. Let X_N be the average number of records read while applying SORT00 or SORT11 to a subfile of N records, when $N > M$, and let Y_N be the corresponding quantity for SORT01 or SORT10. Then we have

$$X_N = \begin{cases} 0, & \text{if } N \leq M; \\ 3N + 1 + \frac{1}{N} \sum_{0 \leq k < N} (Y_k + Y_{N-1-k}), & \text{if } N > M; \end{cases}$$

$$Y_N = \begin{cases} 0, & \text{if } N \leq M; \\ 3N + 2 + \frac{1}{N} \sum_{0 \leq k < N} (Y_k + X_{N-1-k} + k), & \text{if } N > M. \end{cases} \quad (3)$$

The solution to these recurrences (see exercise 2) shows that the total amount of tape reading during the external partitioning phases will be $6\frac{2}{3}N \ln N + O(N)$, on the average, as $N \to \infty$. We also know from Eq. 5.2.2–25 that the average number of internal sort phases will be $2(N+1)/(M+2) - 1$.

If we apply this analysis to the 100,000-record example of Section 5.4.6, using 25,000-character buffers and assuming that the sorting time is $2nC\omega\tau$ for a subfile of $n \leq M = 1000$ records, we obtain an average sorting time of approximately 103 minutes (including the final rewind as in Chart A). Thus the quicksort method isn't bad, on the average; but of course its *worst* case turns out to be even more awful than the bubble sort discussed above.

Radix sorting. The radix exchange method (Algorithm 5.2.2R) can be adapted to two-tape sorting in a similar way, since it is so much like quicksort. The "trick" which makes both of these methods work is the idea of reading a file more than once, something we never did in our previous tape algorithms.

The same trick can be used to do a conventional "least-significant-digit-first" radix sort on two tapes. Given the input data on T1, we copy all records onto T2 whose key ends with 0 in binary notation; then after rewinding T1 we read it again, copying the records whose key ends with 1. Now both tapes are rewound and a similar pair of passes is made, interchanging the roles of T1 and T2, and using the *second* least significant binary digit. At this point T1 will contain all records whose keys are $(\ldots 00)_2$, followed by those whose keys are $(\ldots 01)_2$, then $(\ldots 10)_2$, then $(\ldots 11)_2$. If the keys are b bits long, we need only $2b$ passes over the file in order to complete the sort.

Such a radix sort could be applied only to the *leading* b bits of the keys, for some judiciously chosen number b; this would reduce the number of inversions by a factor of about 2^b, if the keys were uniformly distributed, so a few passes of the P-way bubble sort could be used to complete the job.

A novel but somewhat more complicated approach to two-tape distribution sorting has been suggested by A. I. Nikitin and L. I. Sholmov [*Kibernetika* **2**, 6 (1966), 79–84]. Counts are made of the number of keys having each possible configuration of leading bits, and artificial keys $\kappa_1, \kappa_2, \ldots, \kappa_M$ based on these counts are constructed so that the number of actual keys lying between κ_i and κ_{i+1} is between predetermined limits P_1 and P_2, for each i. Thus, M lies between $\lceil N/P_2 \rceil$ and $\lceil N/P_1 \rceil$. If the leading bit counts do not give sufficient information to determine such $\kappa_1, \kappa_2, \ldots, \kappa_M$, one or more further passes are made to count the frequency of less significant bit patterns, for certain configurations of most significant bits. After the table of artificial keys $\kappa_1, \kappa_2, \ldots, \kappa_M$ have been constructed, $2\lceil \log_2 M \rceil$ passes will suffice to complete the sort. (This method requires memory space proportional to N, so it can't be used for external sorting as $N \to \infty$. In practice we would not use the technique for multireel files, so M will be comparatively small and the table of artificial keys will fit comfortably in memory.)

Simulation of more tapes. F. C. Hennie and R. E. Stearns have devised a general technique for simulating k tapes on only two tapes, in such a way that

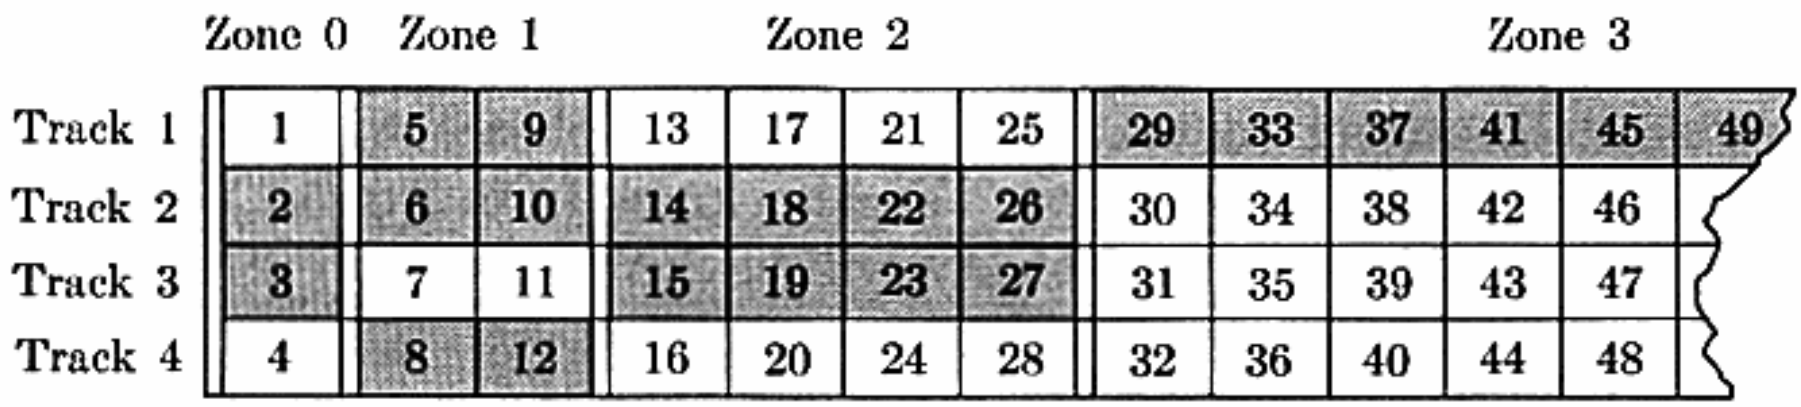


Fig. 86. Layout of tape T1 in the Hennie-Stearns construction; nonblank zones are shaded.

the tape motion required is increased by a factor of only $O(\log L)$, where L is the maximum distance to be traveled on any one tape [*JACM* **13** (1966), 533–546]. Their construction can be simplified slightly in the case of sorting, as in the following method suggested by R. M. Karp.

We shall simulate an ordinary four-tape balanced merge, using two tapes T1 and T2. The first of these, T1, holds the simulated tape contents in a way that may be diagrammed as in Fig. 86; we imagine that the data is written in four "tracks," one for each simulated tape. (In actual fact the tape doesn't have such tracks; blocks 1, 5, 9, 13, . . . are thought of as track 1, and blocks 2, 6, 10, 14, . . . as track 2, etc.) The other tape, T2, is used only for auxiliary storage, to help move things around on T1.

The blocks of each track are divided into *zones*, containing, respectively, 1, 2, 4, 8, . . . , 2^k, . . . blocks per zone. Zone k on each track is either filled with exactly 2^k blocks of data, or it is completely "blank." In Fig. 86, for example, track 1 has data in zones 1 and 3; track 2 in zones 0, 1, 2; track 3 in zones 0 and 2; track 4 in zone 1; and the other zones are blank.

Suppose that we are merging data from Tracks 1 and 2 to Track 3. The internal computer memory contains two buffers used for input to a two-way merge, plus a third buffer for output. When the input buffer for Track 1 becomes empty, we can refill it as follows: Find the first nonempty zone on Track 1, say zone k, and copy its first block into the input buffer; then copy the other $2^k - 1$ blocks of data onto T2, and move them to zones 0, 1, . . . , $k - 1$ of track 1. (Zones 0, 1, . . . , $k - 1$ are now full and zone k is blank.) An analogous procedure is used to refill the input buffer for Track 2, whenever it becomes empty. When the output buffer is ready to be written on Track 3, we reverse the process, scanning across T1 to find the first *blank* zone on T3, say zone k, while copying the data from zones 0, 1, . . . , $k - 1$ onto T2. The data on T2, augmented by the contents of the output buffer, is now used to fill zone k of Track 3.

This procedure requires the ability to write in the middle of tape T1, without destroying subsequent information on that tape. As in the case of read-forward oscillating sort (Section 5.4.5), it is possible to do this reliably if suitable precautions are taken.

The amount of tape motion required to bring $2^l - 1$ blocks of Track 1 into memory is $\sum_{0 \le k < l} 2^{l-1-k} \cdot c \cdot 2^k = cl2^{l-1}$, for some constant c, since we scan up to zone k only once in every 2^k steps. Thus each merge pass requires

$O(N \log N)$ steps. Since there are $O(\log N)$ passes in a balanced merge, the the constant in $O(N(\log N)^2)$ is much too high to be satisfactory when N is asymptotically much better than the worst case of quicksort.

But this method wouldn't actually work very well if we applied it to the 100,000-record example of Section 5.4.6, since the information specified for tape T1 would overflow the contents of one tape reel. Even if we ignore this fact, and if we use optimistic assumptions about read/write/compute overlap and interblock gap lengths, etc., we find that roughly 37 hours would be required to complete the sort! So this method is purely of academic interest; the constant in $O(N(\log N)^2)$ is much too high to be satisfactory when N is in a practical range.

One-tape sorting. Could we live with only one tape? It is not difficult to see that the order-P bubble sort described above could be converted into a one-tape sort, but the result would be ghastly.

H. B. Demuth [Ph. D. thesis (Stanford University, 1956), 85] observed that a computer with bounded internal memory cannot reduce the number of inversions of a permutation by more than a bounded amount as it moves a bounded distance on tape, hence every one-tape sorting algorithm must take at least $d\,N^2$ units of time on the average (for some positive constant d which depends on the computer configuration).

R. M. Karp has pursued this topic in a very interesting way, discovering what amounts to an *optimum* way to sort with one tape. It is convenient to discuss Karp's algorithm by reformulating the problem as follows: *What is the fastest way to transport people between floors using a single elevator?*

Consider a building with n floors, having room for exactly c people on each floor. The building contains no doors, windows, or stairs, but it does have an elevator that can stop on each floor. There are cn people in the building, and exactly c of them want to go to each particular floor. The elevator holds at most b people, and it takes one unit of time to go from floor i to floor $i+1$. We wish to find the quickest way to get all the people onto the proper floors, if the elevator is required to start and finish on floor 1.

The connection between this elevator problem and one-tape sorting is not hard to see: The people are the records and the building is the tape. The floors are individual blocks on the tape, and the elevator is the internal computer memory. A computer program has more flexibility than an elevator operator (it can, for example, duplicate people, or temporarily chop them into two parts on different floors, etc.); but the solution below solves the problem in the fastest conceivable time without doing such operations.

The following two auxiliary tables are required by Karp's algorithm.

$$\begin{aligned} &u_k,\ 1 \le k \le n\text{: Number of people on floors} \le k \text{ whose destination is} > k;\\ &d_k,\ 1 \le k \le n\text{: Number of people on floors} \ge k \text{ whose destination is} < k. \end{aligned} \tag{4}$$

When the elevator is empty, we always have $u_k = d_{k+1}$ for $1 \le k < n$, since there are c people on every floor; the number of misfits on floors $\{1, \ldots, k\}$

must equal the corresponding number on floors $\{k+1, \ldots, n\}$. By definition, $u_n = d_1 = 0$.

It is clear that the elevator must make at least $\lceil u_k/b \rceil$ trips from floor k to floor $k+1$, for $1 \le k < n$, since only b passengers can ascend on each trip. Similarly it must make at least $\lceil d_k/b \rceil$ trips from floor k to floor $k-1$. Therefore the elevator must necessarily take at least

$$\sum_{1 \le k \le n} (\lceil u_k/b \rceil + \lceil d_k/b \rceil) \tag{5}$$

units of time on any correct schedule. Karp discovered that this lower bound can actually be achieved, when $u_1, \ldots, u_{n-1}$ are nonzero.

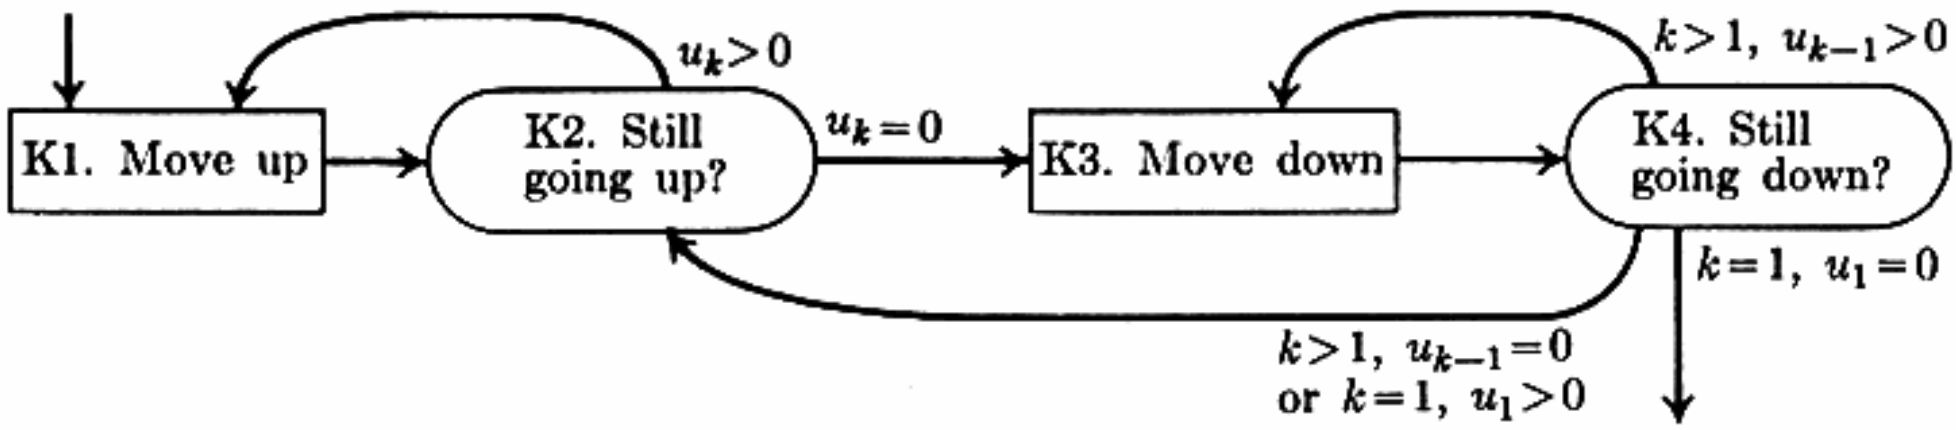

Fig. 87. Karp's elevator algorithm.

Theorem K. *If $u_k > 0$ for $1 \le k < n$, there is an elevator schedule which delivers everyone to his destination in the minimum time* (5).

Proof. Assume that there are b extra people in the building; they start in the elevator and their destination floor is artifically set to 0. The elevator can operate according to the following algorithm, starting with k (the current floor) equal to 1:

K1. [Move up.] From among the $b + c$ people currently in the elevator or on floor k, those b with the highest destinations get into the elevator, and the others remain on floor k.

Let there be u people now in the elevator whose destination is $> k$, and d whose destination is $\le k$. (It will turn out that $u = \min(b, u_k)$; if $u_k < b$ we may therefore be transporting some people away from their destination. This represents their sacrifice to the common good.) Decrease u_k by u, increase d_{k+1} by d, and then increase k by 1.

K2. [Still going up?] If $u_k > 0$, return to step K1.

K3. [Move down.] From among the $b + c$ people currently in the elevator or on floor k, those b with the lowest destinations get into the elevator, and the others remain on floor k.

Let there be u people now in the elevator whose destination is $\ge k$, and d whose destination is $< k$. (It will always turn out that $u = 0$ and $d = b$, but the algorithm is described here in terms of general u and d in order to make the proof a little clearer.) Decrease d_k by d, increase u_{k-1} by u, and then decrease k by 1.

K4. [Still going down?] If $k > 1$ and $u_{k-1} > 0$, return to step K3. If $k = 1$ and $u_1 = 0$, terminate the algorithm (everyone has moved to his destination and the b "extras" are back in the elevator). Otherwise return to step K2.

Figure 88 shows an example of this algorithm, with a nine-floor building and $b = 3$, $c = 2$. Note that one of the 6's is temporarily transported away from his destination in spite of the fact that the elevator travels the minimum possible distance. The idea of testing u_{k-1} in step K4 is the crucial thing which makes the algorithm work, as we shall see.

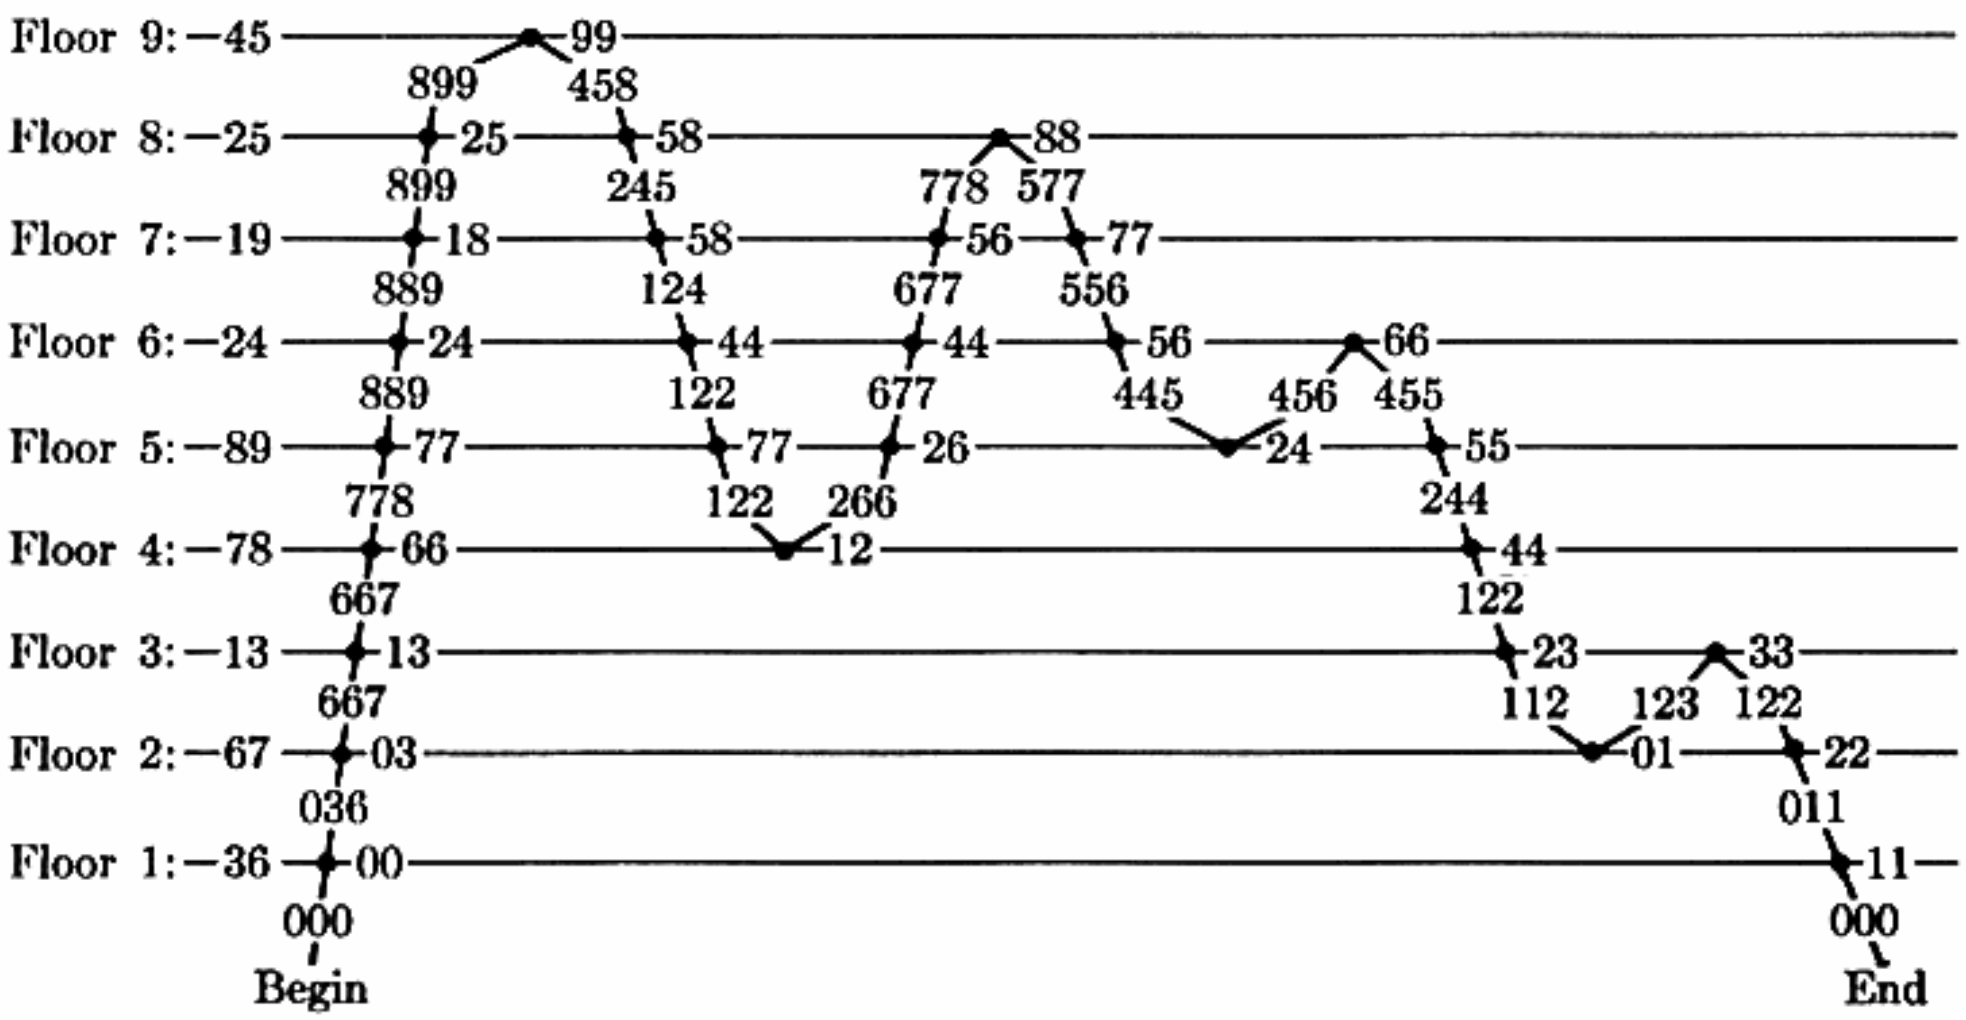

Fig. 88. An optimum way to rearrange people using a small, slow elevator. (Each person is represented by the number of his destination floor.)

To verify the validity of this algorithm, we note that steps K1 and K3 always keep the u and d tables (4) up to date, if we regard the people in the elevator as being on the "current" floor k. It is now possible to prove by induction that the following properties hold at the beginning of each step:

$$u_l = d_{l+1} \quad \text{for} \quad k \le l < n; \tag{6}$$

$$u_l = d_{l+1} - b, \quad \text{for} \quad 1 \le l < k; \tag{7}$$

$$\text{if} \quad u_l = 0 \quad \text{and} \quad k \le l < n \quad \text{then} \quad u_{l+1} = 0. \tag{8}$$

Furthermore, at the beginning of step K1, the min (u_k, b) people with highest destinations, among all people on floors $\le k$ with destination $> k$, are in the elevator or on floor k. At the beginning of step K3, the min (d_k, b) people with lowest destinations, among all people on floors $\ge k$ with destination $< k$, are in the elevator or on floor k. These conditions may also be verified inductively, by considering how we can reach step K1 or K3 (cf. exercise 5).

From these properties it follows that the parenthesized remarks in steps K1 and K3 are valid. Each execution of step K1 therefore decreases $\lceil u_k/b \rceil$ by 1 and leaves $\lceil d_{k+1}/b \rceil$ unchanged; each execution of K3 decreases $\lceil d_k/b \rceil$ by

1 and leaves $\lceil u_{k-1}/b \rceil$ unchanged. The algorithm must therefore terminate in a finite number of steps, and everybody must then be at his destination because of (6) and (8). ∎

When $u_k = 0$ and $u_{k+1} > 0$ we have a "disconnected" situation; the elevator must journey up to floor $k+1$ in order to rearrange the people up there, even though nobody wants to move from floors $\leq k$ to floors $\geq k+1$. Without loss of generality, we may assume that $u_{n-1} > 0$; then every valid elevator schedule must include at least

$$2 \sum_{1 \leq k < n} \max(1, \lceil u_k/b \rceil) \tag{9}$$

moves, since we require the elevator to return to floor 1. A schedule achieving this lower bound is readily constructed (exercise 4).

EXERCISES

1. [*17*] The order-P bubble sort discussed in the text uses only forward reading and rewinding. Can the algorithm be modified to take advantage of *backward* reading?

2. [*M26*] Find explicit "closed form" solutions for the numbers X_N, Y_N defined in (3). [*Hint:* Study the solution to Eq. 5.2.2–19.]

3. [*38*] Is there a two-tape sorting method, based only on comparisons of keys (not digital properties), whose tape motion is $O(N \log N)$ in the worst case, when sorting N records? [Quicksort achieves this on the average, but not in the worst case, and the Hennie-Stearns method (Fig. 86) achieves $O(N(\log(N)^2)$.]

4. [*M23*] In the elevator problem, suppose there are indices p, q with $q \geq p + 2$, $u_p > 0$, $u_q > 0$, and $u_{p+1} = \cdots = u_{q-1} = 0$. Explain how to construct a schedule requiring at most (9) units of time.

▸ **5.** [*M23*] True or false: After step K1 of the algorithm in Theorem K, nobody on the elevator has a lower destination than any person on floors $< k$.

6. [*M30*] (R. M. Karp.) Generalize the elevator problem (Fig. 87) to the case that there are c_j passengers initially on floor j, and c'_j passengers whose destination is floor j, for $1 \leq j \leq n$. Show that a schedule exists which takes $2\sum_{1 \leq k < n} \max(1, \lceil u_k/b \rceil, \lceil d_{k+1}/b \rceil)$ units of time, never allowing more than $\max(c_j, c'_j)$ passengers to be on floor j at any one time. [*Hint:* Introduce fictitious people, if necessary, to make $c_j = c'_j$ for all j.]

7. [*M40*] (R. M. Karp.) Generalize the problem of exercise 6, replacing the linear path followed by the elevator by a network of roads to be traveled by a bus, given that the network forms any *free tree*. The bus has finite capacity, and it is desired to transport passengers to their destinations in such a way that the bus travels a minimum distance.

8. [*M32*] Let $c = 1$ in the elevator problem treated in the text. How many permutations of the n people on the n floors will make $u_k \leq 1$ for $1 \leq k \leq n$ in (4)? [For example, 3 1 4 5 9 2 6 8 7 is such a permutation.]

▸ **9.** [*M25*] Find a significant connection between the "cocktail shaker sort" described

in Section 5.2.2, Fig. 16, and the numbers $u_1, u_2, \ldots, u_n$ of (4) in the case $c = 1$.

10. [*20*] How would you sort a multireel file with only two tapes?

5.4.9. Disks and Drums

So far we have considered tapes as the vehicles for external sorting, but more flexible types of mass storage devices are often available. Although such "bulk memory" or "direct-access storage" units come in many different forms, they may be roughly characterized by the following properties:

i) It doesn't take very long to access any specified part of the stored information;

ii) Blocks of consecutive words can be transmitted rapidly between the internal and external memory.

Magnetic tape satisfies (ii) but not (i), because it takes a long time to get from one end of a tape to the other. Some devices satisfy (i) but not (ii), e.g. bulk core memory units in which the access time to each word is about ten times slower than the internal memory speed.

Every external memory unit has idiosyncrasies which ought to be studied carefully before major programs are written for it; but technology changes so rapidly, it is impossible to give a complete discussion here of all the available varieties of hardware. Therefore we shall consider only some typical memory devices which illustrate useful approaches to the sorting problem.

One of the most common types of external memories satisfying (i) and (ii) is a disk file or disk pack module (see Fig. 89). Data is kept on a number of rapidly-rotating circular disks, covered with magnetic material; a comb-like access arm, containing one or more "read/write heads" for each disk surface, is used to store and retrieve the information. Each individual surface is divided into concentric rings called *tracks*, so that an entire track of data passes a read/write head every time the disk completes one revolution. The access arm can move in and out, shifting the read/write heads from track to track; but this motion takes time. A set of tracks which can be read or written without repositioning the access arm is called a *cylinder* or a *stratum*. For example, Fig. 89

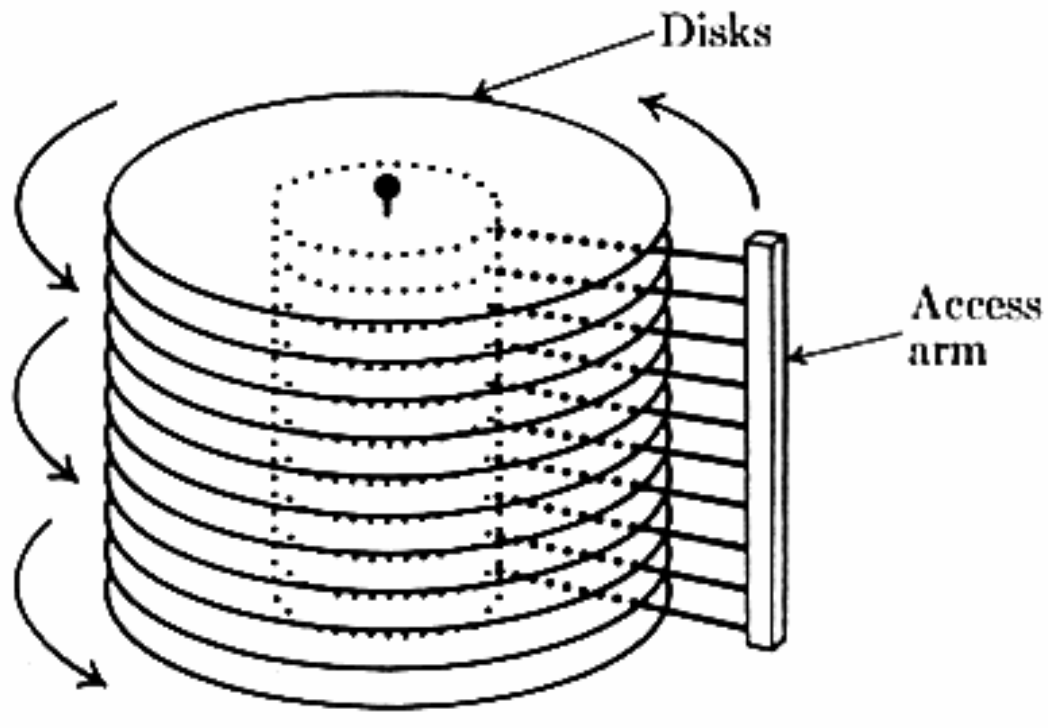

Fig. 89. A disk pack module.

illustrates a disk file which has just one read/write head per surface; the dotted lines show one of the cylinders, consisting of all tracks currently being scanned by the read/write heads.

To fix the ideas, let us consider hypothetical MIXTEC disk pack units, for which

$$\begin{aligned} 1 \text{ track} &= 5000 \text{ characters} \\ 1 \text{ cylinder} &= \quad 20 \text{ tracks} \\ 1 \text{ disk unit} &= \quad 200 \text{ cylinders} \end{aligned}$$

Such a disk unit contains 20 million characters, slightly less than the amount of data that can be stored on a single magnetic tape. On some machines, tracks near the center have fewer characters than tracks near the rim; this tends to make the programming much more complicated, and MIXTEC fortunately avoids such problems.

The amount of time required to read or write on a disk file is essentially the sum of three quantities,

- Seek time (the time to move the access arm to the proper cylinder);
- Latency time (rotational delay until the read/write head reaches the right spot);
- Transmission time (rotational delay while the data passes the read/write head).

On MIXTEC devices the seek time required to go from cylinder i to cylinder j is $25 + \frac{1}{2}|i - j|$ milliseconds. If i and j are randomly-selected integers between 1 and 200, the average value of $|i - j|$ is $2\binom{201}{3}/200^2 \approx 66.7$, so the average seek time is about 60 ms. MIXTEC disks rotate once every 25 ms, so the latency time averages about 12.5 ms. The transmission time for n characters is $(n/5000) \times 25 \text{ ms} = 5n\mu\text{s}$. (This is about $3\frac{1}{3}$ times as fast as the transmission rate of MIXT tapes used in the examples of Section 5.4.6.)

Thus the main differences between MIXTEC disks and MIXT tapes, relative to sorting, are

a) Tapes can only be accessed sequentially;

b) Individual disk operations tend to require significantly more overhead (seek time + latency time compared to stop/start time);

c) The disk transmission rate is faster.

By using clever merge patterns on tape, we were able to compensate somewhat for disadvantage (a). Our goal now is to think of some clever algorithms for disk sorting that will compensate for disadvantage (b).

Overcoming latency time. Let us consider first the problem of minimizing the delays caused by the fact that the disks aren't always positioned properly when we want to start an I/O command. We can't make the disk spin faster, but we can still apply some tricks that reduce or even eliminate all of the latency time.

The addition of more access arms would obviously help, but that would be an expensive hardware modification. Here are some "software" ideas:

1) If we read or write several tracks of a cylinder at a time, we avoid the latency time (*and* the seek time) on all tracks but the first. In general it is often possible to synchronize the computing time with the disk movement in such a way that a sequence of input/output instructions can be carried out without latency delays.

2) Consider the problem of reading half a track of data (Fig. 90): If the read command begins when the heads are at point A, there is no latency delay, and the total time for reading is just the transmission time, $\frac{1}{2} \times 25$ ms. If the command begins with the heads at B, we need $\frac{1}{4}$ of a revolution for latency and $\frac{1}{2}$ for transmission, totalling $\frac{3}{4} \times 25$ ms. The most interesting case occurs when the heads are initially at C: With proper hardware and software we need *not* waste $\frac{3}{4}$ of a revolution for latency delay. Reading can begin immediately, into the second half of the input buffer; then after a $\frac{1}{2} \times 25$ ms pause, reading can resume into the first half of the buffer, so that the instruction is completed when point C is reached again. In a similar manner, we can ensure that the total latency + transmission time will never exceed the time for one revolution, regardless of the initial position of the disk. The average amount of latency delay is reduced by this scheme from half a revolution to $\frac{1}{2}(1 - x^2)$ of a revolution, if we are reading or writing a given fraction x of a track, for $0 < x \leq 1$. When an entire track is being read or written ($x = 1$), this technique eliminates *all* the latency time.

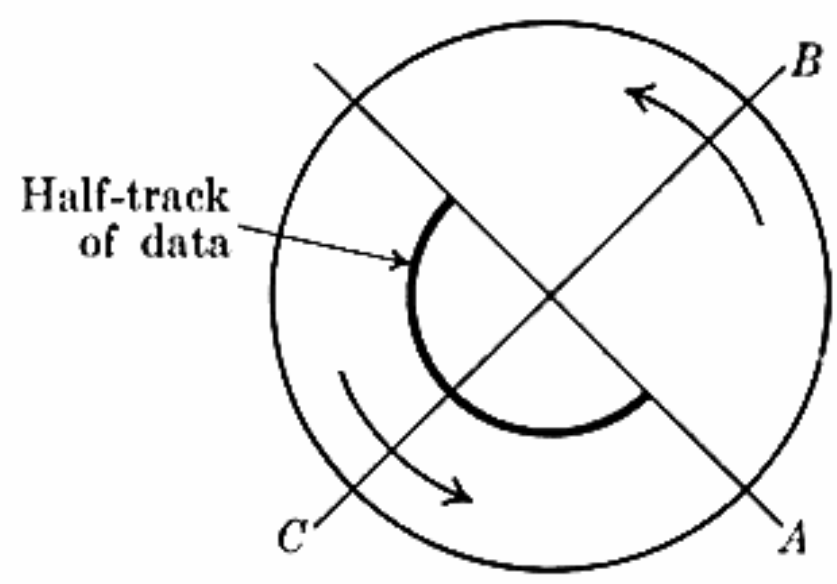

Fig. 90. Analysis of the latency time when reading half of a track.

Drums: The no-seek case. Some external memory units eliminate the seek time by having one read/write head for every track. If the technique of Fig. 90 is employed on such devices, both seek time and latency time reduce to zero, provided that we always read or write a track at a time; this is the ideal situation in which transmission time is the only limiting factor.

Let us consider again the example application of Section 5.4.6, sorting 100,000 records of 100 characters each, with a 100,000-character internal memory. The total amount of data to be sorted fills half of a MIXTEC disk. It is usually impossible to read and write simultaneously on a single disk unit; we shall assume that two disks are available, so that reading and writing can overlap

each other. For the moment we shall assume, in fact, that the "disks" are actually *drums*, containing 4000 tracks of 5000 characters each, with no seek time required.

What sorting algorithm should be used? The method of merging is a fairly natural choice; other methods of internal sorting do not lend themselves so well to a disk implementation, except possibly radix techniques, but the considerations of Section 5.4.7 show that radix sorting is usually inferior to merging for general applications. (It is not hard to see that the duality theorem of that section applies to disks as well as to tapes.)

To begin a merge sort for this problem we can use replacement selection, with two 5000-character input buffers and two 5000-character output buffers. In fact, it is possible to reduce this to *three* 5000-character buffers, if records in the current input buffer are replaced by records that come off the selection tree. That leaves 85,000 characters (850 records) for a selection tree, so one pass over our example data will form about 60 initial runs. (See Eq. 5.4.6–3.) This pass takes only about 50 seconds, if we assume that the internal processing time is fast enough to keep up with the input/output rate (one record moving to the output buffer every 500 microseconds). If the input to be sorted appeared on a MIXT tape, instead of on a drum, this pass would be slower, governed by the tape speed.

With two drums and full-track reading/writing, it is not hard to see that the total transmission time for P-way merging is minimized if we let P be as large as possible. Unfortunately we can't simply do a 60-way merge on all of the initial runs, since there isn't room for 60 buffers in memory. (A buffer of less than 5000 characters would introduce unwanted latency time.) If we do P-way merges, passing all the data from one drum to the other so that reading and writing are overlapped, the number of merge passes is $\lceil \log_P 60 \rceil$, so we may complete the job in two passes if $8 \le P \le 59$. The smallest such P reduces the amount of internal computing, so we choose $P = 8$; if 65 initial runs had been formed we would take $P = 9$. If 82 or more initial runs had been formed, we could take $P = 10$, but since there is room for only 18 input buffers and 2 output buffers there would be a possibility of hangup during the merge (see Algorithm 5.4.6F); it may be better in such a case to do two partial passes over a small portion of the data, reducing the number of initial runs to 81 or less.

Under our assumptions, both of the merging passes will take about 50 seconds, so the entire sort in this ideal situation will be completed in just $2\frac{1}{2}$ minutes (plus a few seconds for bookkeeping, initialization, etc.). This is six times faster than the best six-tape sort considered in Section 5.4.6; the reasons for this speedup are the improved external/internal transmission rate ($3\frac{1}{2}$ times faster), the higher order of merge (we can't do an eight-way tape merge unless we have nine or more tapes), and the fact that the output was left on disk (no final rewind, etc., was necessary). If the initial input and sorted output were required to be on MIXT tapes, with the drums used for merging only, the corresponding sorting time would have been about 8.2 minutes.

If only one drum were available instead of two, the input-output time

would take twice as long, since reading and writing must be done separately. (In fact, the input-output operations would take *three times* as long, since we would be overwriting the initial input data; in such a case it is prudent to follow each write by a "read-back check" operation, lest some of the input data be irretrievably lost, if the hardware does not provide automatic verification of written information.) But some of this excess time can be recovered because we can use partial pass methods which process some data records more often than others. The two-drum case requires all data to be processed an even number or an odd number of times, but the one-drum case can use more general merge patterns.

We observed in Section 5.4.4 that merge patterns can be represented by trees, and that the transmission time corresponding to a merge pattern is proportional to the external path length of its tree. Only certain trees ("T-lifo" or "strongly T-fifo") could be used as efficient tape merging patterns, because some runs get buried in the middle of a tape as the merging proceeds. But *on disks or drums, all trees define usable merge patterns* as long as the degrees of their internal nodes are not too large (i.e., compatible with the available internal memory size).

Therefore we can minimize transmission time by choosing a tree with minimum external path length, such as a complete P-ary tree where P is as large as possible. By Eq. 5.4.4–9, the external path length of such a tree is equal to

$$qS - \lfloor (P^q - S)/(P - 1) \rfloor, \qquad q = \lceil \log_P S \rceil, \tag{1}$$

if there are S external nodes (leaves).

It is particularly easy to design an algorithm which merges according to the complete P-ary tree pattern. See, for example, Fig. 91, which shows the case $P = 3$, $S = 6$. First we add "dummy runs," if necessary, to make $S \equiv 1$ (modulo $P - 1$); then we combine runs according to a "first-in-first-out" discipline, at every stage merging the P "oldest" runs at the front of the queue into a single run which is placed at the rear.

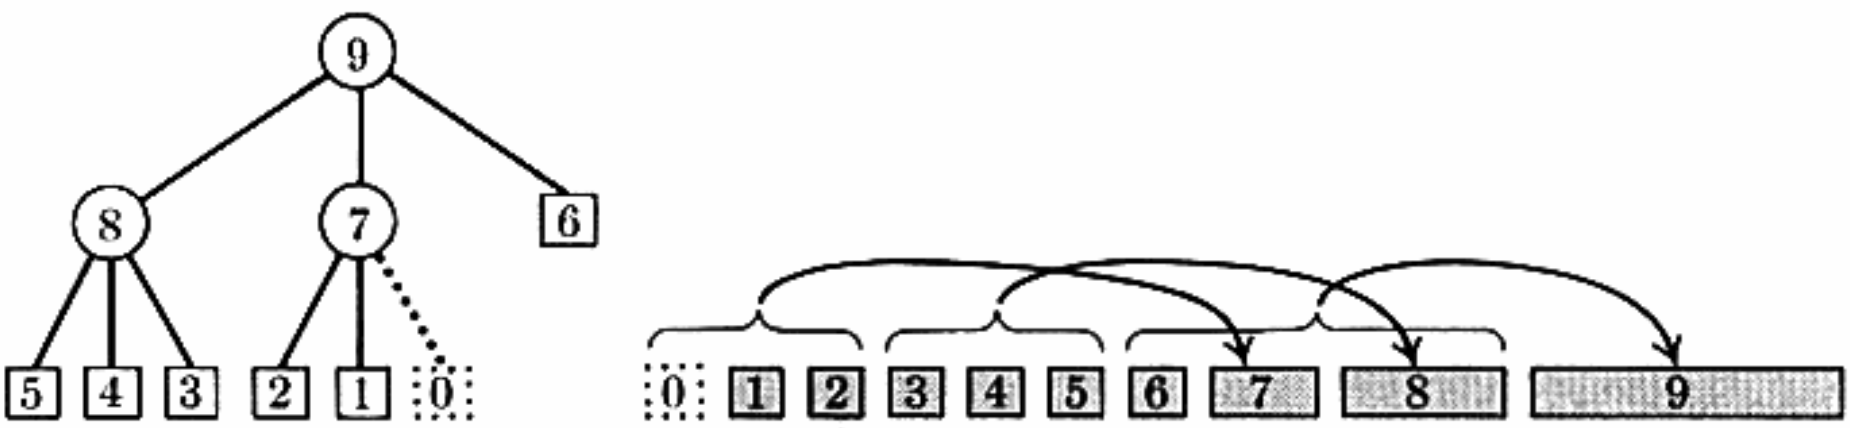

Fig. 91. Complete ternary tree with six leaves, and the corresponding merge pattern.

The complete P-ary tree gives an optimum pattern if all of the initial runs are the same length, but we can often do better if some runs are longer than others. An optimum pattern for this general situation can be constructed without difficulty by using Huffman's method (exercise 2.3.4.5–10), which may be stated in merging language as follows: "First add $(1 - S)$ mod $(P - 1)$

dummy runs of length 0. Then repeatedly merge together the P *shortest* existing runs until only one run is left." When all initial runs have the same length this method reduces to the fifo discipline described above.

In our 100,000-record example we can do nine-way merging, since 18 input buffers and two output buffers will fit in memory and Algorithm 5.4.6F will overlap all compute time. The complete 9-ary tree with 60 leaves corresponds to a merging pattern with $1\frac{29}{30}$ passes, if all initial runs have the same length. The total sorting time with one drum, using "read-back check" after every write, therefore comes to about 7.4 minutes. A higher value of P may reduce this running time slightly; but the situation is very unclear because "reading hangup" may occur, since the buffers might become too full or too empty.

The influence of seek time. The above discussion shows that it is relatively easy to construct "optimum" merging patterns for drums, because seek time and latency time can be essentially nonexistent. But when disks are used it often takes longer to seek out information than to read it, so the seek time has a considerable influence on the sorting strategy. Decreasing the order of merge, P, makes it possible to use larger buffers, so fewer seeks are required; this often compensates for the extra transmission time demanded by the smaller value of P.

Seek time depends on the distance traveled by the access arm, and we could try to arrange things so that this distance is minimized. For example, it may be wise to sort the records within cylinders first. However, large-scale merging requires a good deal of jumping around between cylinders (cf. exercise 2). Furthermore, the multiprogramming capability of modern operating systems means that a user rarely has much actual control over the position of disk access arms; fancy seek-minimization schemes usually work only on weekends! We are often justified, therefore, in assuming that each disk command involves a "random" seek.

Our goal is to discover a tree (i.e., a merge pattern) which achieves the best balance between seek time and transmission time; for this purpose we need some way to estimate the goodness of any particular tree with respect to a particular hardware configuration. Consider, for example, the tree in Fig. 92; we want to estimate how long it will take to carry out the corresponding merge, so that we can compare this tree to other trees.

In the following discussion we shall make some simple assumptions about disk merging, in order to illustrate some of the general ideas. Let us suppose that (1) it takes $72.5 + 0.005n$ milliseconds to read or write n characters; (2) 100,000 characters of internal memory are available for working storage; (3) an average of 0.004 milliseconds of computation time are required to transmit each character from input to output; (4) there is to be *no overlap* between reading, writing, or computing; and (5) the buffer size used on output need not be the same as the buffer size used to read the data on the following pass. An analysis of the sorting problem under these simple assumptions will give us some insights when we turn to more complicated situations.

If we do a P-way merge, we can divide the internal working storage into $P + 1$ buffer areas, P for input and one for output, with $B = 100000/(P + 1)$ characters per buffer. Suppose the files being merged contain a total of L characters; then we will do approximately L/B output operations and about the same number of input operations, so the total merging time under our assumptions will be approximately

$$2\left(72.5\,\frac{L}{B} + 0.005L\right) + 0.004L = (0.00145P + 0.01545)L \qquad (2)$$

milliseconds.

In other words, a P-way merge of L characters takes about $(\alpha P + \beta)L$ units of time, for some constants α and β depending on the seek time, latency time, compute time, and memory size. This formula leads to an interesting way to construct good merge patterns for disks. Consider Fig. 92, for example, and assume that all initial runs (represented by square "leaf" nodes) have length L_0. Then the merges at nodes 9 and 10 each take $(2\alpha + \beta)(2L_0)$ units of time, the merge at node 11 takes $(3\alpha + \beta)(4L_0)$, and the final merge at node 12 takes $(4\alpha + \beta)(8L_0)$. The total merging time therefore comes to $(52\alpha + 16\beta)L_0$ units. The coefficient "16" here is well-known to us, it is simply the external path length of the tree. The coefficient "52" of α is, however, a new concept, which we may call the *degree path length* of the tree; it is the sum, taken over all leaf nodes, of the internal-node degrees on the path from the leaf to the root. For example, in Fig. 92 the degree path length is $(2 + 4) + (2 + 4) + (3 + 4) + (2 + 3 + 4) + (2 + 3 + 4) + (3 + 4) + (4) + (4) = 52$.

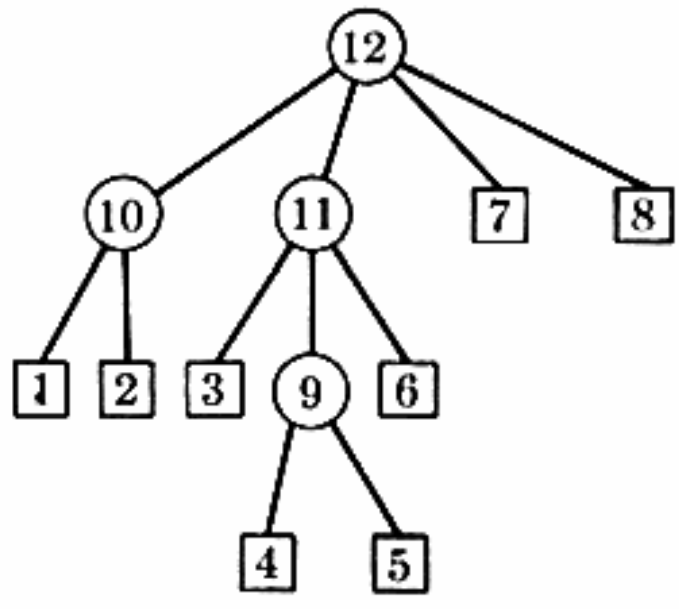

Fig. 92. A tree whose external path length is 16 and whose degree path length is 52.

If $\mathfrak{I}$ is any tree, let $D(\mathfrak{I})$, $E(\mathfrak{I})$ denote its degree path length and its external path length, respectively. Our analysis may be summarized as follows:

Theorem H. *If the time required to do a P-way merge on L characters has the form $(\alpha P + \beta)L$, and if there are S equal-length runs to be merged, the best merge pattern corresponds to a tree $\mathfrak{I}$ for which $\alpha D(\mathfrak{I}) + \beta E(\mathfrak{I})$ is a minimum, over all trees having S leaves.* ∎

(This theorem was implicitly contained in an unpublished paper which George U. Hubbard presented at the ACM National Conference in 1963.)

Let α and β be fixed constants; we shall say a tree is *optimal* if it has the minimum value of $\alpha D(\mathfrak{I}) + \beta E(\mathfrak{I})$ over all trees, $\mathfrak{I}$, with the same number of leaves. It is not difficult to see that *all subtrees of an optimal tree are optimal*, and therefore we can construct optimal trees with n leaves by piecing together optimal trees with $< n$ leaves.

Theorem K. *Let the sequence of numbers $A_m(n)$ be defined for $1 \le m \le n$ by the rules*

$$A_1(1) = 0; \tag{3}$$

$$A_m(n) = \min_{1 \le k \le n/m} \left(A_1(k) + A_{m-1}(n-k)\right), \quad \text{for} \quad 2 \le m \le n; \tag{4}$$

$$A_1(n) = \min_{2 \le m \le n} \left(\alpha m n + \beta n + A_m(n)\right), \quad \text{for} \quad n \ge 2. \tag{5}$$

Then $A_1(n)$ is the minimum value of $\alpha D(\mathfrak{I}) + \beta E(\mathfrak{I})$, over all trees $\mathfrak{I}$ with n leaves.

Proof. Equation (4) implies that $A_m(n)$ is the minimum value of $A_1(n_1) + \cdots + A_1(n_m)$ taken over all positive integers $n_1, \ldots, n_m$ such that $n_1 + \cdots + n_m = n$. The result now follows by induction on n. ∎

The recurrence relations (3), (4), (5) can also be used to construct the optimal trees themselves: Let $k_m(n)$ be a value for which the minimum occurs in the definition of $A_m(n)$. Then we can construct an optimal tree with n leaves by joining $m = k_1(n)$ subtrees at the root; the subtrees are optimal trees with $k_m(n)$, $k_{m-1}(n - k_m(n))$, $k_{m-2}(n - k_m(n) - k_{m-1}(n - k_m(n)))$, . . . leaves, respectively.

For example, Table 1 illustrates this construction when $\alpha = \beta = 1$. A compact specification of the corresponding optimal trees appears at the right of the table; the entry "4:9:9" when $n = 22$ means, for example, that an optimal tree $\mathfrak{I}_{22}$ with 22 leaves may be obtained by combining $\mathfrak{I}_4$, $\mathfrak{I}_9$, and $\mathfrak{I}_9$ (see Fig. 93). Optimal trees are not unique; for instance, 5:8:9 would be just as good as 4:9:9.

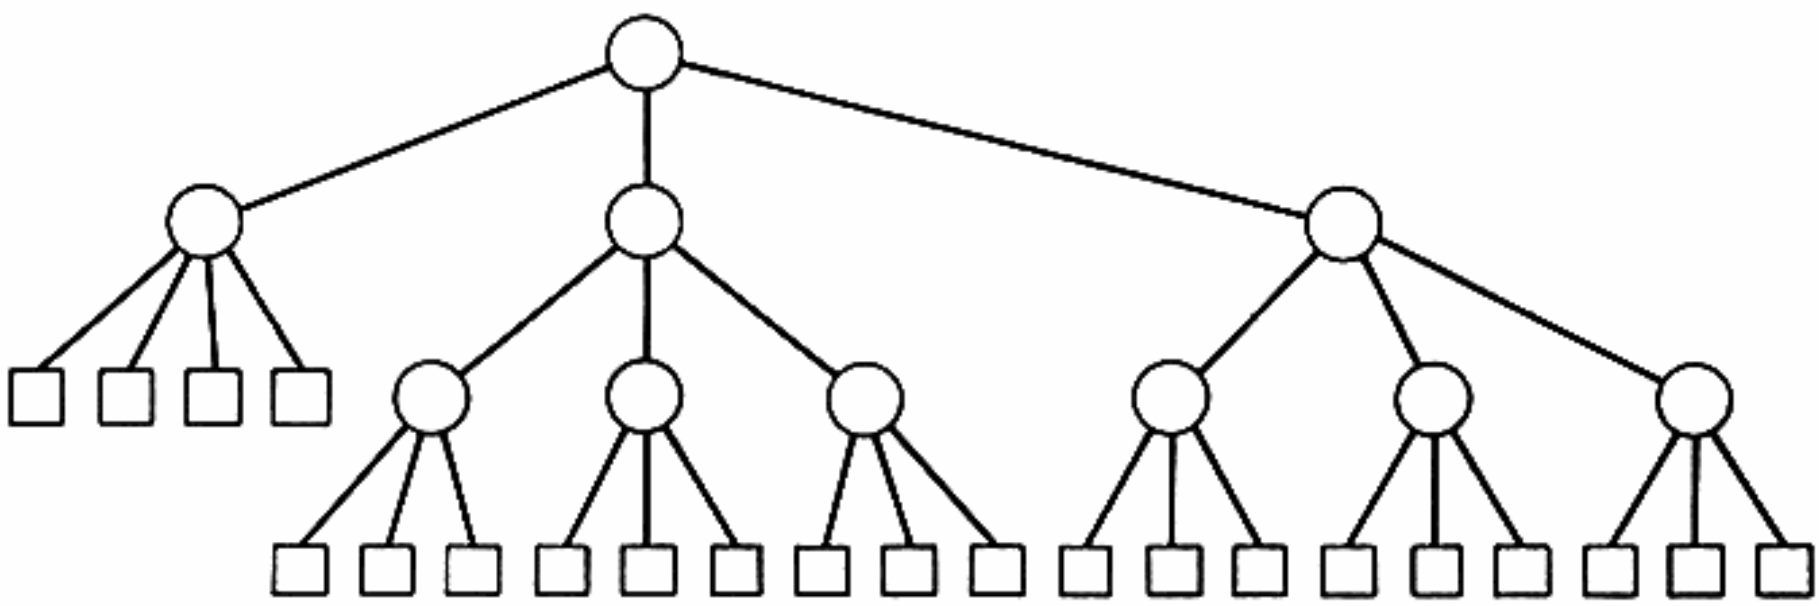

Fig. 93. An optimum way to merge 22 initial runs of equal length, when $\alpha = \beta$ in Theorem H. This pattern minimizes the seek time, under the assumptions leading to Eq. (2) in the text.

Table 1

OPTIMAL TREE CHARACTERISTICS $A_m(n)$, $k_m(n)$ WHEN $\alpha = \beta = 1$

	$m=1$	$m=2$	$m=3$	$m=4$	$m=5$	$m=6$	$m=7$	$m=8$	$m=9$	$m=10$	$m=11$	$m=12$	Tree specification	
$n=1$	0, 0												—	$n=1$
$n=2$	6, 2	0, 1											1:1	$n=2$
$n=3$	12, 3	6, 1	0, 1										1:1:1	$n=3$
$n=4$	20, 4	12, 1	6, 1	0, 1									1:1:1:1	$n=4$
$n=5$	30, 5	18, 2	12, 1	6, 1	0, 1								1:1:1:1:1	$n=5$
$n=6$	42, 2	24, 3	18, 1	12, 1	6, 1	0, 1							3:3	$n=6$
$n=7$	52, 3	32, 3	24, 1	18, 1	12, 1	6, 1	0, 1						1:3:3	$n=7$
$n=8$	62, 3	40, 4	30, 2	24, 1	18, 1	12, 1	6, 1	0, 1					2:3:3	$n=8$

$n=21$	236, 5	180, 9	154, 4	132, 4	110, 4	96, 3	84, 3	78, 1	72, 1	66, 1	60, 1	54, 1	4:4:4:4:5	$n=21$
$n=22$	252, 3	192, 10	164, 4	142, 4	120, 4	104, 3	92, 3	84, 1	78, 1	72, 1	66, 1	60, 1	4:9:9	$n=22$
$n=23$	266, 3	204, 11	174, 5	152, 4	130, 4	112, 3	100, 3	90, 2	84, 1	78, 1	72, 1	66, 1	5:9:9	$n=23$
$n=24$	282, 3	216, 12	186, 5	162, 5	140, 4	120, 4	108, 3	96, 3	90, 1	84, 1	78, 1	72, 1	5:9:10	$n=24$
$n=25$	296, 3	229, 12	196, 7	174, 4	150, 5	130, 4	116, 3	104, 3	96, 1	90, 1	84, 1	78, 1	7:9:9	$n=25$

Our derivation of (2) shows that the relation $\alpha \leq \beta$ will hold whenever $P + 1$ equal buffer areas are used. The limiting case $\alpha = \beta$, shown in Table 1 and Fig. 93, occurs when the seek time itself is to be minimized without regard to transmission time.

Returning to our original application, we still haven't considered how to get the initial runs in the first place; without read/write/compute overlap, replacement selection loses some of its advantages. Perhaps we should fill the entire internal memory, sort it, and output the results; such input and output operations can each be done with one seek. Or perhaps we are better off using, say, 20 percent of the memory as a combination input/output buffer, and doing replacement selection. This requires five times as many seeks (an extra 60 seconds or so!), but it reduces the number of initial runs from 100 to 64; the reduction would be more dramatic if the input file were pretty much in order already.

If we decide not to use replacement selection, the optimum tree for $S = 100$, $\alpha = 0.00145$, $\beta = 0.01545$ [cf. (2)] turns out to be rather prosaic: It is simply a 10-way merge, completed in two passes over the data. Allowing 30 seconds for internal sorting (100 quicksorts, say), the initial distribution pass takes about $2\frac{1}{2}$ minutes, and the merge passes each take almost 5 minutes, for a total of 12.4 minutes. If we decide to use replacement selection, the optimal tree for $S = 64$ turns out to be equally uninteresting (two 8-way merge passes); the initial distribution pass takes about $3\frac{1}{2}$ minutes, the merge passes each take about $4\frac{1}{2}$ minutes, and the estimated total time comes to 12.6 minutes. Remember that both of these methods give up virtually all read/write/compute overlap in order to have larger buffers (reducing seek time). None of these estimated

times includes the time which might be necessary for "read-back check" operations.

In practice the final merge pass tends to be quite different from the others; for example, the output is often expanded and/or written onto tape. In such cases the tree pattern should be chosen using a different optimality criterion at the root.

***Another way to allocate buffers.** David E. Ferguson [*CACM* **14** (1971), 476–478] has pointed out that seek time can be reduced if we don't make all buffers the same size. The same idea occurred at about the same time to several other people [S. J. Waters, *Comp. J.* **14** (1971), 109–112; Ewing S. Walker, Software Age **4** (August-September, 1970), 16–17].

Suppose we are doing a four-way merge on runs of equal length L_0, with M characters of memory. If we divide the memory into equal buffers of size $B = M/5$, we need about L_0/B seeks on each input file and $4L_0/B$ seeks for the output, totalling $8L_0/B = 40L_0/M$ seeks. But if we use four input buffers of size $M/6$ and one output buffer of size $M/3$, we need only about $4 \times (6L_0/M) + 4 \times (3L_0/M) = 36L_0/M$ seeks! The transmission time is the same in both cases, so we haven't lost anything by the change.

In general, suppose that we want to merge sorted files of lengths $L_1, \ldots, L_P$ into a sorted file of length $L_{P+1} = L_1 + \cdots + L_P$, and assume that a buffer of size B_k is being used for the kth file. Thus

$$B_1 + \cdots + B_P + B_{P+1} = M, \tag{6}$$

where M is the total size of available internal memory. The number of seeks will be approximately

$$\frac{L_1}{B_1} + \cdots + \frac{L_P}{B_P} + \frac{L_{P+1}}{B_{P+1}}. \tag{7}$$

Let's try to minimize this quantity, subject to condition (6), assuming for convenience that the B_k's don't have to be integers. If we increase B_j by δ and decrease B_k by the same small amount, the number of seeks changes by

$$\frac{L_j}{B_j + \delta} - \frac{L_j}{B_j} + \frac{L_k}{B_k - \delta} - \frac{L_k}{B_k} = \left(\frac{L_k}{B_k(B_k - \delta)} - \frac{L_j}{B_j(B_j + \delta)}\right)\delta,$$

so the allocation can be improved if $L_j/B_j^2 \neq L_k/B_k^2$. Therefore we get the minimum number of seeks only if

$$\frac{L_1}{B_2^2} = \cdots = \frac{L_P}{B_P^2} = \frac{L_{P+1}}{B_{P+1}^2}. \tag{8}$$

Since a minimum does exist it must occur when

$$B_k = \sqrt{L_k}\, M/(\sqrt{L_1} + \cdots + \sqrt{L_{P+1}}), \qquad 1 \le k \le P + 1, \tag{9}$$

for these are the only values of $B_1, \ldots, B_{P+1}$ which simultaneously satisfy (6) and (8). Putting these values into (7) gives a fairly simple formula for the total number of seeks,

$$(\sqrt{L_1} + \cdots + \sqrt{L_{P+1}})^2/M, \tag{10}$$

which may be compared with the number $(P+1)(L_1 + \cdots + L_{P+1})/M$ obtained if all buffers are equal in length. By exercise 1.2.3–31, the improvement is $\sum_{1 \le j < k \le P+1} (\sqrt{L_j} - \sqrt{L_k})^2/M$. Unfortunately formula (10) does not lend itself to an easy determination of optimum merge patterns as in Theorem K (cf. exercise 14).

Further considerations. If two disk units are being used, one for reading and one for writing, we can overlap some of the write time at the expense of an extra output buffer. If the "forecasting" technique is used (i.e., looking at the last keys in each input buffer in order to determine which buffer will empty first), we can overlap some of the read time. Unfortunately a simple synchronization procedure like that of Algorithm 5.4.6F does not provide continuous input/output, since the variable behavior of seek time means that input and output operations won't finish at the same time. The exact amount of overlap is hard to estimate, and it may be best to simulate the merging process in order to find constants α and β which approximate the running time as in Theorem H.

If we use "floating" input buffers (not dedicated to a particular file), they must all be the same size, so the above buffer allocation technique cannot be used except that the output buffers may be chosen larger than those for input. If $2P$ input buffers are used instead of P, we overlap a good deal of the input time yet double the seek time, so we may be gaining nothing; perhaps $P+1$ or $P+2$ input buffers would be best.

It should be clear to the reader by now that no clear cut strategy for optimum disk sorting has been worked out; the number of available options greatly exceeds the number of strategies that have been theoretically analyzed. Although the theory developed in this section provides some useful insights, a good deal of experimentation still needs to be done.

***A closer look at optimal trees.** It is interesting to examine the extreme case $\beta = 0$ in Theorems H and K, even though practical situations usually lead to parameters with $0 \le \alpha \le \beta$. What tree with n leaves has the smallest possible degree path length? Curiously it turns out that three-way merging is best in this case.

Theorem L. *The degree path length of a tree with n leaves is never less than*

$$f(n) = \begin{cases} 3qn + 2(n - 3^q), & \text{if } 2 \cdot 3^{q-1} \le n \le 3^q; \\ 3qn + 4(n - 3^q), & \text{if } 3^q \le n \le 2 \cdot 3^q. \end{cases} \tag{11}$$

Ternary trees $\mathfrak{I}_n$ defined by the rules

$$\mathfrak{I}_1 = \square, \qquad \mathfrak{I}_2 = \text{  }, \qquad \mathfrak{I}_n = \text{  } \tag{12}$$

have the minimum degree path length.

Proof. It is important to observe that $f(n)$ is a *convex function*, i.e. that

$$f(n+1) - f(n) \geq f(n) - f(n-1) \qquad \text{for all} \qquad n \geq 2. \tag{13}$$

The relevance of this property is due to the following lemma.

Lemma C. *A function $g(n)$ defined on the positive integers satisfies*

$$\min_{1\leq k\leq n} \big(g(k) + g(n-k)\big) = g(\lfloor n/2 \rfloor) + g(\lceil n/2 \rceil), \qquad n \geq 2, \tag{14}$$

if and only if it is convex.

Proof. If $g(n+1) - g(n) < g(n) - g(n-1)$ for some $n \geq 2$, we have $g(n+1) + g(n-1) < g(n) + g(n)$, contradicting (14). Conversely, if (13) holds for g, and $1 \leq k < n-k$, we have $g(k+1) + g(n-k-1) \leq g(k) + g(n-k)$ by convexity. ∎

The latter part of Lemma C's proof can be extended for any $m \geq 2$ to show that

$$\min_{\substack{n_1+\cdots+n_m=n \\ n_1,\cdots,n_m\geq 1}} \big(g(n_1) + \cdots + g(n_m)\big)$$
$$= g(\lfloor n/m \rfloor) + g(\lfloor (n+1)/m \rfloor) + \cdots + g(\lfloor (n+m-1)/m \rfloor), \tag{15}$$

whenever g is convex. Let

$$f_m(n) = f(\lfloor n/m \rfloor) + f(\lfloor (n+1)/m \rfloor) + \cdots + f(\lfloor (n+m-1)/m \rfloor); \tag{16}$$

the proof of Theorem L is completed by proving that $f_3(n) + 3n = f(n)$ and $f_m(n) + mn \geq f(n)$ for all $m \geq 2$. (See exercise 11.) ∎

It would be very nice if optimal trees could always be characterized neatly as in Theorem L. But the results we have seen for $\alpha = \beta$ in Table 1 show that the function $A_1(n)$ is not always convex. In fact, Table 1 is sufficient to disprove most simple conjectures about optimal trees! We can, however, salvage part of Theorem L in the general case; M. Schlumberger and J. Vuillemin have shown that *large* orders of merge can always be avoided:

Theorem M. *Given α and β as in Theorem H, there exists an optimal tree in which the degree of every node is at most*

$$d(\alpha, \beta) = \left\lceil \min_{k\geq 1} \left(k + \left(1 + \frac{1}{k}\right)\left(1 + \frac{\beta}{\alpha}\right)\right)\right\rceil. \tag{17}$$

Proof. Let $n_1, \ldots, n_m$ be positive integers such that $n_1 + \cdots + n_m = n$, $A(n_1) + \cdots + A(n_m) = A_m(n)$, and $n_1 \leq \cdots \leq n_m$, and assume that $m \geq d(\alpha, \beta) + 1$. Let k be the value which minimizes (17); we shall show that

$$\alpha n(m-k) + \beta n + A_{m-k}(n) \leq \alpha nm + \beta n + A_m(n), \tag{18}$$

hence the minimum value in (4) is always achieved for some $m \le d(\alpha, \beta)$.

By definition, since $m \ge k+2$, we must have

$$\begin{aligned} A_{m-k}(n) &\le A_1(n_1 + \cdots + n_{k+1}) + A_1(n_{k+2}) + \cdots + A_1(n_m) \\ &\le \alpha(n_1 + \cdots + n_{k+1})(k+1) + \beta(n_1 + \cdots + n_{k+1}) \\ &\quad + A_1(n_1) + \cdots + A_1(n_m) \\ &= \big(\alpha(k+1) + \beta\big)(n_1 + \cdots + n_{k+1}) + A_m(n) \\ &\le \big(\alpha(k+1) + \beta\big)(k+1)n/m + A_m(n), \end{aligned}$$

and (18) now follows easily. (Careful inspection of this proof shows that (17) is "best possible," in the sense that some optimal trees must have nodes of degree $d(\alpha, \beta)$; see exercise 13.) ∎

The construction in Theorem K requires $O(N^2)$ memory cells and $O(N^2 \log N)$ steps to evaluate $A_m(n)$ for $1 \le m \le n \le N$; Theorem M shows that only $O(N)$ cells and $O(N^2)$ steps are needed. Schlumberger and Vuillemin have discovered several more very interesting properties of optimal trees ["Optimal disk merge patterns," to appear].

The use of chaining. M. A. Goetz [*CACM* **6** (1963), 245–248] has suggested an interesting way to avoid seek time on output, by linking individual tracks together. His idea requires a fairly fancy set of disk storage management routines, but it applies to many problems besides sorting, and it may therefore be a very worthwhile technique for general-purpose use.

The concept is simple: Instead of allocating tracks sequentially within cylinders of the disk, we link them together and maintain lists of available space, one for each cylinder. When it is time to output a track of information, we write it on the current cylinder (wherever the access arm happens to be), unless that cylinder is full. In this way the seek time usually disappears.

The catch is that we can't store a link-to-next-track within the track itself, since the necessary information isn't known at the right time. (We could store a link-to-previous-track and read the file backward on the next pass, if that were suitable.) A separate table of link addresses for the tracks of each file can be maintained, perhaps partly on disk itself. The available space lists can be compactly represented by using bit tables, with 1000 bits specifying the availability or unavailability of 1000 tracks.

Will keysorting help? When records are long and keys are short, it is very tempting to create a new file consisting simply of the keys together with a serial number specifying their original file location. After sorting this key file, we can replace the keys by the successive numbers 1, 2, . . .; the new file can then be sorted by original file location and we will have a convenient specification of how to unshuffle the records for the final rearrangement. Schematically, the process has the following form:

a) Original file	$(K_1, I_1)(K_2, I_2) \ldots (K_N, I_N)$	long
b) Key file	$(K_1, 1)(K_2, 2) \ldots (K_N, N)$	short
c) Sorted (b)	$(K_{p_1}, p_1)(K_{p_2}, p_2) \ldots (K_{p_N}, p_N)$	short
d) Edited (c)	$(1, p_1)(2, p_2) \ldots (N, p_N)$	short
e) Sorted (d)	$(q_1, 1)(q_2, 2) \ldots (q_N, N)$	short
f) Edited (a)	$(q_1, I_1)(q_2, I_2) \ldots (q_N, I_N)$	long

Here $p_j = k$ if and only if $q_k = j$; the two sorting processes in (c), (e) are comparatively fast (perhaps even internal sorts), since the records aren't very long. In stage (f) we have reduced the problem to sorting a file whose keys are simply the numbers $\{1, 2, \ldots, N\}$; each record now specifies exactly where it is to be moved.

The external rearrangement problem which remains after stage (f) seems trivial, at first glance; but in fact it is rather difficult, and no really good algorithms (significantly better than sorting) have yet been found. We could obviously do the rearrangement in N steps, moving one record at a time; for large enough N this is better than the $N \log N$ of a sorting method. But N is never that large, and N seeks are unthinkable!

A radix sorting method can be used efficiently on the edited records, since their keys have a perfectly uniform distribution. On many high-speed computers with high-speed peripheral devices, the processing time for an eight-way distribution is much faster than the processing time for an eight-way merge; hence a distribution sort may be the best procedure. (See Section 5.4.7, and see also exercise 17.)

But it seems wasteful to do a key sort only to follow it by a full sort! One reason the external rearrangement problem is unexpectedly difficult has been discovered by R. W. Floyd, who found a nontrivial lower bound on the number of seeks required to rearrange records on a disk file.

It is convenient to describe Floyd's result in terms of the elevator problem of Section 5.4.8; this time we want to find an elevator schedule which minimizes the number of *stops*, instead of minimizing the distance traveled. (Minimizing the number of stops is not precisely equivalent to finding the minimum-seek rearrangement algorithm, since a stop combines input to the elevator with output from the elevator; but the stop-minimization criterion is close enough to indicate the basic ideas.)

We shall make use of the "discrete entropy" function

$$F(n) = \sum_{1<k\le n} (\lceil \log_2 k \rceil + 1) = B(n) + n - 1 = n\lceil \log_2 n \rceil - 2^{\lceil \log_2 n \rceil} + n, \tag{19}$$

where $B(n)$ is the "binary insertion" function, Eq. 5.3.1–3. By Eq. 5.3.1–33, $F(n)$ is the minimum external path length of a binary tree with n leaves, and

$$n \log_2 n \le F(n) \le n \log_2 n + 0.0861n. \tag{20}$$

Since $F(n)$ is convex and satisfies $F(n) = n + F(\lfloor n/2 \rfloor) + F(\lceil n/2 \rceil)$, we know by Lemma C above that

$$F(n) \le F(k) + F(n - k) + n, \qquad \text{for} \qquad 0 \le k \le n. \tag{21}$$

This relation is also evident from the external path length characterization of F; it is the crucial fact used in what follows.

As in Section 5.4.8 we shall assume that the elevator holds b people, each floor holds c people, and there are n floors. Let s_{ij} be the number of people currently on floor i whose destination is floor j. The *togetherness rating* of any configuration of people in the building is defined to be the sum $\sum_{1 \le i,j \le n} F(s_{ij})$.

For example, assume that $b = c = n = 6$ and that the 36 people are initially scattered among the floors as follows:

```
␣␣␣␣␣␣
123456  123456  123456  123456  123456  123456
```
(22)

The elevator is empty, sitting on floor 1; "␣" denotes a vacant position. Each floor contains one person with each possible destination, so all s_{ij} are 1 and the togetherness rating is zero. If the elevator now transports six people to floor 2, we have the configuration

```
        123456
␣␣␣␣␣␣  123456  123456  123456  123456  123456
```
(23)

and the togetherness rating becomes $6F(0) + 24F(1) + 6F(2) = 12$. Suppose the elevator carries 1, 1, 2, 3, 3, 4 to floor 3:

```
              112334
␣␣␣␣␣␣  245566  123456  123456  123456  123456
```
(24)

The togetherness rating has jumped to $4F(2) + 2F(3) = 18$. When everyone has finally been transported to his or her destination, the togetherness rating will be $6F(6) = 96$.

Floyd observed that the togetherness rating can never increase by more than $b + c$ at each stop, since a set of s equal-destination people joining with a similar set of size s' improves the rating by $F(s + s') - F(s) - F(s') \le s + s'$. Therefore we have the following result.

Theorem F. *Let t be the togetherness rating of an initial configuration of people, in terms of the definitions above. The elevator must make at least*

$$\lceil (nF(c) - t)/(b + c) \rceil$$

stops in order to bring them all to their destinations. ▮

Translating this result into disk terminology, let there be N records, with B per block, and suppose the internal memory can hold M records at a time.

Every disk read brings one block into memory, every disk write stores one block, and s_{ij} is the number of records in block i that belong in block j. If $N \geq B^2$, there are initial configurations in which all the s_{ij} are ≤ 1, so at least $(N/B)F(B)/M \approx (N \log_2 B)/M$ block-reading operations are necessary to rearrange the records. (The factor $\log_2 B$ makes this lower bound nontrivial when B is large, but when $B = 1$ the lower bound can obviously be improved.)

EXERCISES

1. [*M22*] The text explains a method by which the average latency time required to read a fraction x of a track is reduced from $\frac{1}{2}$ to $\frac{1}{2}(1 - x^2)$ revolutions. This is the minimum possible value, when there is one access arm. What is the corresponding minimum average latency time if there are *two* access arms, 180° apart, assuming that only one arm can transmit data at any one time?

2. [*M30*] (A. G. Konheim.) The purpose of this problem is to investigate how far the access arm of a disk must move while merging files that are allocated "orthogonally" to the cylinders. Suppose there are P files, each containing L blocks of records, and assume that the first block of each file appears on cylinder 1, the second on cylinder 2, etc. The relative order of the last keys in each block governs the access arm motion during the merge, hence we may represent the situation in the following mathematically tractable way: Consider a set of PL ordered pairs

$$\begin{array}{cccc} (a_{11}, 1) & (a_{21}, 1) & \ldots & (a_{p1}, 1) \\ (a_{12}, 2) & (a_{22}, 2) & \ldots & (a_{p2}, 2) \\ \vdots & \vdots & & \vdots \\ (a_{1L}, L) & (a_{2L}, L) & \ldots & (a_{pL}, L) \end{array}$$

where the set $\{a_{ij} \mid 1 \le i \le P, 1 \le j \le L\}$ consists of the numbers $\{1, 2, \ldots, PL\}$ in some order, and where $a_{ij} < a_{i,j+1}$ for $1 \le j < L$. (Rows represent cylinders, columns represent input files.) Sort the pairs on their first components and let the resulting sequence be $(1, j_1)\ (2, j_2) \ldots (PL, j_{PL})$. Show that, if each of the $(PL)!/L!^P$ choices of the a_{ij} is equally likely, the average value of

$$|j_2 - j_1| + |j_3 - j_2| + \cdots + |j_{PL} - j_{PL-1}|$$

is

$$(L - 1)\left(1 + (P - 1)2^{2L-2} \Big/ \binom{2L}{L}\right).$$

[*Hint:* See exercise 5.2.1–14.] Note that as $L \to \infty$ this value is asymptotically $\frac{1}{4}(P - 1)L\sqrt{\pi L}$.

3. [*M15*] Suppose the internal memory is limited so that 10-way merging is not feasible. How can recurrence relations (3), (4), (5) be modified so that $A_1(n)$ is the minimum value of $\alpha D(\mathfrak{T}) + \beta E(\mathfrak{T})$, over all n-leaved trees $\mathfrak{T}$ having no internal nodes of degree greater than 9?

▸ **4.** [*M21*] (a) Derive a formula corresponding to (2), for the running time of an L-character P-way merge, when a modified form of the square root buffer allocation is used: All P of the input buffers should have equal length, but the output buffer size should be chosen so as to minimize seek time.

(b) Show that the construction in Theorem K can be modified in order to obtain a merge pattern which is optimal according to your formula from part (a).

5. [*M20*] When two disks are being used, so that reading on one is overlapped with writing on the other, we cannot use merge patterns like that of Fig. 93 since some leaves are at even levels and some are at odd levels. Show how to modify the construction of Theorem K in order to produce trees that are optimal subject to the constraint that all leaves appear on even levels or all on odd levels.

▸ **6.** [*22*] Find a tree which is optimum in the sense of exercise 5, when $n = 23$ and $\alpha = \beta = 1$. (You may wish to use a computer.)

▸ **7.** [*M24*] When the initial runs are not all the same length, the best merge pattern (in the sense of Theorem H) minimizes $\alpha D(\mathfrak{I}) + \beta E(\mathfrak{I})$, where $D(\mathfrak{I})$ and $E(\mathfrak{I})$ now represent *weighted* path lengths: Weights $w_1, \ldots, w_n$ (corresponding to the lengths of the initial runs) are attached to each leaf of the tree, and the degree sums and path lengths are multiplied by the appropriate weights. For example, if $\mathfrak{I}$ is the tree of Fig. 92, we would have $D(\mathfrak{I}) = 6w_1 + 6w_2 + 7w_3 + 9w_4 + 9w_5 + 7w_3 + 4w_7 + 4w_8$, $E(\mathfrak{I}) = 2w_1 + 2w_2 + 2w_3 + 3w_4 + 3w_5 + 2w_6 + w_7 + w_8$.

Prove that there is always an optimal pattern in which the *shortest* k runs are merged first, for some k.

8. [*49*] Is there an algorithm which finds optimal trees for given α, β and weights $w_1, \ldots, w_n$, in the sense of exercise 7, taking only $O(n^c)$ steps for some c?

9. [*M49*] (Schlumberger and Vuillemin.) Do there exist n-leaf optimal trees in the sense of Theorem H, such that all leaves appear on at most two adjacent levels, for all n, α, and β? When α and β are fixed, is there a number m such that $A_1(n) = \alpha mn + \beta n + A_m(n)$ for all sufficiently large n? (Both of these conjectures have been verified when $\alpha/\beta \geq 4$.)

10. [*HM49*] Given α and β, what is the asymptotic value of $A_1(n)$ as $n \to \infty$?

11. [*M29*] In the notation of (11) and (16), prove that $f_m(n) + mn \geq f(n)$ for all $m, n \geq 2$, and determine all m and n for which equality holds.

12. [*25*] Prove that, for all $n > 0$, there is a tree with n leaves and minimum degree path length (11), with all leaves at the same level.

13. [*M24*] Show that for $2 \leq n \leq d(\alpha, \beta)$, the unique best merge pattern in the sense of Theorem H is an n-way merge. (Cf. (17).)

14. [*40*] Using the square root method of buffer allocation, the seek time for the merge pattern in Fig. 92 would be proportional to $(\sqrt{2}+\sqrt{4}+\sqrt{1}+\sqrt{1}+\sqrt{8})^2 + (\sqrt{1}+\sqrt{1}+\sqrt{2})^2 + (\sqrt{1}+\sqrt{2}+\sqrt{1}+\sqrt{4})^2 + (\sqrt{1}+\sqrt{1}+\sqrt{2})^2$; this is the sum, over each internal node, of $(\sqrt{n_1}+\cdots+\sqrt{n_m}+\sqrt{n_1+\cdots+n_m})^2$, where that node's respective subtrees have $(n_1, \ldots, n_m)$ leaves. Write a computer program which generates minimum-seek time trees having 1, 2, 3, . . . leaves, using this formula to estimate the seek time.

15. [*M22*] Show that Theorem F can be improved slightly if the elevator is initially

empty and if $nF(c) \neq t$: At least $\lceil (nF(c) + b - t)/(b + c) \rceil$ stops are necessary in such a case.

16. [*23*] (R. W. Floyd.) Find an elevator schedule which transports all the people of (22) to their destinations in 12 stops or less. (Configuration (23) shows the situation after one, not two, stops.)

17. [*25*] (B. T. Bennett and A. C. McKellar, 1971.) Consider the following approach to keysorting, illustrated on an example file with 10 keys:

a) Original file: (50, I_0)(08, I_1)(51, I_2)(06, I_3)(90, I_4)(17, I_5)(89, I_6)(27, I_7)(65, I_8)(42, I_9)
b) Key file: (50, 0)(08, 1)(51, 2)(06, 3)(90, 4)(17, 5)(89, 6)(27, 7)(65, 8)(42, 9)
c) Sorted (b): (06, 3)(08, 1)(17, 5)(27, 7)(42, 9)(50, 0)(51, 2)(65, 8)(89, 6)(90, 4)
d) Bin assignments: (3, 3)(3, 9)(2, 1)(2, 5)(2, 7)(2, 8)(1, 0)(1, 2)(1, 4)(1, 6)
e) Sorted (d): (1, 0)(2, 1)(1, 2)(3, 3)(1, 4)(2, 5)(1, 6)(2, 7)(2, 8)(3, 9)
f) (a) distributed into bins using (e):
   Bin 1: (50, I_0)(51, I_2)(90, I_4)(89, I_6)
   Bin 2: (08, I_1)(17, I_5)(27, I_7)(65, I_8)
   Bin 3: (06, I_3)(42, I_9)
g) The result of replacement selection, reading first bin 3, then bin 2, then bin 1: (06, I_3)(08, I_1)(17, I_5)(27, I_7)(42, I_9)(50, I_0)(51, I_2)(65, I_8)(89, I_6)(90, I_4)

The assignment of bin numbers in step (d) is made by doing *replacement selection* on (c), *from right to left*, in *decreasing* order of the second component. The bin number is the run number. The above example uses replacement selection with only two elements in the selection tree; the same size tree should be used for replacement selection in both (d) and (g). Note that the bin contents are not necessarily in sorted order!

Prove that this method will sort, i.e., that the replacement selection in (g) will produce only one run. (This technique reduces the number of bins needed in a conventional keysort by distribution, especially if the input is largely in order already.)

▸ **18.** [*25*] Some hardware/software systems provide programmers with a *virtual memory:* Programs can be written as if there were a very large internal memory, able to contain all of the data. This memory is divided into *pages*, only a few of which are in the actual internal memory at any one time; the others are on disks or drums. The programmer need not concern himself with such details, since the system takes care of everything; new pages are automatically brought into memory when needed.

It would seem that the advent of virtual memory technology makes external sorting methods obsolete, since the job can simply be done using the techniques developed for internal sorting. Discuss this situation; in what ways might a hand-tailored external sorting method be better than the application of a general-purpose paging technique to an internal sorting method?

5.5. SUMMARY, HISTORY, AND BIBLIOGRAPHY

Now that we have nearly reached the end of this enormously long chapter, we had better "sort out" the most important facts we have studied.

An algorithm for sorting is a procedure which rearranges a file of records so that the keys are in ascending order. This orderly arrangement is useful because it brings equal-key records together, it allows efficient processing of multiple files sorted on the same key, it leads to efficient retrieval algorithms, and it makes computer output look more authentic.

Internal sorting is used when all of the records fit in the computer's high speed internal memory. We have studied more than two dozen algorithms for internal sorting, in various degrees of detail; and perhaps we would be happier if we didn't know so many different approaches to the problem! It was fun to learn all the techniques, but now we must face the horrible prospect of actually deciding which method ought to be used in a given situation.

It would be nice if only one or two of the sorting methods would dominate all of the others, regardless of the application or the computer being used. But in fact, each method has its own peculiar virtues. For example, the bubble sort (Algorithm 5.2.2B) has no apparent redeeming features, since there is always a better way to do what it does; but even this technique, suitably generalized, turns out to be useful for two-tape sorting (cf. Section 5.4.8). Thus we find that nearly all of the algorithms deserve to be remembered, since there are some applications in which they turn out to be best.

The following brief survey gives the highlights of the most significant algorithms we have encountered for internal sorting. As usual, N stands for the number of records in the given file.

1. *Distribution counting*, Algorithm 5.2D, is very useful when the keys have a small range. It is stable (doesn't affect the order of records with equal keys), but requires memory space for counters and for $2N$ records. A modification which saves N of these record spaces at the cost of stability appears in exercise 5.2–13.

2. *Straight insertion*, Algorithm 5.2.1S, is the simplest method to program, requires no extra space, and is quite efficient for small N (say $N \leq 25$). For large N it is unbearably slow unless the input is nearly in order.

3. *Diminishing increment sort*, Algorithm 5.2.1D (Shell's method), is also quite easy to program, and uses minimum memory space; and it is reasonably efficient for moderately large N (say $N \leq 1000$).

4. *List insertion*, Algorithm 5.2.1L, uses the same basic idea as straight insertion, so it is suitable only for small N. Like the other list sorting methods described below, it saves the cost of moving long records by manipulating links; this is particularly advantageous when the records have variable length or are part of other data structures.

5. *Address calculation* techniques are efficient when the keys have a known

(usually uniform) distribution; the principal variants of this approach are *multiple list insertion* (Algorithm 5.2.1M), and MacLaren's combined radix-insertion method (discussed at the close of Section 5.2.5). The latter can be done with only $O(\sqrt{N})$ cells of additional memory.

6. *Merge exchange*, Algorithm 5.2.2M (Batcher's method) and its cousin the *bitonic sort* (exercise 5.3.4–10) are useful when a large number of comparisons can be made simultaneously.

7. *Partition exchange*, Algorithm 5.2.2Q (Hoare's method, commonly known as *quicksort*) is probably the most useful general-purpose technique for internal sorting, because it requires very little memory space and its average running time on most computers beats that of its competitors. It can run *very* slowly in its worst case, however, so a careful choice of the partitioning elements should be made whenever nonrandom data are likely. Choosing the median of three elements, as suggested in exercise 5.2.2–55, makes the worst-case behavior extremely unlikely and also gives a slight improvement to the average running time.

8. *Straight selection*, Algorithm 5.2.3S, is a simple method especially suitable when special hardware is available to find the smallest element of a list at high speed.

9. *Heapsort*, Algorithm 5.2.3H, requires minimum memory and is guaranteed to run pretty fast; its average time and its maximum time are both roughly twice the average running time of quicksort.

10. *List merging*, Algorithm 5.2.4L, is a list sort which, like heapsort, is guaranteed to be rather fast even in its worst case; moreover, it is stable with respect to equal keys.

11. *Radix sorting*, using Algorithm 5.2.5R, is a list sort especially appropriate for keys which are either rather short or which have an unusual lexicographic collating sequence. Alternatively, the distribution counting method (point 1 above) could be used instead of links; such a procedure requires $2N$ record spaces, plus a table of counters, but the simple form of its inner loop makes it especially good for ultra-fast, "number-crunching" computers which have look-ahead control. *Caution:* Radix sorting should not be used for small N!

12. *Merge insertion*, see Section 5.3.1, is especially suitable for very small N, in a "straight-line-coded" routine; for example, it would be the appropriate method in an application which requires the sorting of numerous five- or six-record groups.

13. Hybrid methods, combining one or more of the above techniques, are also possible. For example, merge insertion could be used for sorting short subfiles that arise in quicksort.

14. Finally, an unnamed method appearing in the answer to exercise 5.2.1–3 seems to require the shortest possible sorting program. But its average running time, proportional to N^3, makes it the slowest sorting routine in this book!

Table 1

A COMPARISON OF INTERNAL SORTING METHODS USING THE MIX COMPUTER

Method	Reference	Stable?	Length of MIX code	Space	Running time: Average	Running time: Maximum	Running time: $N = 16$	Running time: $N = 1000$	Notes
Comparison counting	Ex. 5.2–5	Yes	22	$N(1+\epsilon)$	$4N^2+10N$	$5.5N^2$	1065	3992427	c
Distribution counting	Ex. 5.2–9	Yes	26	$2N+1000\epsilon$	$22N+10000$	$22N$	10352	32000	a
Straight insertion	Ex. 5.2.1–33	Yes	12	N	$2N^2+9N$	$4N^2$	494	1985566	
Diminishing increments	Prog. 5.2.1D	No	21	N	$15N^{1.25}$	$cN^{1.5}$	529	131002	d, h
List insertion	Ex. 5.2.1–33	Yes	19	$N(1+\epsilon)$	$1.25N^2+13.25N$	$2.5N^2$	433	1248615	b, c
Multiple list insertion	Prog. 5.2.1M	No	18	$N+\epsilon(N+100)$	$.0175N^2+18N$	$3.5N^2$	645	35246	b, c, f, i
Merge exchange	Ex. 5.2.2–12	No	36	N	$3.7N(\log_2 N)^2$	$cN\ln^2 N$	1284	379104	h
Partition exchange	Prog. 5.2.2Q	No	63	$N+2\epsilon\log_2 N$	$12.67N\ln N-1.92N$	$\geq 2N^2$	518	81946	
Median-of-3 quicksort	Ex. 5.2.2–55	No	91	$N+2\epsilon\log_2 N$	$11.66N\ln N+1.89N$	$\geq N^2$	567	81485	e
Radix exchange	Prog. 5.2.2R	No	45	$N+68\epsilon$	$14.43N\ln N+23.9N$	$272N$	1135	137614	g, i, j
Straight selection	Prog. 5.2.3S	Yes	15	N	$2.5N^2+3N\ln N$	$3.25N^2$	853	2525287	j
Heapsort	Prog. 5.2.3H	No	30	N	$23.08N\ln N+0.2N$	$26N\ln N$	1068	159714	h, j
List merge	Prog. 5.2.4L	Yes	44	$N(1+\epsilon)$	$14.43N\ln N+4.92N$	$14.4N\ln N$	761	104716	b, c, j
Radix list sort	Prog. 5.2.5R	Yes	36	$N+\epsilon(N+200)$	$32N+4838$	$32N$	4250	36838	b, c

a: three-digit keys only.
b: six-digit (i.e., three-byte) keys only.
c: Output not rearranged; final sequence is specified implicitly by links or counters.
d: Increments chosen as in 5.2.1–8; a slightly better sequence appears in exercise 5.2.1–29.
e: $M = 10$, using SRB; for the version with DIV, add $\frac{13}{7}N$ to the average running time.
f: $M = 100$ (the byte size).
g: $M = 34$, since $2^{34} > 10^{10} > 2^{33}$.
h: Average time is based on empirical estimate, since the theory is incomplete.
i: Average time based on the assumption of uniformly distributed keys.
j: Further refinements, mentioned in the text and exercises accompanying this program, would reduce the running time.

Table 1 summarizes the speed and space characteristics of many of these methods, when programmed for MIX. It is important to realize that the figures in this table are only rough indications of the relative sorting times; they apply to one computer only, and the assumptions made about input data are not completely consistent for all programs. Comparative tables such as this have been given by many authors, with no two people reaching the same conclusions! On the other hand, the timings do give at least an indication of the kind of speed to be expected from each algorithm, when sorting one-word records, since MIX is a fairly typical computer.

The "space" column in Table 1 gives some information about the amount of auxiliary memory used by each algorithm, in units of record length. Here "ϵ" denotes the fraction of a record needed for one link field; thus, for example, $N(1 + \epsilon)$ means that the method requires space for N records plus N link fields.

The asymptotic average and maximum times appearing in Table 1 give only the leading terms which dominate for large N, assuming random input; c denotes an unspecified constant. These formulas can often be misleading, so actual total running times have also been listed, for sample runs of the program on two particular sequences of input data. The case $N = 16$ refers to the sixteen keys which appear in so many of the examples of Section 5.2; and the case $N = 1000$ refers to the sequence $K_1, K_2, \ldots, K_{1000}$ defined by

$$K_0 = 0; \qquad K_{n+1} = (3141592621K_n + 2113148651) \bmod 10^{10}.$$

A reasonably "high-quality" MIX program has been used to represent each algorithm in the table, often incorporating improvements that have been suggested in the exercises. The byte size for these runs was 100.

External sorting techniques are different from internal sorting, because they must use comparatively primitive data structures, and because there is a great emphasis on minimizing their input/output time. Section 5.4.6 summarizes the interesting methods that have been developed for tape merging, and Section 5.4.9 discusses the use of disks and drums.

Of course, sorting isn't the whole story. While studying all of these sorting techniques, we have learned a good deal about how to handle data structures, how to deal with external memories, and how to analyze algorithms; and perhaps we have even learned a little about how to discover new algorithms.

Early developments. A search for the origin of today's sorting techniques takes us back to the nineteenth century, when the first machines for sorting were invented. The United States conducts a census of all its citizens, every ten years, and by 1880 the problem of processing the voluminous census data was becoming very acute; in fact, the total number of single (as opposed to married) people was never tabulated that year, although the necessary information had been gathered. Herman Hollerith, a 20-year-old employee of the Census Bureau, devised an ingenious electric tabulating machine to meet the need for better statistics-gathering, and about 100 of his machines were successfully used to tabulate the 1890 census rolls.

Figure 94 shows Hollerith's original battery-driven apparatus; of chief interest to us is the "sorting box" at the right, which has been opened to show half of the 26 inner compartments. The operator would insert a $6\frac{5}{8}'' \times 3\frac{1}{4}''$ punched card into the "press" and lower the handle; this caused spring-actuated pins in the upper plate to make contact with pools of mercury in the lower plate, wherever a hole was punched in the card. The corresponding completed circuits would cause associated dials on the panel to advance by one unit; and furthermore, one of the 26 lids of the sorting box would pop open. At this point the operator would reopen the press, put the card into the open compartment, and close the lid. One man reportedly ran 19071 cards through this machine in a single $6\frac{1}{2}$-hour working day, an average of about 49 cards per minute! (A typical operator would work at about one-third this speed.)

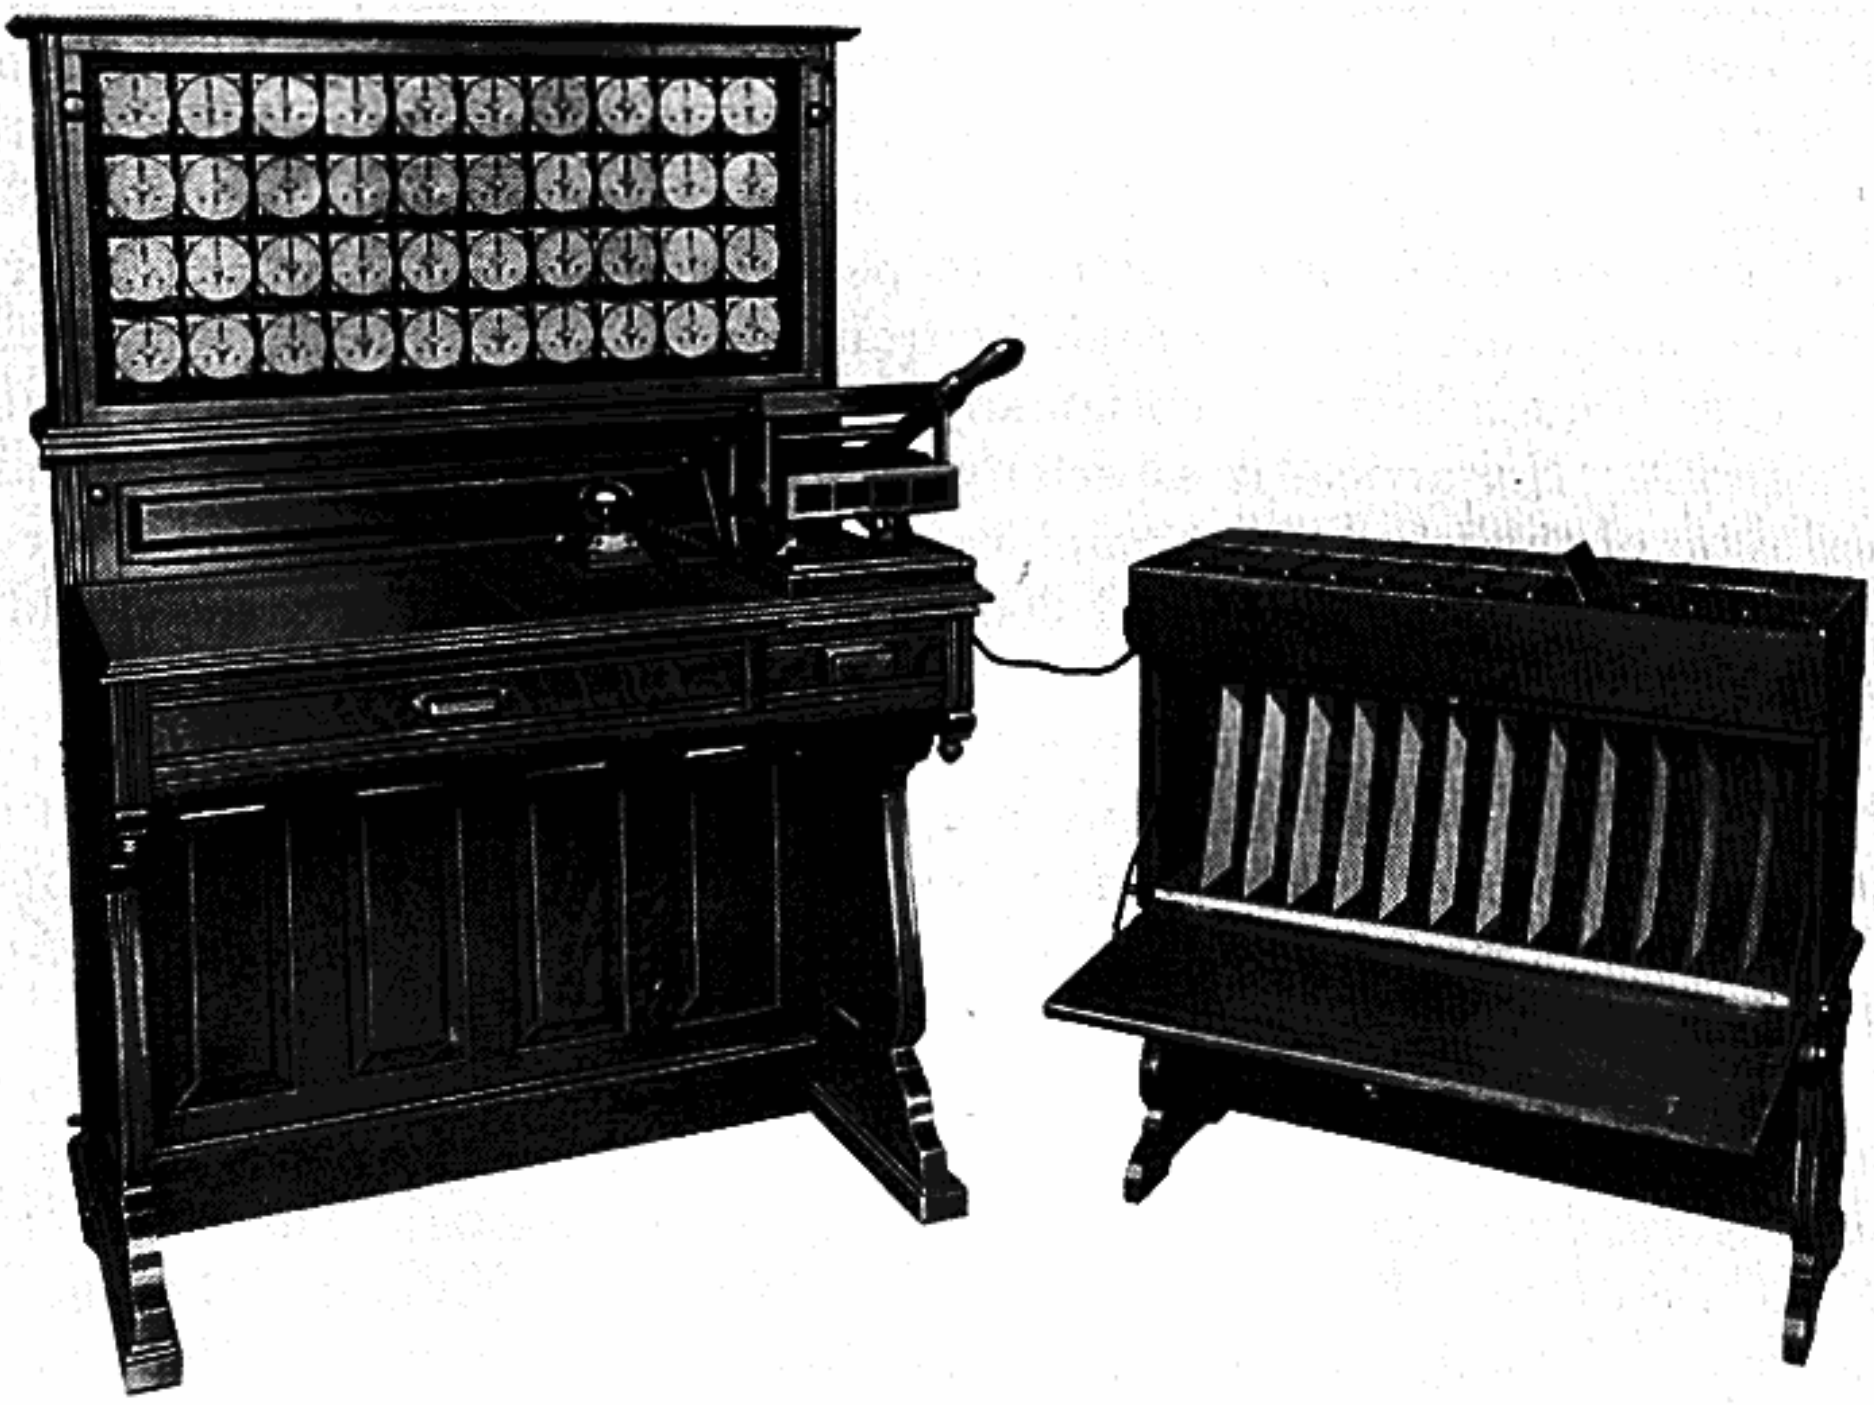

Fig. 94. Hollerith's original tabulating and sorting machine. (Photo courtesy of IBM Archives.)

Population continued its inexorable growth pattern, and the original tabulator-sorters were not fast enough to handle the 1900 census; so Hollerith devised another machine to stave off another data processing crisis. His new device (patented in 1901 and 1904) had an automatic card feed, and in fact it looked essentially like modern card sorters. The story of Hollerith's early machines has been told in interesting detail by Leon E. Truesdell, *The Development of Punch Card Tabulation* (Washington: U.S. Bureau of the Census, 1965); see also the contemporary accounts in *Columbia College School of Mines Quarterly* **10** (1889), 238–255; *J. Franklin Inst.* **129** (1890), 300–306; *The Electrical Engi-*

neer **12** (Nov. 11, 1891), 521–530; *J. Amer. Statistical Assn.* **2** (1891), 330–341, **4** (1895), 365; *J. Royal Statistical Soc.* **55** (1892), 326–327; *Allgemeines Statistisches Archiv* **2** (1892), 78–126; *J. Soc. Statistique de Paris* **33** (1892), 87–96; *U.S. Patents 395781* (1889), *685608* (1901), *777209* (1904). Hollerith and another former Census Bureau employee, James Powers, went on to found rival companies which eventually became part of IBM and Remington Rand corporations, respectively.

Hollerith's sorting machine is, of course, the basis for radix sorting methods now used in digital computers. His patent mentions that two-column numerical items are to be sorted "separately for each column," but he didn't say whether or not the units or the tens columns should be considered first. The nonobvious trick of using the units column first was presumably discovered by some anonymous machine operator and passed on to others (cf. Section 5.2.5); it appears in the earliest extant IBM sorter manual (1936). The first known mention of this right-to-left technique is an incidental remark which appears in an article by L. J. Comrie, *Trans. of the Office Machinery Users' Assoc.* (London, 1930), 25–37. Incidentally, Comrie was the first person to make the important observation that tabulating machines could be fruitfully employed in scientific calculations, even though they were originally designed for statistical and accounting applications. His article is especially interesting because it gives a detailed description of the tabulating equipment available in England in 1930. Sorting machines at that time processed 360 to 400 cards per minute, and could be rented for £9 per month.

The idea of merging goes back to another card-walloping machine, the *collator*, which was a much later invention (1938). With its two feeding stations, it could merge two sorted decks of cards into one, in only one pass; the technique for doing this was clearly explained in the first IBM collator manual (April, 1939). [Cf. James W. Bryce, *U.S. Patent 2189024* (1940).]

Then computers arrived on the scene, and sorting was intimately involved in this development; in fact, there is evidence that a sorting routine was the first program ever written for a stored program computer. The designers of EDVAC were especially interested in sorting, because it epitomized the potential non-numerical applications of computers; they realized that a satisfactory order code should not only be capable of expressing programs for the solution of difference equations, it must also have enough flexibility to handle the combinatorial "decision-making" aspects of algorithms. John von Neumann therefore prepared programs for internal merge sorting in 1945, in order to test the adequacy of some instruction codes he was proposing for the EDVAC computer; the existence of efficient special-purpose sorting machines provided a natural standard by which the merits of his proposed computer organization could be evaluated. Details of this interesting development have been described in an article by D. E. Knuth, *Computing Surveys* **2** (1970), 247–260; see also von Neumann's *Collected Works* **5** (New York: Macmillan, 1963), 196–214, for the final "polished" form of his original sorting programs.

The limited internal memory size planned for early computers made it

natural to think of external sorting as well as internal sorting, and a "Progress Report on the EDVAC" prepared by J. P. Eckert and J. W. Mauchly of the Moore School of Electrical Engineering (September 30, 1945) pointed out that a computer augmented with magnetic wire or tape devices could simulate the operations of card equipment, achieving a faster sorting speed. This progress report described balanced two-way radix sorting, and balanced two-way merging (called "collating"), using four magnetic wire or tape units, reading or writing "at least 5000 pulses per second."

John Mauchly lectured on "Sorting and Collating" at the special session on computing presented at the Moore School in 1946, and the notes of his lecture constitute the first published discussion of computer sorting [*Theory and techniques for the design of electronic digital computers*, ed. by G. W. Patterson, **3** (1946), 22.1–22.20]. Mauchly began his presentation with an interesting remark: "To ask that a single machine combine the abilities to compute and to sort might seem like asking that a single device be able to perform both as a can opener and a fountain pen." Then he observed that machines capable of carrying out sophisticated mathematical procedures must also have the ability to sort and classify data, and he showed that sorting may even be useful in connection with numerical calculations. He described straight insertion and binary insertion, observing that the former method uses about $N^2/4$ comparisons on the average, while the latter never needs more than about $N \log_2 N$. Yet binary insertion requires a rather complex data structure, and he went on to show that two-way merging achieves the same low number of comparisons using only sequential accessing of lists. The last half of his lecture notes were devoted to a discussion of partial-pass radix sorting methods which simulate digital card sorting on four tapes, using less than four passes per digit (cf. Section 5.4.7).

Shortly afterwards, Eckert and Mauchly started a company which produced some of the earliest electronic computers, the BINAC (for military applications) and the UNIVAC (for commercial applications). Again the U.S. Census Bureau played a part in this development, receiving the first UNIVAC. At this time it was not at all clear that computers would be economically profitable; computing machines could sort faster than card equipment, but they cost more. Therefore the UNIVAC programmers, led by Frances E. Holberton, put considerable effort into the design of high-speed external sorting routines, and their preliminary programs also influenced the hardware design. According to their estimates, 100 million 10-word records could be sorted on UNIVAC in 9000 hours (i.e., 375 days).

UNIVAC I, officially dedicated in July, 1951, had an internal memory of 1000 12-character (72-bit) words. It was designed to read and write 60-word blocks on tapes, at a rate of 500 words per second; reading could be either forward or backward, and simultaneous reading/writing/computing was possible. In 1948, Mrs. Holberton devised an interesting way to do two-way merging with perfect overlap of reading, writing, and computing, using six input buffers: Let there be one "current buffer" and two "auxiliary buffers" for each input file; it is possible to merge in such a way that, whenever it is time

to output one block, the two current input buffers contain a total of exactly one block's worth of unprocessed records. Therefore exactly one input buffer becomes empty while each output block is being formed, and we can arrange to have three of the four auxiliary buffers full at all times while we are reading into the other. This method is slightly faster than the forecasting method of Algorithm 5.4.6F, since it is not necessary to inspect the result of one input before initiating the next. [Cf. "Collation Methods for the UNIVAC System," (Eckert-Mauchly Computer Corp., 1950), 2 vols.]

The culmination of this work was a sort generator program, which was the first major "software" routine ever developed for automatic programming. The user would specify the record size, the positions of up to five keys in partial fields of each record, and the "sentinel" keys which mark file's end, and the sort generator would produce a copyrighted sorting program for one-reel files. The first pass of this program was an internal sort of 60-word blocks, using comparison counting (Algorithm 5.2C); then came a number of balanced two-way merge passes, reading backwards and avoiding tape interlock as described above. [Cf. "Master Generating Routine for 2-way Sorting" (Eckert-Mauchly Div. of Remington Rand, 1952); the first draft of this report was entitled "Master Prefabrication Routine for 2-way Collation"! See also F. E. Holberton, *Symposium on Automatic Programming* (Office of Naval Research, 1954), 34–39.]

By 1952, many approaches to internal sorting were well known in the programming folklore, but comparatively little theory had been developed. Daniel Goldenberg ["Time analyses of various methods of sorting data," Digital Computer Laboratory memo M-1680 (Mass. Inst. of Tech., October 17, 1952)] coded five different methods for the Whirlwind computer, and made best-case and worst-case analyses of each program. When sorting one hundred 15-bit words on an 8-bit key, he found that the fastest method was to use a 256-word table, storing each record into a unique position corresponding to its key, then compressing the table. But this technique had an obvious disadvantage, since it would eliminate a record whenever a subsequent one had the same key. The other four methods he analyzed were ranked as follows: straight two-way merging beat radix-2 sorting beat straight selection beat bubble sort.

These results were extended by Harold H. Seward in his 1954 Master's thesis ["Information sorting in the application of electronic digital computers to business operations," Digital Computer Lab. report R-232 (Mass. Inst. of Tech., May 24, 1954; 60 pp.)]. Seward introduced the ideas of distribution counting and replacement selection; he showed that the first run in a random permutation has an average length of $e - 1$; and he analyzed external sorting as well as internal sorting, on various types of bulk memories as well as tapes.

An even more noteworthy thesis—a Ph.D. thesis in fact—was written by Howard B. Demuth in 1956 ["Electronic Data Sorting" (Stanford University, October, 1956), 92 pp.]. This work helped to lay the foundations of computational complexity theory. It considered three abstract models of the sorting

problem, using cyclic, linear, and random-access memories; and optimal or near-optimal methods were developed for each model. (Cf. exercise 5.3.4–6.) Although no practical consequences flowed immediately from Demuth's thesis, it established important ideas about how to link theory with practice.

Thus the history of sorting has been closely associated with many "firsts" in computing: The first data-processing machines, the first stored programs, the first software, the first buffering methods, the first work on algorithmic analysis and computational complexity.

None of the computer-related documents mentioned so far actually appeared in the "open literature"; in fact, most of the early history of computing appears in comparatively inaccessible reports, because comparatively few people were involved with computers at the time. Literature about sorting finally broke into print in 1955–1956, in the form of three major survey articles.

The first paper was prepared by J. C. Hosken [*Proc. Eastern Joint Computer Conference* **8** (1955), 39–55]. He began with an astute observation: "To lower costs per unit of output, people usually increase the size of their operations. But under these conditions, the unit cost of sorting, instead of falling, rises." Hosken surveyed all the available special-purpose equipment then being marketed, as well as the methods of sorting on computers. His bibliography of 54 items is mostly based on manufacturer's brochures.

The comprehensive paper "Sorting on Electronic Computer Systems" by E. H. Friend [*JACM* **3** (1956), 134–168] was a major milestone in the development of sorting. Although numerous techniques have been developed since 1956, this paper is still remarkably up-to-date in many respects. Friend gave careful descriptions of quite a few internal and external sorting algorithms, and he paid special attention to buffering techniques and the characteristics of magnetic tape units. He introduced some new methods (e.g., tree selection, amphisbaenic sorting, and forecasting), and developed some of the mathematical properties of the older methods.

The third survey of sorting to appear about this time was prepared by D. W. Davies [*Proc. Inst. Elect. Engineers* **103B**, Supplement 1 (1956), 87–93]. In the following years several other notable surveys were published, by D. A. Bell [*Comp. J.* **1** (1958), 71–77]; A. S. Douglas [*Comp. J.* **2** (1959), 1–9]; D. D. McCracken, H. Weiss, and T. Lee [*Programming Business Computers* (New York: Wiley, 1959), Chapter 15, pp. 298–332]; I. Flores [*JACM* **8** (1961), 41–80]; K. E. Iverson [*A Programming Language* (New York: Wiley, 1962), Chapter 6, 176–245]; C. C. Gotlieb [*CACM* **6** (1963), 194–201]; T. N. Hibbard [*CACM* **6** (1963), 206–213]; M. A. Goetz [*Digital Computer User's Handbook*, ed. by M. Klerer and G. A. Korn (New York: McGraw-Hill, 1967), Chapter 1.10, pp. 1.292–1.320]. A symposium on sorting was sponsored by ACM in November, 1962; most of the papers presented at that symposium were published in the May, 1963, issue of *CACM*, and they constitute a good representation of the state of the art at that time. C. C. Gotlieb's survey of contemporary sort generators, T. N. Hibbard's survey of minimal storage internal sorting, and

G. U. Hubbard's early exploration of disk file sorting are particularly noteworthy articles in this collection.

New sorting methods were being discovered throughout this period: Address calculation (1956), merge insertion (1959), radix exchange (1959), cascade merge (1959), Shell's diminishing increment sort (1959), polyphase merge (1960), tree insertion (1960), oscillating sort (1962), Hoare's quicksort (1962), Williams's heapsort (1964), Batcher's merge exchange (1964). The history of each individual algorithm has been traced in the particular section of this chapter where that method is described. The late 1960's saw an intensive development of the corresponding theory.

A complete bibliography of all papers on sorting examined by the author as this chapter was being written appears in *Computing Reviews* **13** (1972), 283–289.

EXERCISES

1. [*05*] Summarize the content of this chapter by stating a generalization of Theorem 5.4.6A.

2. [*20*] Based on the information in Table 1, what is the best list-sorting method for six-digit keys, for use on the MIX computer?

3. [*47*] (*Stable sorting in minimum storage.*) A sorting algorithm is said to require *minimum storage* if it uses only $O((\log N)^2)$ bits of memory space for its variables besides the space needed to store the N records. The algorithm must be general in the sense that it works for all N, not just for a particular value of N, assuming that a sufficient amount of random access memory has been made available whenever the algorithm is actually called upon to sort.

Many of the sorting methods we have studied violate this minimum-storage requirement; in particular, the use of N link fields is forbidden. Quicksort (Algorithm 5.2.2Q) satisfies the minimum-storage requirement, but its worst case running time is proportional to N^2. Heapsort (Algorithm 5.2.3H) is the only $O(N \log N)$ algorithm we have studied which uses minimum storage, although another such algorithm could be formulated using the idea of exercise 5.2.4–18.

The fastest general algorithm we have considered which sorts keys in a *stable* manner is the list merge sort (Algorithm 5.2.4L), but it does not use minimum storage. In fact, the only stable minimum-storage sorting algorithms we have seen are $O(N^2)$ methods (straight insertion, bubble sorting, and a variant of straight selection).

Is there a stable minimum-storage sorting algorithm which requires less than $O(N^2)$ units of time in its worst case, and/or on the average?

I shall have accomplished my purpose if I have sorted and put in logical order the gist of the great volume of material which has been generated about sorting over the past few years.

—J. C. HOSKEN (1955)

CHAPTER SIX

SEARCHING

Let's look at the record.

—AL SMITH (1928)

This chapter might have been given the more pretentious title, "Storage and Retrieval of Information"; on the other hand, it might simply have been called "Table Look-Up." We are concerned with the process of collecting information in a computer's memory, and with the subsequent recovery of that information as quickly as possible. Sometimes we are confronted with more data than we can really use, and it may be wisest to forget and to destroy most of it; but at other times it is important to retain and organize the given facts in such a way that fast retrieval is possible.

Most of this chapter is devoted to the study of a very simple search problem: how to find the data that has been stored with a given identification. For example, in a numerical application we might want to find $f(x)$, given x and a table of the values of f; in a nonnumerical application, we might want to find the English translation of a given Russian word.

In general, we shall suppose that a set of N records has been stored, and the problem is to locate the appropriate one. As in the case of sorting, we assume that each record includes a special field called its *key*, perhaps because many people spend so much time every day searching for their keys. We generally require the N keys to be distinct, so that each key uniquely identifies its record. The collection of all records is called a *table* or a *file*, where the word "table" is usually used to indicate a small file, and "file" is usually used to indicate a large table. A large file or a group of files is frequently called a *data base*.

Algorithms for searching are presented with a so-called *argument*, K, and the problem is to find which record has K as its key. After the search is complete, two possibilities can arise: Either the search was *successful*, having located the unique record containing K, or it was *unsuccessful*, having determined that K is nowhere to be found. After an unsuccessful search it is sometimes desirable to enter a new record, containing K, into the table; a method which does this is called a "search and insertion" algorithm. Some hardware devices known as "associative memories" solve the search problem automatically, in a way that resembles the functioning of a human brain; but we shall study techniques for searching on a conventional general-purpose digital computer.

Although the goal of searching is to find the information stored in the record associated with K, the algorithms in this chapter generally ignore everything but the keys themselves. In practice we can find the associated data once we have located K; for example, if K appears in location TABLE $+ i$, the associated data (or a pointer to it) might be in location TABLE $+ i + 1$, or in DATA $+ i$, etc. It is therefore convenient to gloss over the details of what should be done after K has been successfully found.

Searching is the most time-consuming part of many programs, and the substitution of a good search method for a bad one often leads to a substantial increase in speed. In fact it is often possible to arrange the data or the data structure so that searching is eliminated entirely, i.e., so that we always know just where to find the information we need. Linked memory is a common way to achieve this; for example, a doubly-linked list makes it unnecessary to search for the predecessor or successor of a given item. Another way to avoid searching occurs if we are allowed to choose the keys freely, since we might as well let them be the numbers $\{1, 2, \ldots, N\}$; then the record containing K can simply be placed in location TABLE $+ K$. Both of these techniques were used to eliminate searching from the topological sorting algorithm discussed in Section 2.2.3. However, there are many cases when a search is necessary (for example, if the objects in the topological sorting algorithm had been given symbolic names instead of numbers), so it is important to have efficient algorithms for searching.

Search methods might be classified in several ways. We might divide them into internal vs. external searching, just as we divided the sorting algorithms of Chapter 5 into internal vs. external sorting. Or we might divide search methods into static vs. dynamic searching, where "static" means that the contents of the table are essentially unchanging (so that it is important to minimize the search time without regard for the time required to set up the table), and "dynamic" means that the table is subject to frequent insertions (and perhaps also deletions). A third possible scheme is to classify search methods according to whether they are based on comparisons between keys or on digital properties of the keys, analogous to the distinction between sorting by comparison and sorting by distribution. Finally we might divide searching into those methods which use the actual keys and those which work with transformed keys.

The organization of this chapter is essentially a combination of the latter two modes of classification. Section 6.1 considers "brute force" sequential methods of search, then Section 6.2 discusses the improvements which can be made based on comparisons between keys, using alphabetic or numeric order to govern the decisions. Section 6.3 treats digital searching, and Section 6.4 discusses an important class of methods called hashing techniques, based on arithmetic transformations of the actual keys. Each of these sections treats both internal and external searching, in both the static and the dynamic case;

and each section points out the relative advantages and disadvantages of the various algorithms.

There is a certain amount of interaction between searching and sorting. For example, consider the following problem:

> Given two sets of numbers, $A = \{a_1, a_2, \ldots, a_m\}$ and $B = \{b_1, b_2, \ldots, b_n\}$, determine whether or not $A \subseteq B$.

Three solutions suggest themselves, namely

1. Compare each a_i sequentially with the b_j's until finding a match.
2. Enter the b_j's in a table, then search for each of the a_i.
3. Sort the a's and b's, then make one sequential pass through both files, checking the appropriate condition.

Each of these solutions is attractive for a different range of values of m and n. Solution 1 will take roughly c_1mn units of time, for some constant c_1, and solution 3 will take about $c_2(m \log_2 m + n \log_2 n)$ units, for some (larger) constant c_2. With a suitable hashing method, solution 2 will take roughly $c_3m + c_4n$ units of time, for some (still larger) constants c_3 and c_4. It follows that solution 1 is good for very small m and n, but solution 3 soon becomes better as m and n grow larger. Eventually solution 2 becomes preferable, until n exceeds the internal memory size; then solution 3 is usually again superior until n gets much larger still. Thus we have a situation where sorting is sometimes a good substitute for searching, and searching is sometimes a good substitute for sorting.

More complicated search problems can often be reduced to the simpler case considered here. For example, suppose that the keys are words which might be slightly misspelled; we might want to find the correct record in spite of this error. If we make two copies of the file, one in which the keys are in normal alphabetic order and another in which they are ordered from right to left (as if the words were spelled backwards), a misspelled search argument will probably agree up to half or more of its length with an entry in one of these two files. The search methods of Sections 6.2 and 6.3 can therefore be adapted to find the key that was probably intended.

A related problem has received considerable attention in connection with airline reservation systems, and in other applications involving people's names when there is a good chance that the name will be misspelled due to poor handwriting or voice transmission. The goal is to transform the argument into some code that tends to bring together all variants of the same name. The following "Soundex" method, which was originally developed by Margaret K. Odell and Robert C. Russell [cf. *U.S. Patents 1261167* (1918), *1435663* (1922)], has often been used for encoding surnames:

1. Retain the first letter of the name, and drop all occurrences of a, e, h, i, o, u, w, y in other positions.
2. Assign the following numbers to the remaining letters after the first:

   b, f, p, v → 1
   c, g, j, k, q, s, x, z → 2
   d, t → 3
   l → 4
   m, n → 5
   r → 6

3. If two or more letters with the same code were adjacent in the original name (before step 1), omit all but the first.
4. Convert to the form "letter, digit, digit, digit" by adding trailing zeros (if there are less than three digits), or by dropping rightmost digits (if there are more than three).

For example, the names Euler, Gauss, Hilbert, Knuth, Lloyd, and Łukasiewicz have the respective codes E460, G200, H416, K530, L300, L222. Of course this system will bring together names that are somewhat different, as well as names that are similar; the same six codes would be obtained for Ellery, Ghosh, Heilbronn, Kant, Ladd, and Lissajous. And on the other hand a few related names like Rogers and Rodgers, or Sinclair and St. Clair, or Tchebysheff and Chebyshev, remain separate. But by and large the Soundex code greatly increases the chance of finding a name in one of its disguises. [For further information, cf. C. P. Bourne and D. F. Ford, *JACM* **8** (1961), 538–552; Leon Davidson, *CACM* **5** (1962), 169–171; *Federal Population Censuses* 1790–1890 (Washington, D.C.: National Archives, 1971), 90.]

When using a scheme like Soundex, we need not give up the assumption that all keys are distinct; we can make lists of all records with equivalent codes, treating each list as a unit.

Large data bases tend to make the retrieval process more complex, since people often want to consider many different fields of each record as potential keys, with the ability to locate items when only part of the key information is specified. For example, given a large file about stage performers, a producer might wish to find all unemployed actresses between 25 and 30 with dancing talent and a French accent; given a large file of baseball statistics, a sports-writer may wish to determine the total number of runs scored by the Cincinnati Redlegs in 1964, during the seventh inning of night games, against lefthanded pitchers. Given a large file of data about anything, people like to ask arbitrarily complicated questions. Indeed, we might consider an entire library as a data base, and a searcher may want to find everything that has been published about information retrieval. An introduction to the techniques for such *multi-attribute retrieval* problems appears below in Section 6.5.

Before entering into a detailed study of searching, it may be helpful to put things in historical perspective. During the pre-computer era, many books of logarithm tables, trigonometry tables, etc., were compiled, so that mathematical calculations could be replaced by searching. Eventually these tables were transferred to punched cards, and used for scientific problems in connection

with collators, sorters, and duplicating punch machines. But when stored-program computers were introduced, it soon became apparent that it was now cheaper to recompute $\log x$ or $\cos x$ each time, instead of looking up the answer in a table.

Although the problem of sorting received considerable attention already in the earliest days of computers, comparatively little was done about algorithms for searching. With small internal memories, and with nothing but sequential media like tapes for storing large files, searching was either trivially easy or almost impossible.

But the development of larger and larger random-access memories during the 1950's eventually led to the recognition that searching was an interesting problem in its own right. After years of complaining about the limited amounts of space in the early machines, programmers were suddenly confronted with larger amounts of memory than they knew how to use efficiently.

The first surveys of the searching problem were published by A. I. Dumey, *Computers & Automation* **5**, 12 (December 1956), 6–9; W. W. Peterson, *IBM J. Research & Development* **1** (1957), 130–146; A. D. Booth, *Information and Control* **1** (1958), 159–164; A. S. Douglas, *Comp. J.* **2** (1959), 1–9. More extensive treatments were given later by Kenneth E. Iverson, *A Programming Language* (New York: Wiley, 1962), 133–158, and by Werner Buchholz, *IBM Systems J.* **2** (1963), 86–111.

During the early 1960's, a number of interesting new search procedures based on tree structures were introduced, as we shall see; and research about searching is still actively continuing at the present time.

6.1. SEQUENTIAL SEARCHING

"Begin at the beginning, and go on till you find the right key: then stop." This sequential procedure is the obvious way to search, and it makes a useful starting point for our discussion of searching because many of the more intricate algorithms are based on it. We shall see that sequential searching involves some very interesting ideas, in spite of its simplicity.

The algorithm might be formulated more precisely as follows:

Algorithm S (*Sequential search*). Given a table of records $R_1, R_2, \ldots, R_N$, whose respective keys are $K_1, K_2, \ldots, K_N$, this algorithm searches for a given argument K. We assume that $N \geq 1$.

S1. [Initialize.] Set $i \leftarrow 1$.

S2. [Compare.] If $K = K_i$, the algorithm terminates successfully.

S3. [Advance.] Increase i by 1.

S4. [End of file?] If $i \leq N$, go back to S2. Otherwise the algorithm terminates unsuccessfully. ▮

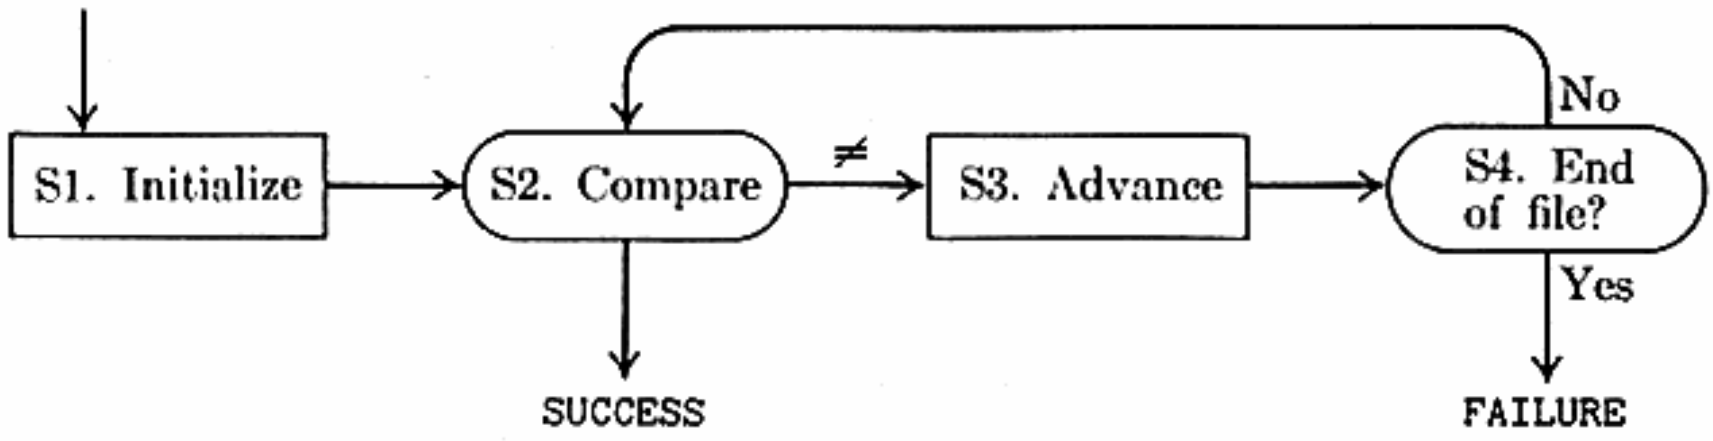

Fig. 1. Sequential search.

Note that this algorithm can terminate in two different ways, *successfully* (having located the desired key) or *unsuccessfully* (having established that the given argument is not present in the table). The same will be true of most other algorithms in this chapter.

A MIX program can be written down immediately:

Program S (*Sequential search*). Assume that K_i appears in location KEY + i, and that the remainder of record R_i appears in location INFO + i. The following program uses rA $\equiv K$, rI1 $\equiv i - N$.

```
01    START   LDA   K          1        S1. Initialize.
02            ENT1  1-N        1        i ← 1.
03    2H      CMPA  KEY+N,1    C        S2. Compare.
04            JE    SUCCESS    C        Exit if K = K_i.
05            INC1  1          C - S    S3. Advance.
06            J1NP  2B         C - S    S4. End of file?
07    FAILURE EQU   *          1 - S    Exit if not in table.
```

At location SUCCESS, the instruction "LDA INFO+N,1" will now bring the desired information into rA. ∎

The analysis of this program is straightforward; it shows that the running time of Algorithm S depends on two things,

$$\begin{aligned} C &= \text{the number of key comparisons;} \\ S &= 1 \text{ if successful, } 0 \text{ if unsuccessful.} \end{aligned} \tag{1}$$

Program S takes $5C - 2S + 3$ units of time. If the search successfully finds $K = K_i$, we have $C = i$, $S = 1$; hence the total time is $(5i + 1)u$. On the other hand if the search is unsuccessful, we have $C = N$, $S = 0$, for a total time of $(5N + 3)u$. If every input key occurs with equal probability, the average value of C in a successful search will be

$$\frac{1 + 2 + \cdots + N}{N} = \frac{N + 1}{2}\,; \tag{2}$$

the standard deviation is, of course, rather large, about $0.289N$ (see exercise 1).

The above algorithm is surely familiar to all programmers. But too few people know that it is *not* always the right way to do a sequential search! A straightforward change makes the algorithm faster, unless the list of records is quite short:

Algorithm Q (*Quick sequential search*). This algorithm is the same as Algorithm S, except that it assumes the presence of a "dummy" record R_{N+1} at the end of the file.

Q1. [Initialize.] Set $i \leftarrow 1$, and set $K_{N+1} \leftarrow K$.

Q2. [Compare.] If $K = K_i$, go to Q4.

Q3. [Advance.] Increase i by 1 and return to Q2.

Q4. [End of file?] If $i \leq N$, the algorithm terminates successfully; otherwise it terminates unsuccessfully ($i = N + 1$). ∎

Program Q (*Quick sequential search*). rA $\equiv K$, rI1 $\equiv i - N$.

```
01    BEGIN    LDA    K           1          Q1. Initialize.
02             STA    KEY+N+1     1          K_{N+1} ← K.
03             ENT1   -N          1          i ← 0.
04             INC1   1           C+1-S      Q3. Advance.
05             CMPA   KEY+N,1     C+1-S      Q2. Compare.
06             JNE    *-2         C+1-S      To Q3 if K_i ≠ K.
07             J1NP   SUCCESS     1          Q4. End of file?
08    FAILURE  EQU    *           1-S        Exit if not in table. ∎
```

In terms of the quantities C and S in the analysis of Program S, the running time has decreased to $(4C - 4S + 10)u$; this is an improvement whenever $C \geq 6$ in a successful search, and it is an improvement whenever $N \geq 8$ in an unsuccessful search.

The transition from Algorithm S to Algorithm Q makes use of an important "speed-up" principle: When an inner loop of a program tests two or more conditions, an attempt should be made to reduce it to just one condition.

Another technique will make Program Q *still* faster.

Program Q′ (*Quicker sequential search*). rA $\equiv K$, rI1 $\equiv i - N$.

```
01    BEGIN    LDA    K           1                  Q1. Initialize.
02             STA    KEY+N+1     1                  K_{N+1} ← K.
03             ENT1   -1-N        1                  i ← -1.
04    3H       INC1   2           ⌊(C-S+2)/2⌋        Q3. Advance. (twice)
05             CMPA   KEY+N,1     ⌊(C-S+2)/2⌋        Q2. Compare.
06             JE     4F          ⌊(C-S+2)/2⌋        To Q4 if K = K_i.
07             CMPA   KEY+N+1,1   ⌊(C-S+1)/2⌋        Q2. Compare. (next)
08             JNE    3B          ⌊(C-S+1)/2⌋        To Q3 if K ≠ K_{i+1}.

```

The inner loop has been duplicated; this avoids about half of the "$i \leftarrow i + 1$" instructions, so it reduces the running time to

$$3.5C - 3.5S + 10 + \frac{(C - S) \bmod 2}{2}$$

units. We have saved 30 percent of the running time of Program S, when large tables are being searched; many existing programs can be improved in this way.

A slight variation of the algorithm is appropriate if we know that the keys are in increasing order:

Algorithm T (*Sequential search in ordered table*). Given a table of records $R_1, R_2, \ldots, R_N$ whose keys are in increasing order $K_1 < K_2 < \cdots < K_N$, this algorithm searches for a given argument K. For convenience and speed, the algorithm assumes that there is a dummy record R_{N+1} whose key value is $K_{N+1} = \infty > K$.

T1. [Initialize.] Set $i \leftarrow 1$.

T2. [Compare.] If $K \leq K_i$, go to T4.

T3. [Advance.] Increase i by 1 and return to T2.

T4. [Equality?] If $K = K_i$, the algorithm terminates successfully. Otherwise it terminates unsuccessfully. ▮

If all input keys are equally likely, this algorithm takes essentially the same average time as Algorithm Q, for a successful search. But unsuccessful searches are performed about twice as fast, since the absence of a record can be established more quickly.

Each of the above algorithms uses subscripts to denote the table entries. It is convenient to describe the methods in terms of these subscripts, but the same search procedures can be used for tables which have a *linked* representation, since the data is being traversed sequentially. (See exercises 2, 3, and 4.)

Frequency of access. So far we have been assuming that every argument occurs as often as every other. This is not always a realistic assumption; in a general situation, key K_i will occur with probability p_i, where $p_1 + p_2 + \cdots + p_N = 1$. The time required to do a successful search is essentially proportional to the number of comparisons, C, which now has the average value

$$\overline{C}_N = p_1 + 2p_2 + \cdots + Np_N. \tag{3}$$

If we have the option of putting the records into the table in any desired order, this quantity $\overline{C}_N$ is smallest when

$$p_1 \geq p_2 \geq \cdots \geq p_N, \tag{4}$$

i.e., when the most frequently used records appear near the beginning.

Let's look at several probability distributions, in order to see how much of a saving is possible when the records are arranged in the "optimal" manner specified in (4). If $p_1 = p_2 = \cdots = p_N = 1/N$, formula (3) reduces to $\overline{C}_N = (N+1)/2$; we have already derived this in Eq. (2). Suppose, on the other hand, that

$$p_1 = \frac{1}{2}, \quad p_2 = \frac{1}{4}, \quad \cdots, \quad p_{N-1} = \frac{1}{2^{N-1}}, \quad p_N = \frac{1}{2^{N-1}}. \tag{5}$$

Then by exercise 7, $\overline{C}_N = 2 - 2^{1-N}$; the average number of comparisons is *less than two*, for this distribution, if the records appear in the proper order within the table.

Another probability distribution that suggests itself is

$$p_1 = Nc, \qquad p_2 = (N-1)c, \qquad \ldots, \qquad p_N = c,$$

where

$$c = 2/N(N+1). \tag{6}$$

This "wedge-shaped" distribution is not as dramatic a departure from uniformity as (5). In this case we find

$$\overline{C}_N = c \sum_{1 \le k \le N} k \cdot (N+1-k) = \frac{N+2}{3}; \tag{7}$$

the optimum arrangement saves about one-third of the search time which would have been obtained if the records had appeared in random order.

Of course the probability distributions in (5) and (6) are rather artificial, and they may never be a very good approximation to reality. A more typical distribution is "Zipf's law,"

$$p_1 = c/1, \quad p_2 = c/2, \quad \ldots, \quad p_N = c/N, \quad \text{where } c = 1/H_N. \tag{8}$$

This distribution was formulated by G. K. Zipf, who observed that the nth most common word in natural language text seems to occur with a frequency inversely proportional to n. [*Human Behavior and the Principle of Least Effort, an Introduction to Human Ecology* (Reading, Mass.: Addison-Wesley, 1949).] He observed the same phenomenon in census tables, when metropolitan areas are ranked in order of decreasing population. If Zipf's law governs the frequency of the keys in a table, we have immediately

$$\overline{C}_N = N/H_N; \tag{9}$$

searching such a file is about $\frac{1}{2} \ln N$ times as fast as searching the same file with randomly-ordered records. [Cf. A. D. Booth et al., *Mechanical Resolution of Linguistic Problems* (New York: Academic Press, 1958), 79.]

Another approximation to realistic distributions is the "80-20" rule of thumb that has been commonly observed in commercial applications [cf. W. P. Heising, *IBM Systems J.* **2** (1963), 114–115]. This rule states that 80 percent of the transactions deal with the most active 20 percent of a file; and the same applies to this 20 percent, so that 64 percent of the transactions deal with the most active 4 percent, etc. In other words,

$$\frac{p_1 + p_2 + \cdots + p_{.20n}}{p_1 + p_2 + p_3 + \cdots + p_n} \approx .80, \qquad \text{for all } n. \tag{10}$$

One distribution which satisfies this rule exactly whenever n is a multiple of 5 is

$$p_1 = c, \quad p_2 = (2^\theta - 1)c, \quad p_3 = (3^\theta - 2^\theta)c, \quad \ldots, \quad p_N = (N^\theta - (N-1)^\theta)c, \tag{11}$$

where

$$c = 1/N^\theta, \qquad \theta = \frac{\log .80}{\log .20} = 0.1386, \tag{12}$$

since $p_1 + p_2 + \cdots + p_n = cn^\theta$ for all n in this case. It is not especially easy to work with the probabilities in (11); we have, however, $n^\theta - (n-1)^\theta = \theta n^{\theta-1}(1 + O(1/n))$, so there is a simpler distribution which approximately fulfills the 80-20 rule, namely

$$p_1 = c/1^{1-\theta}, \quad p_2 = c/2^{1-\theta}, \quad \ldots, \quad p_N = c/N^{1-\theta}, \quad \text{where } c = 1/H_N^{(1-\theta)}. \tag{13}$$

Here $\theta = \log .80/\log .20$ as before, and $H_N^{(s)}$ is the Nth harmonic number of order s, namely $1^{-s} + 2^{-s} + \cdots + N^{-s}$. Note that this probability distribution is very similar to that of Zipf's law (8); as θ varies from 1 to 0, the probabilities vary from a uniform distribution to a Zipfian one. (Indeed, Zipf found that $\theta \approx \frac{1}{2}$ in the distribution of personal income.). Applying (3) to (13) yields

$$C_N = H_N^{(-\theta)}/H_N^{(1-\theta)} = \frac{\theta N}{\theta + 1} + O(N^{1-\theta}) \approx 0.122N \tag{14}$$

as the mean number of comparisons for the 80-20 law (see exercise 8).

A study of word frequencies carried out by E. S. Schwartz [see the interesting graph on p. 422 of *JACM* **10** (1963)] suggests that a more appropriate substitute for Zipf's law is

$$p_1 = c/1^{1+\theta}, \; p_2 = c/2^{1+\theta}, \; \ldots, \; p_N = c/N^{1+\theta}, \; \text{where } c = 1/H_N^{(1+\theta)}, \tag{15}$$

for a small *positive* value of θ. [Cf. with (13); the sign of θ has been reversed.] In this case

$$C_N = H_N^{(\theta)}/H_N^{(1+\theta)} = N^{1-\theta}/(1-\theta)\zeta(1+\theta) + O(N^{1-2\theta}), \tag{16}$$

which is substantially smaller than (9) as $N \to \infty$.

A "self-organizing" file. The above calculations with probabilities are very nice, but in most cases we don't know the probabilities are. We could keep a count in each record of how often it has been accessed, reallocating the records on the basis of these counts; the formulas derived above suggest that this procedure would often lead to a worthwhile savings. But we probably don't want to devote so much memory space to the count fields, since we can make better use of that memory (e.g. by using nonsequential search techniques which are explained later in this chapter).

A simple scheme, which has been in use for many years although its origin is unknown, can be used to keep the records in a pretty good order without

auxiliary count fields: Whenever a record has been successfully located, it is moved to the beginning of the table. This procedure is readily implemented if the table is a linked linear list, especially because the record being moved to the beginning often has to be substantially updated anyway.

The idea behind this "self-organizing" technique is that the oft-used items will tend to be located fairly near the beginning of the table, when we need them. If we assume that the N keys occur with respective probabilities $\{p_1, p_2, \ldots, p_N\}$, with each search being completely *independent* of previous searches, it can be shown that the average number of comparisons needed to find an item in such a self-organizing file tends to the limiting value

$$\overline{C}_N = 1 + 2 \sum_{1 \le i < j \le N} \frac{p_i p_j}{p_i + p_j} = \frac{1}{2} + \sum_{i,j} \frac{p_i p_j}{p_i + p_j}. \tag{17}$$

(See exercise 11.) For example, if $p_i = 1/N$ for $1 \le i \le N$, the self-organizing table is always in completely random order, and this formula reduces to the familiar expression $(N + 1)/2$ derived above.

Let us see how well the self-organizing procedure works when the key probabilities obey Zipf's law (8). We have

$$\begin{aligned}
\overline{C}_N &= \frac{1}{2} + \sum_{1 \le i,j \le N} \frac{(c/i)(c/j)}{c/i + c/j} = \frac{1}{2} + c \sum_{1 \le i,j \le N} \frac{1}{i + j} \\
&= \frac{1}{2} + c \sum_{1 \le i \le N} (H_{N+i} - H_i) = \frac{1}{2} + c \sum_{1 \le i \le 2N} H_i - 2c \sum_{1 \le i \le N} H_i \\
&= \tfrac{1}{2} + c((2N + 1)H_{2N} - 2N - 2(N + 1)H_N + 2N) \\
&= \tfrac{1}{2} + c(N \ln 4 - \ln N + O(1)) \\
&\approx 2N/\log_2 N,
\end{aligned} \tag{18}$$

by Eqs. 1.2.7–8, 3. This is substantially better than $\frac{1}{2}N$, when N is reasonably large, and it is only about $\ln 4 \approx 1.386$ times as many comparisons as would be obtained in the optimum arrangement (cf. 9).

Computational experiments involving actual compiler symbol tables indicate that the self-organizing method works even better than the above formulas predict, because successive searches are not independent (small groups of keys tend to occur in bunches).

A somewhat similar self-organizing scheme has been studied by G. Schay, Jr. and F. W. Dauer, *SIAM J. Appl. Math.* **15** (1967), 874–888.

Tape searching with unequal-length records. Now let's give the problem still another twist: Suppose the table we are searching is stored on tape, and the individual records have varying lengths. For example, in an old-fashioned operating system, the "system library tape" was such a file; standard system programs such as compilers, assemblers, loading routines, report generators, etc. were the "records" on this tape, and most user jobs would start by searching

down the tape until the appropriate routine had been input. This setup makes our previous analysis of Algorithm S inapplicable, since step S3 takes a variable amount of time each time we reach it. The number of comparisons is therefore not the only criterion of interest.

Let L_i be the length of record R_i, and let p_i be the probability that this record will be sought. The running time of the search method will now be approximately proportional to

$$p_1L_1 + p_2(L_1 + L_2) + \cdots + p_N(L_1 + L_2 + L_3 + \cdots + L_N). \tag{19}$$

When $L_1 = L_2 = \cdots = L_N = 1$, this reduces to (3), the case already studied.

It seems logical to put the most frequently-needed records at the beginning of the tape; but this is sometimes a bad idea! For example, assume that the tape contains just two programs, A and B; A is needed twice as often as B, but it is four times as long. Thus, $N = 2$, $p_A = \frac{2}{3}$, $L_A = 4$, $p_B = \frac{1}{3}$, $L_B = 1$. If we place A first on tape, according to the "logical" principle stated above, the average running time is $\frac{2}{3} \cdot 4 + \frac{1}{3} \cdot 5 = \frac{13}{3}$; but if we use an "illogical" idea, placing B first, the average running time is reduced to $\frac{1}{3} \cdot 1 + \frac{2}{3} \cdot 5 = \frac{11}{3}$.

The optimum arrangement of programs on a library tape may be determined as follows.

Theorem S. *Let L_i and p_i be as defined above. The arrangement of records in the table is optimal if and only if*

$$p_1/L_1 \geq p_2/L_2 \geq \cdots \geq p_N/L_N. \tag{20}$$

In other words, the minimum value of

$$p_{a_1}L_{a_1} + p_{a_2}(L_{a_1} + L_{a_2}) + \cdots + p_{a_N}(L_{a_1} + \cdots + L_{a_N}),$$

over all permutations $a_1\, a_2 \ldots a_N$ of $\{1, 2, \ldots, N\}$, is equal to (19) if and only if (20) holds.

Proof. Suppose that R_i and R_{i+1} are interchanged on the tape; the cost (19) changes from

$$\cdots + p_i(L_1 + \cdots + L_{i-1} + L_i) + p_{i+1}(L_1 + \cdots + L_{i+1}) + \cdots$$

to

$$\cdots + p_{i+1}(L_1 + \cdots + L_{i-1} + L_{i+1}) + p_i(L_1 + \cdots + L_{i+1}) + \cdots,$$

a net change of $p_iL_{i+1} - p_{i+1}L_i$. Therefore if $p_i/L_i < p_{i+1}/L_{i+1}$, such an interchange will improve the running time, and the given arrangement is not optimal. It follows that (20) holds in any optimal arrangement.

Conversely, assume that (20) holds; we need to prove that the arrangement is optimal. The argument just given shows that the arrangement is "locally optimal" in the sense that adjacent interchanges make no improvement; but

there may conceivably be a long, complicated sequence of interchanges which leads to a better "global optimum." We shall consider two proofs, one which uses computer science and one which uses a mathematical trick.

First proof. Assume that (20) holds. We know that any permutation of the records can be "sorted" into the order $R_1 R_2 \ldots R_N$ by using a sequence of interchanges of adjacent records. Each of these interchanges replaces $\ldots R_j R_i \ldots$ by $\ldots R_i R_j \ldots$ for some $i < j$, so it decreases the search time by the nonnegative amount $p_i L_j - p_j L_i$. Therefore the order $R_1 R_2 \ldots R_N$ must have minimum search time.

Second proof. Replace each probability p_i by

$$p_i(\epsilon) = p_i + \epsilon^i - (\epsilon^1 + \epsilon^2 + \cdots + \epsilon^N)/N, \tag{21}$$

where ϵ is an extremely small positive number. When ϵ is sufficiently small, we will never have $x_1 p_1(\epsilon) + \cdots + x_N p_N(\epsilon) = y_1 p_1(\epsilon) + \cdots + y_N p_N(\epsilon)$ unless $x_1 = y_1, \ldots, x_N = y_N$; and in particular, equality will not hold in (20). Consider now the $N!$ permutations of the records; at least one of these is optimum, and we know that it satisfies (20); but only one permutation satisfies (20) because there are no equalities. Therefore (20) uniquely characterizes the optimum arrangement of records in the table for the probabilities $p_i(\epsilon)$, whenever ϵ is sufficiently small. By continuity, the same arrangement must also be optimum when ϵ is set equal to zero. (This "tie-breaking" type of proof is often useful in connection with combinatorial optimization.) ∎

Theorem S is due to W. E. Smith, *Naval Research Logistics Quarterly* **3** (1956), 59–66. The exercises below contain further results about optimum file arrangements.

File compression. Sequential searching on tape and other external memory devices goes faster if we can pack the data so that it takes up less space; therefore it is a good idea to consider alternative ways to represent a file. We need not always store the keys explicitly.

For example, suppose that we want to have a table of all the prime numbers less than one million, for use in factoring 12-digit numbers. (Cf. Section 4.5.4.) There are 78498 such primes; so if we use 20 bits for each one, the file will be 1,569,960 bits long. This is obviously wasteful, since we could have a million-bit table, with each bit telling us whether or not the corresponding number is prime. Since all primes (except 2) are odd, the file could in fact be shortened to 500,000 bits.

Another way to cut down the size of this file is to list the sizes of *gaps* between primes, instead of the primes themselves. According to Table 1, the difference $(p_{k+1} - p_k)/2$ is less than 64 for all primes less than 1,357,201, so we can represent all primes between 3 and 1000000 by simply storing 78496 six-bit values of (gap size)/2; this makes the file about 471,000 bits long. Further compression can be achieved by using a variable-length binary code for the gaps (cf. Section 6.2.2).

Table 1

RECORD-BREAKING GAPS BETWEEN CONSECUTIVE PRIME NUMBERS

Gap $(p_{k+1} - p_k)$	p_k	Gap $(p_{k+1} - p_k)$	p_k
1	2	52	19609
2	3	72	31397
4	7	86	155921
6	23	96	360653
8	89	112	370261
14	113	114	492113
18	523	118	1349533
20	887	132	1357201
22	1129	148	2010733
34	1327	154	4652353
36	9551	180	17051707
44	15683	210	20831323

This table lists $p_{k+1} - p_k$ whenever it exceeds $p_{j+1} - p_j$ for all $j < k$. For further information, see "Statistics on the first six million prime numbers" by F. Gruenberger and G. Armerding, RAND Corp. report P-2460 (October, 1961).

EXERCISES

1. [*M20*] When all the search keys are equally probable, what is the standard deviation of the number of comparisons made in a successful sequential search through a table of N records?

2. [*16*] Restate the steps of Algorithm S, using linked-memory notation instead of subscript notation. (If `P` points to a record in the table, assume that `KEY(P)` is the key, `INFO(P)` is the associated information, and that `LINK(P)` is a pointer to the next record. Assume also that `FIRST` points to the first record, and that the last record points to Λ.)

3. [*16*] Write a `MIX` program for the algorithm of exercise 2. What is the running time of your program, in terms of the quantities C and S in (1)?

▸ **4.** [*17*] Does the idea of Algorithm Q carry over from subscript notation to linked-memory notation? (Cf. exercise 2.)

5. [*20*] Program Q′ is, of course, noticeably faster than Program Q, when C is large. But are there any small values of C and S for which Program Q′ actually takes more time than Program Q?

▸ **6.** [*20*] Add three more instructions to Program Q′, reducing its running time to about $(3.33C + \text{constant})u$.

7. [*M20*] Evaluate the average number of comparisons, (3), using the "binary" probability distribution (5).

8. [*HM22*] Find an asymptotic series for $H_n^{(x)}$ as $n \to \infty$, when $x \neq 1$.

▸ **9.** [*M23*] The text observes that the probability distributions given by (11) and (13) are roughly equivalent, and that the mean number of comparisons using (13) is $\theta N/(\theta+1) + O(N^{1-\theta})$. Is the mean number of comparisons equal to $\theta N/(\theta+1) + O(N^{1-\theta})$ also when the probabilities of (11) are used?

10. [*M20*] The best arrangement of records in a sequential table is specified by (4); what is the *worst* arrangement? Show that the average number of comparisons in the worst arrangement has a simple relation to the average number of comparisons in the best arrangement.

11. [*M30*] The purpose of this exercise is to analyze the behavior of the text's self-organizing file. First we need to define some rather complicated notation: Let $f_m(x_1, x_2, \ldots, x_m)$ be the infinite sum of all distinct ordered products $x_{i_1}x_{i_2}\ldots x_{i_k}$ such that $1 \le i_1, \ldots, i_k \le m$, where each of $x_1, x_2, \ldots, x_m$ appears in every term. For example,

$$f_2(x, y) = \sum_{j,k\ge 0} (x^{1+j}y(x+y)^k + y^{1+j}x(x+y)^k) = \frac{xy}{1-x-y}\left(\frac{1}{1-x}+\frac{1}{1-y}\right).$$

Given a set X of n variables $\{x_1, \ldots, x_n\}$, let

$$p_{nm} = \sum_{1\le j_1<\cdots<j_m\le n} f_m(x_{j_1}, \ldots, x_{j_m}); \quad Q_{nm} = \sum_{1\le j_1<\cdots<j_m\le n} \frac{1}{1-x_{j_1}-\cdots-x_{j_m}}.$$

For example, $P_{32} = f_2(x_1, x_2) + f_2(x_1, x_3) + f_2(x_2, x_3)$ and $Q_{32} = 1/(1-x_1-x_2) + 1/(1-x_1-x_3) + 1/(1-x_2-x_3)$. By convention we set $P_{n0} = Q_{n0} = 1$.

a) Assume that the text's self-organizing file has been servicing requests for item R_i with probability p_i. After the system has been running a long time, show that R_i will be the mth item from the front with limiting probability $p_i P_{N-1,m-1}$, where $X = \{p_1, \ldots, p_{i-1}, p_{i+1}, \ldots, p_N\}$.

b) By summing the result of (a) for $m = 1, 2, \ldots$, we obtain the identity

$$P_{nn} + P_{n,n-1} + \cdots + P_{n0} = Q_{nn}.$$

Prove that, consequently,

$$P_{nm} + \binom{n-m+1}{1} P_{n,m-1} + \cdots + \binom{n-m+m}{m} P_{n0} = Q_{nm};$$

$$Q_{nm} - \binom{n-m+1}{1} Q_{n,m-1} + \cdots + (-1)^m \binom{n-m+m}{m} Q_{n0} = P_{nm}.$$

c) Compute the limiting average distance $d_i = \sum_{m\ge 1} m p_i P_{N-1,m-1}$ of R_i from the front of the list; then evaluate $\bar{C}_N = \sum_{1\le i\le n} p_i d_i$.

12. [*M23*] Use (17) to evaluate the average number of comparisons needed to search the self-organizing file when the search keys have the binary probability distribution (5).

13. [*M27*] Use (17) to evaluate $\bar{C}_N$ for the probability distribution (6).

14. [*M21*] Given two sequences $\langle x_1, x_2, \ldots, x_n\rangle$ and $\langle y_1, y_2, \ldots, y_n\rangle$ of real numbers, what permutation $a_1\, a_2 \ldots a_n$ of the subscripts will make $\sum x_i y_{a_i}$ a maximum? a minimum?

▸**15.** [*M22*] The text shows how to arrange programs optimally on a "system library tape," when only one program is being sought. But another set of assumptions is more appropriate for a *subroutine* library tape, from which we may wish to load various subroutines called for in a user's program.

For this case let us suppose that subroutine i is desired with probability P_i, independently of whether or not other subroutines are desired. Then, for example, the probability that no subroutines at all are needed is $(1 - P_1)(1 - P_2) \ldots (1 - P_N)$; and the probability that the search will end just after loading the ith subroutine is $P_i(1 - P_{i+1}) \ldots (1 - P_N)$. If L_i is the length of subroutine i, the average search time will therefore be essentially proportional to

$$L_1P_1(1 - P_2) \ldots (1 - P_N) + (L_1 + L_2)P_2(1 - P_3) \ldots (1 - P_N) + \cdots + (L_1 + \cdots + L_N)P_N.$$

What is the optimum arrangement of subroutines on the tape, under these assumptions?

16. [*M22*] (H. Riesel.) A programmer wants to test whether or not n given conditions are all simultaneously true. (For example, he may want to test whether both $x > 0$ and $y < z^2$, and it is not immediately clear which condition should be tested first.) Suppose that it costs T_i units of time to test condition i, and that the condition will be true with probability p_i, independent of the outcomes of all the other conditions. In which order should he make the tests?

17. [*M23*] (W. E. Smith.) Suppose you have to do n jobs; the ith job takes T_i units of time, and it has a *deadline* D_i. In other words, the ith job is supposed to be finished after at most D_i units of time have elapsed. What schedule for processing the jobs will minimize the *maximum tardiness*, i.e.,

$$\max (T_{a_1} - D_{a_1}, T_{a_1} + T_{a_2} - D_{a_2}, \ldots, T_{a_1} + T_{a_2} + \cdots + T_{a_n} - D_{a_n})?$$

18. [*M30*] (*Catenated search.*) Suppose N records are located in a linear array $R_1 \ldots R_N$, with probability p_i that record R_i will be sought. A search process is called "catenated" if each search begins where the last one left off. If consecutive searches are independent, the average time required will be $\sum_{1 \le i,j \le N} p_i p_j d(i, j)$, where $d(i, j)$ represents the amount of time to do a search that starts at position i and ends at position j. This model can be applied, for example, to disk file seek time, if $d(i, j)$ is the time needed to travel from cylinder i to cylinder j.

The object of this exercise is to characterize the optimum placement of records for catenated searches, whenever $d(i, j)$ is an increasing function of $|i - j|$, i.e., whenever we have $d(i, j) = d_{|i-j|}$ for $d_1 < d_2 < \cdots < d_{N-1}$. (The value of d_0 is irrelevant.) Prove that in this case the records are optimally placed, among all $N!$ permutations, if and only if either $p_1 \le p_N \le p_2 \le p_{N-1} \le \cdots \le p_{\lfloor N/2 \rfloor + 1}$ or $p_N \le p_1 \le p_{N-1} \le p_2 \le \cdots \le p_{\lfloor N/2 \rfloor}$. (Thus, an "organ pipe" arrangement of probabilities is best, as shown in Fig. 2.) *Hint:* Consider any arrangement where the respective probabilities are $q_1\, q_2 \ldots q_k\, s\, r_k \ldots r_2\, r_1\, t_1 \ldots t_m$, for some $m \ge 0$ and $k > 0$; $N = 2k + m + 1$. Show that the rearrangement $q'_1\, q'_2 \ldots q'_k\, s\, r'_k \ldots r'_2\, r'_1\, t_1 \ldots t_m$ is better, where $q'_i = \min(q_i, r_i)$ and $r'_i = \max(q_i, r_i)$, except when $q'_i = q_i$ and $r'_i = r_i$ for all i or when $q'_i = r_i$ and $r'_i = q_i$ and $t_j = 0$ for all i, j. The same holds when s is not present and $N = 2k + m$.

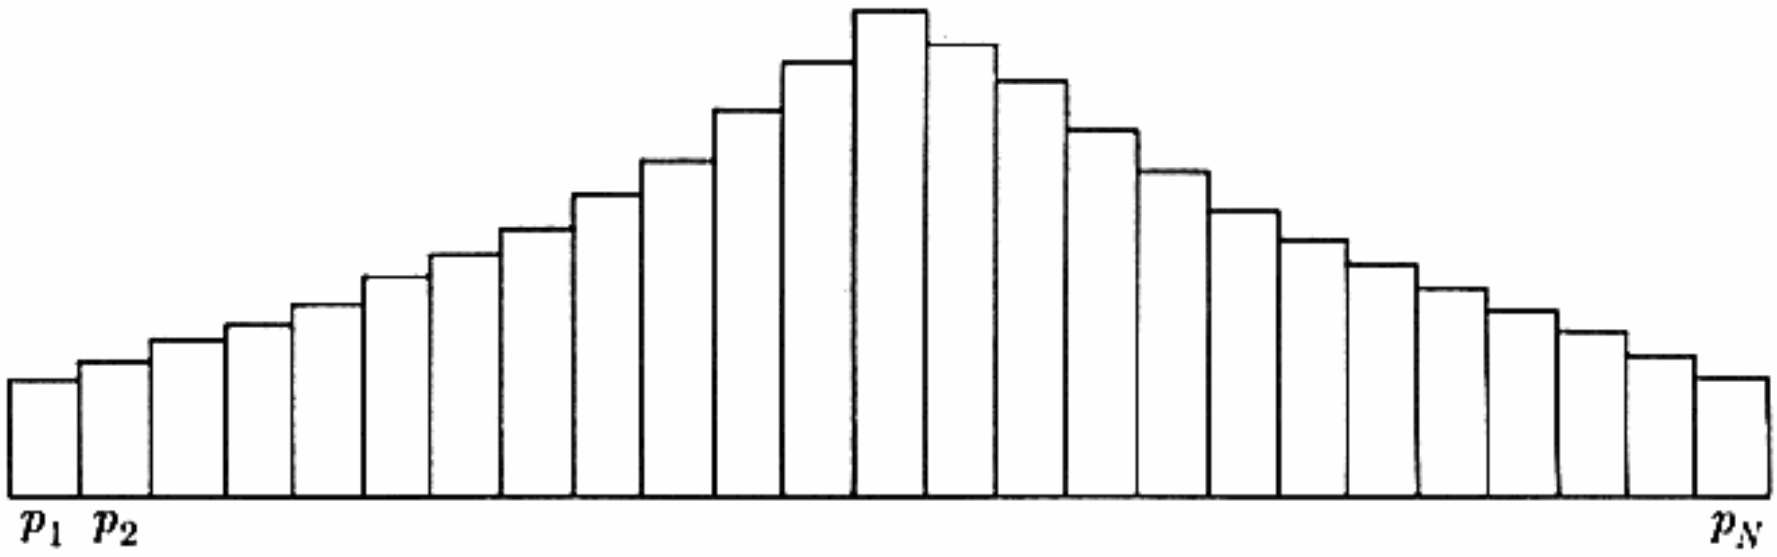

Fig. 2. An "organ-pipe arrangement" of probabilities minimizes the average seek time in a catenated search.

19. [*M20*] Continuing exercise 18, what are the optimal arrangements for catenated searches when the function $d(i, j)$ has the property that $d(i, j) + d(j, i) = c$ for all i, j? [This situation occurs, for example, on tapes without read-backwards capability, when we do not know the appropriate direction to search; for $i < j$ we have, say, $d(i, j) = a + b(L_{i+1} + \cdots + L_j)$ and $d(j, i) = a + b(L_{j+1} + \cdots + L_N) + r + b(L_1 + \cdots + L_i)$, where r is the rewind time.]

20. [*M28*] Continuing exercise 18, what are the optimal arrangements for catenated searches when the function $d(i, j) = \min(d_{|i-j|}, d_{n-|i-j|})$, for $d_1 < d_2 < \cdots$? [This situation occurs, for example, in a two-way linked circular list, or in a two-way shift-register storage device.]

21. [*M28*] Consider an n-dimensional cube whose vertices have coordinates $(d_n, \ldots, d_1)$ with $d_i = 0$ or 1; two vertices are called *adjacent* if they differ in exactly one coordinate. Suppose that a set of 2^n numbers $x_0 \le x_1 \le \cdots \le x_{2^n-1}$ is to be assigned to the 2^n vertices in such a way that $\sum|x_i - x_j|$ is minimized, where the sum is over all i and j such that x_i and x_j have been assigned to adjacent vertices. Prove that this minimum will be achieved if x_i is assigned to the vertex whose coordinates are the binary representation of i, for all i.

▸**22.** [*20*] Suppose you want to search a large file, not for equality but to find the 1000 records which are *closest* to a given key, in the sense that these 1000 records have the smallest values of $d(K_i, K)$ for some given distance function d. What data structure is most appropriate for such a sequential search?

6.2. SEARCHING BY COMPARISON OF KEYS

In this section we shall discuss search methods which are based on a linear ordering of the keys (e.g., alphabetic order or numeric order). After comparing the given argument K to a key K_i in the table, the search continues in three different ways, depending on whether $K < K_i$, $K = K_i$, or $K > K_i$. The sequential search methods of Section 6.1 were essentially limited to a two-way decision ($K = K_i$ vs. $K \neq K_i$), but if we free ourselves from the restriction of sequential access it becomes possible to make effective use of an order relation.

6.2.1. Searching an Ordered Table

What would you do if someone handed you a large telephone directory and told you to find the name of the man whose number is 795-6841? There is no better way to tackle this problem than to use the sequential methods of Section 6.1. (However, a clever private detective might try dialing the number and finding out who answers; or he might have a friend at the telephone company who has access to a special directory that is sorted by number instead of by name.) The point is that it is much easier to find an entry by the party's name, instead of by number, although the telephone directory contains all the information necessary in both cases. When a large file must be searched, sequential scanning is almost out of the question, but an ordering relation simplifies the job enormously.

With so many sorting methods at our disposal (Chapter 5), we will have little difficulty rearranging a file into order so that it may be searched conveniently. Of course, if we only need to search the table once, it is faster to do a sequential search than to do a complete sort of the file; but if we need to make repeated searches in the same file, we are better off having it in order. Therefore in this section we shall concentrate on methods which are appropriate for searching a table whose keys are in order,

$$K_1 < K_2 < \cdots < K_N,$$

making random accesses to the table entries. After comparing K to K_i in such a table, we either have

- $K < K_i$ [$R_i, R_{i+1}, \ldots, R_N$ are eliminated from consideration];

or

- $K = K_i$ [the search is done];

or

- $K > K_i$ [$R_1, R_2, \ldots, R_i$ are eliminated from consideration].

In each of these three cases, substantial progress has been made, unless i is near one of the ends of the table; this is why the ordering leads to an efficient algorithm.

Binary search. Perhaps the first such method which suggests itself is to start by comparing K to the middle key in the table; the result of this probe tells

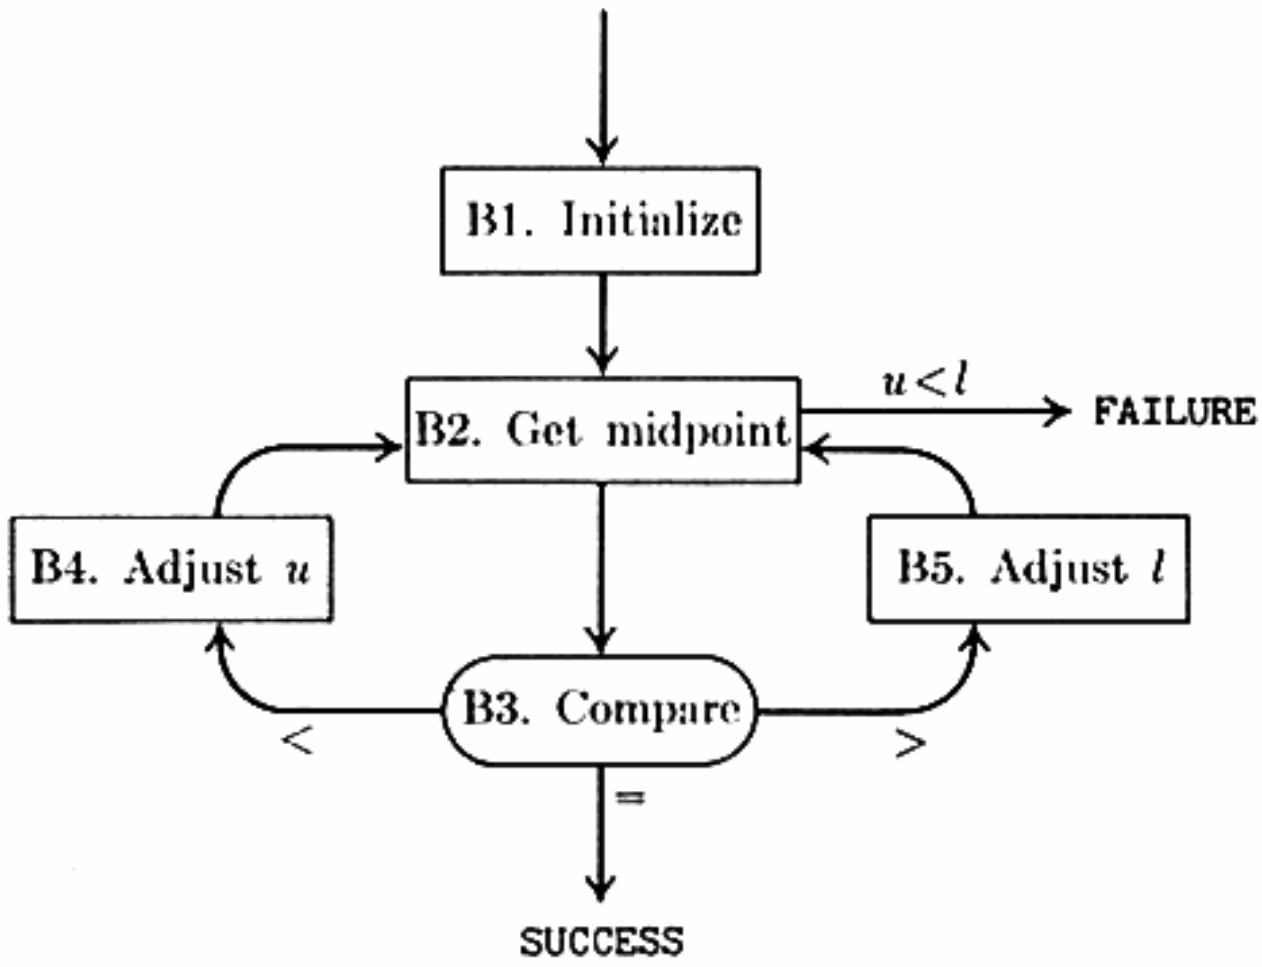

Fig. 3. Binary search.

which half of the table should be searched next, and the same procedure can be used again, comparing K to the middle key of the selected half, etc. After at most about $\log_2 N$ comparisons, we will have found the key or we will have established that it is not present. This procedure is sometimes known as "logarithmic search" or "bisection," but it is most commonly called *binary search*.

Although the basic idea of binary search is comparatively straightforward, the details can be somewhat tricky, and many good programmers have done it wrong the first few times they tried. One of the most popular correct forms of the algorithm makes use of two pointers, l and u, which indicate the current lower and upper limits for the search, as follows:

Algorithm B (*Binary search*). Given a table of records $R_1, R_2, \ldots, R_N$ whose keys are in increasing order $K_1 < K_2 < \cdots < K_N$, this algorithm searches for a given argument K.

B1. [Initialize.] Set $l \leftarrow 1$, $u \leftarrow N$.

B2. [Get midpoint.] (At this point we know that if K is in the table, it satisfies $K_l \le K \le K_u$. A more precise statement of the situation appears in exercise 1 below.) If $u < l$, the algorithm terminates unsuccessfully. Otherwise, set $i \leftarrow \lfloor (l + u)/2 \rfloor$, the approximate midpoint of the relevant table area.

B3. [Compare.] If $K < K_i$, go to B4; if $K > K_i$, go to B5; and if $K = K_i$, the algorithm terminates successfully.

B4. [Adjust u.] Set $u \leftarrow i - 1$ and return to B2.

B5. [Adjust l.] Set $l \leftarrow i + 1$ and return to B2. ∎

Figure 4 illustrates two cases of this binary search algorithm: first to search for the argument 653, which is present in the table, and then to search for 400,

a) Searching for 653 :

[061 087 154 170 275 426 503 509 512 612 653 677 703 765 897 908]
061 087 154 170 275 426 503 509 [512 612 653 677 703 765 897 908]
061 087 154 170 275 426 503 509 [512 612 653] 677 703 765 897 908
061 087 154 170 275 426 503 509 512 612 [653] 677 703 765 897 908

b) Searching for 400 :

[061 087 154 170 275 426 503 509 512 612 653 677 703 765 897 908]
[061 087 154 170 275 426 503] 509 512 612 653 677 703 765 897 908
061 087 154 170 [275 426 503] 509 512 612 653 677 703 765 897 908
061 087 154 170 [275] 426 503 509 512 612 653 677 703 765 897 908
061 087 154 170 275] [426 503 509 512 612 653 677 703 765 897 908

Fig. 4. Examples of binary search.

which is absent. The brackets indicate l and u, and the underlined key represents K_i. In both examples the search terminates after making four comparisons.

Program B (*Binary search*). As in the programs of Section 6.1, we assume here that K_i is a full-word key appearing in location KEY + i. The following code uses rI1 ≡ l, rI2 ≡ u, rI3 ≡ i.

```
01     START  ENT1  1          1          B1. Initialize. l ← 1.
02            ENT2  N          1          u ← N.
03            JMP   2F         1          To B2.
04     5H     JE    SUCCESS    C1         Jump if K = K_i.
05            ENT1  1,3        C1 − S     B5. Adjust l. l ← i + 1.
06     2H     ENTA  0,1        C + 1 − S  B2. Get midpoint.
07            INCA  0,2        C + 1 − S  rA ← l + u.
08            SRB   1          C + 1 − S  rA ← ⌊rA/2⌋.
09            STA   TEMP       C + 1 − S
10            CMP1  TEMP       C + 1 − S
11            JG    FAILURE    C + 1 − S  Jump if u < l.
12            LD3   TEMP       C          i ← midpoint.
13     3H     LDA   K          C          B3. Compare.
14            CMPA  KEY,3      C
15            JGE   5B         C          Jump if K ≥ K_i.
16            ENT2  -1,3       C2         B4. Adjust u. u ← i − 1.
17            JMP   2B         C2         To B2.
```

This procedure doesn't blend with MIX quite as "smoothly" as the other algorithms we have seen, because MIX does not allow much arithmetic in index registers. The running time is $(18C - 10S + 12)u$, where $C = C1 + C2$ is the number of comparisons made (the number of times step B3 is performed), and $S = 1$ or 0 depending on whether the outcome is successful or not. Note that line 08 of this program is "shift right binary 1," which is legitimate only on binary versions of MIX; for general byte size, this instruction should be replaced by "MUL =1//2+1=", increasing the running time to $(26C - 18S + 20)u$.

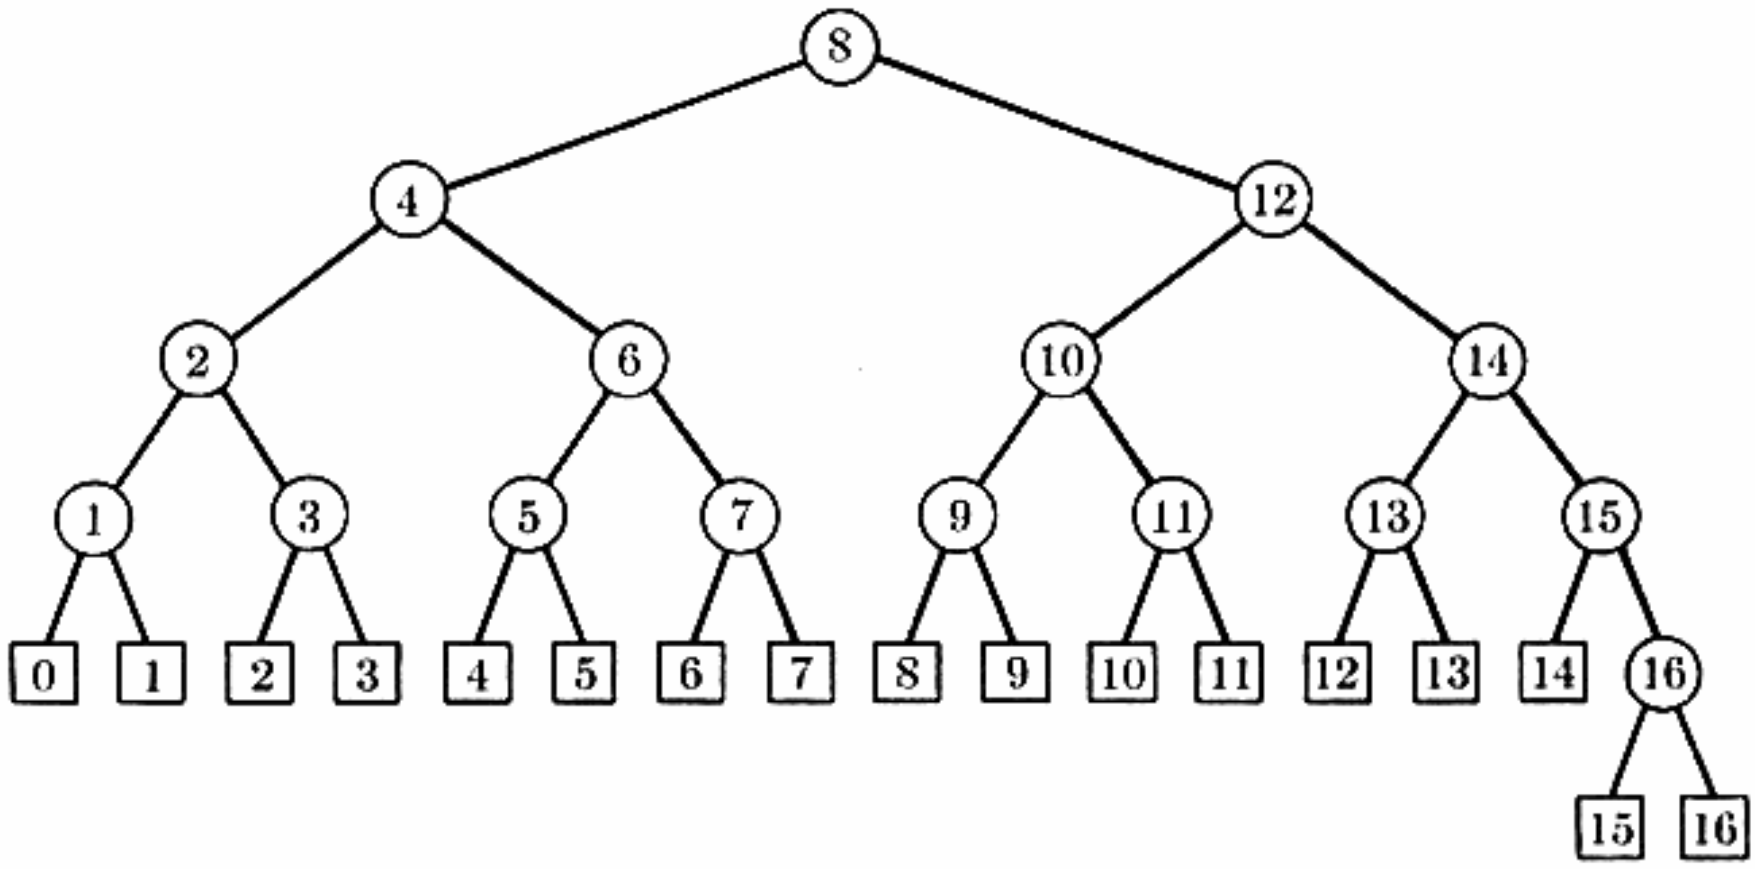

Fig. 5. A binary tree which corresponds to binary search when $N = 16$.

A tree representation. In order to really understand what is happening in Algorithm B, it is best to think of it as a binary decision tree, as shown in Fig. 5 for the case $N = 16$.

When N is 16, the first comparison made by the algorithm is $K:K_8$; this is represented by the root node (8) in the figure. Then if $K < K_8$, the algorithm follows the left subtree, comparing K to K_4; similarly if $K > K_8$, the right subtree is used. An unsuccessful search will lead to one of the "external" square nodes numbered $\boxed{0}$ through $\boxed{N}$; for example, we reach node $\boxed{6}$ if and only if $K_6 < K < K_7$.

The binary tree corresponding to a binary search on N records can be constructed as follows: If $N = 0$, the tree is simply $\boxed{0}$. Otherwise the root node is

$$\left(\lceil N/2 \rceil\right),$$

the left subtree is the corresponding binary tree with $\lceil N/2 \rceil - 1$ nodes, and the right subtree is the corresponding binary tree with $\lfloor N/2 \rfloor$ nodes and with all node numbers increased by $\lceil N/2 \rceil$.

In an analogous fashion, *any* algorithm for searching an ordered table of length N by means of comparisons can be represented as a binary tree in which the nodes are labelled with the numbers 1 to N (unless the algorithm makes redundant comparisons). Conversely, any binary tree corresponds to a valid method for searching an ordered table; we simply label the nodes

$$\boxed{0} \quad (1) \quad \boxed{1} \quad (2) \quad \boxed{2} \quad \ldots \quad \boxed{N-1} \quad (N) \quad \boxed{N} \qquad (1)$$

in symmetric order, from left to right.

If the search argument input to Algorithm B is K_{10}, the algorithm makes the comparisons $K > K_8$, $K < K_{12}$, $K = K_{10}$. This corresponds to the path from the root to (10) in Fig. 5. Similarly, the behavior of Algorithm B on

other keys corresponds to the other paths leading from the root of the tree. The method of constructing the binary trees corresponding to Algorithm B therefore makes it easy to prove the following result by induction on N:

Theorem B. If $2^{k-1} \le N < 2^k$, a successful search using Algorithm B requires (min 1, max k) comparisons. If $N = 2^k - 1$, an unsuccessful search requires k comparisons; and if $2^{k-1} \le N < 2^k - 1$, an unsuccessful search requires either $k - 1$ or k comparisons. ∎

Further analysis of binary search. (Nonmathematical readers, skip to Eq. 4.) The tree representation shows us also how to compute the *average* number of comparisons in a simple way. Let C_N be the average number of comparisons in a successful search, assuming that each of the N keys is an equally likely argument; and let C'_N be the average number of comparisons in an *un*successful search, assuming that each of the $N + 1$ intervals between keys is equally likely. Then we have

$$C_N = 1 + \frac{\text{internal path length of tree}}{N},$$

$$C'_N = \frac{\text{external path length of tree}}{N+1},$$

by the definition of internal and external path length. We have seen in Eq. 2.3.4.5–3 that the external path length is always $2N$ more than the internal path length; hence there is a rather unexpected relationship between C_N and C'_N:

$$C_N = \left(1 + \frac{1}{N}\right) C'_N - 1. \tag{2}$$

This formula, which is due to Hibbard [*JACM* **9** (1962), 16–17], holds for all search methods which correspond to binary trees, i.e., for all methods which are based on nonredundant comparisons. The variance of C_N can also be expressed in terms of the variance of C'_N (see exercise 25).

From the above formulas we can see that the "best" way to search by comparisons is one whose tree has minimum external path length, over all binary trees with N internal nodes. Fortunately it can be proved that *Algorithm B is optimum* in this sense, for all N; for we have seen (exercise 5.3.1–20) that a binary tree has minimum path length if and only all its external nodes occur on at most two adjacent levels. It follows that the external path length of the tree corresponding to Algorithm B is

$$(N+1)(\lfloor \log_2 N \rfloor + 2) - 2^{\lfloor \log_2 N \rfloor + 1}. \tag{3}$$

(See Eq. 5.3.1–33.) From this formula and (2) we can compute the exact average number of comparisons, assuming that all search arguments are equally probable.

$N =$	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16
$C_N =$	1	$1\frac{1}{2}$	$1\frac{2}{3}$	2	$2\frac{1}{5}$	$2\frac{2}{6}$	$2\frac{3}{7}$	$2\frac{5}{8}$	$2\frac{7}{9}$	$2\frac{9}{10}$	3	$3\frac{1}{12}$	$3\frac{2}{13}$	$3\frac{3}{14}$	$3\frac{4}{15}$	$3\frac{6}{16}$
$C'_N =$	1	$1\frac{2}{3}$	2	$2\frac{2}{5}$	$2\frac{4}{6}$	$2\frac{6}{7}$	3	$3\frac{2}{9}$	$3\frac{4}{10}$	$3\frac{6}{11}$	$3\frac{8}{12}$	$3\frac{10}{13}$	$3\frac{12}{14}$	$3\frac{14}{15}$	4	$4\frac{2}{17}$

In general, if $k = \lfloor \log_2 N \rfloor$, we have (cf. Eq. 5.3.1–34)

$$\begin{aligned} C_N &= k + 1 - (2^{k+1} - k - 2)/N = \log_2 N - 1 + \epsilon + (k+2)/N, \\ C'_N &= k + 2 - 2^{k+1}/(N+1) \qquad\quad = \log_2 N + \epsilon', \end{aligned} \tag{4}$$

where $0 \le \epsilon, \epsilon' < 0.0861$.

To summarize: Algorithm B never makes more than $\lfloor \log_2 N \rfloor + 1$ comparisons, and it makes about $\log_2 N - 1$ comparisons in an average successful search. No search method based on comparisons can do better than this. The average running time of Program B is approximately

$$\begin{aligned} &(18 \log_2 N - 15)u \qquad \text{for a successful search,} \\ &(18 \log_2 N + 13)u \qquad \text{for an unsuccessful search,} \end{aligned} \tag{5}$$

if we assume that all outcomes of the search are equally likely.

An important variation. Instead of using three pointers l, i, and u in the search, it is tempting to use only two, the current position i and its rate of change, δ; after each unequal comparison, we could then set $i \leftarrow i \pm \delta$ and $\delta \leftarrow \delta/2$ (approximately). It is possible to do this, but only if extreme care is paid to the details, as in the following algorithm; simpler approaches are doomed to failure!

Algorithm U (*Uniform binary search*). Given a table of records $R_1, R_2, \ldots, R_N$ whose keys are in increasing order $K_1 < K_2 < \cdots < K_N$, this algorithm searches for a given argument K. If N is even, the algorithm will sometimes refer to a dummy key K_0 which should be set to $-\infty$ (or any value less than K). We assume that $N \ge 1$.

U1. [Initialize.] Set $i \leftarrow \lceil N/2 \rceil$, $m \leftarrow \lfloor N/2 \rfloor$.

U2. [Compare.] If $K < K_i$, go to U3; if $K > K_i$, go to U4; and if $K = K_i$, the algorithm terminates successfully.

U3. [Decrease i]. (We have pinpointed the search to an interval which contains either m or $m - 1$ records; i points just to the right of this interval.) If $m = 0$, the algorithm terminates unsuccessfully. Otherwise set $i \leftarrow i - \lceil m/2 \rceil$; then set $m \leftarrow \lfloor m/2 \rfloor$ and return to U2.

U4. [Increase i.] (We have pinpointed the search to an interval which contains either m or $m - 1$ records; i points just to the left of this interval.) If $m = 0$, the algorithm terminates unsuccessfully. Otherwise set $i \leftarrow i + \lceil m/2 \rceil$; then set $m \leftarrow \lfloor m/2 \rfloor$ and return to U2. ∎

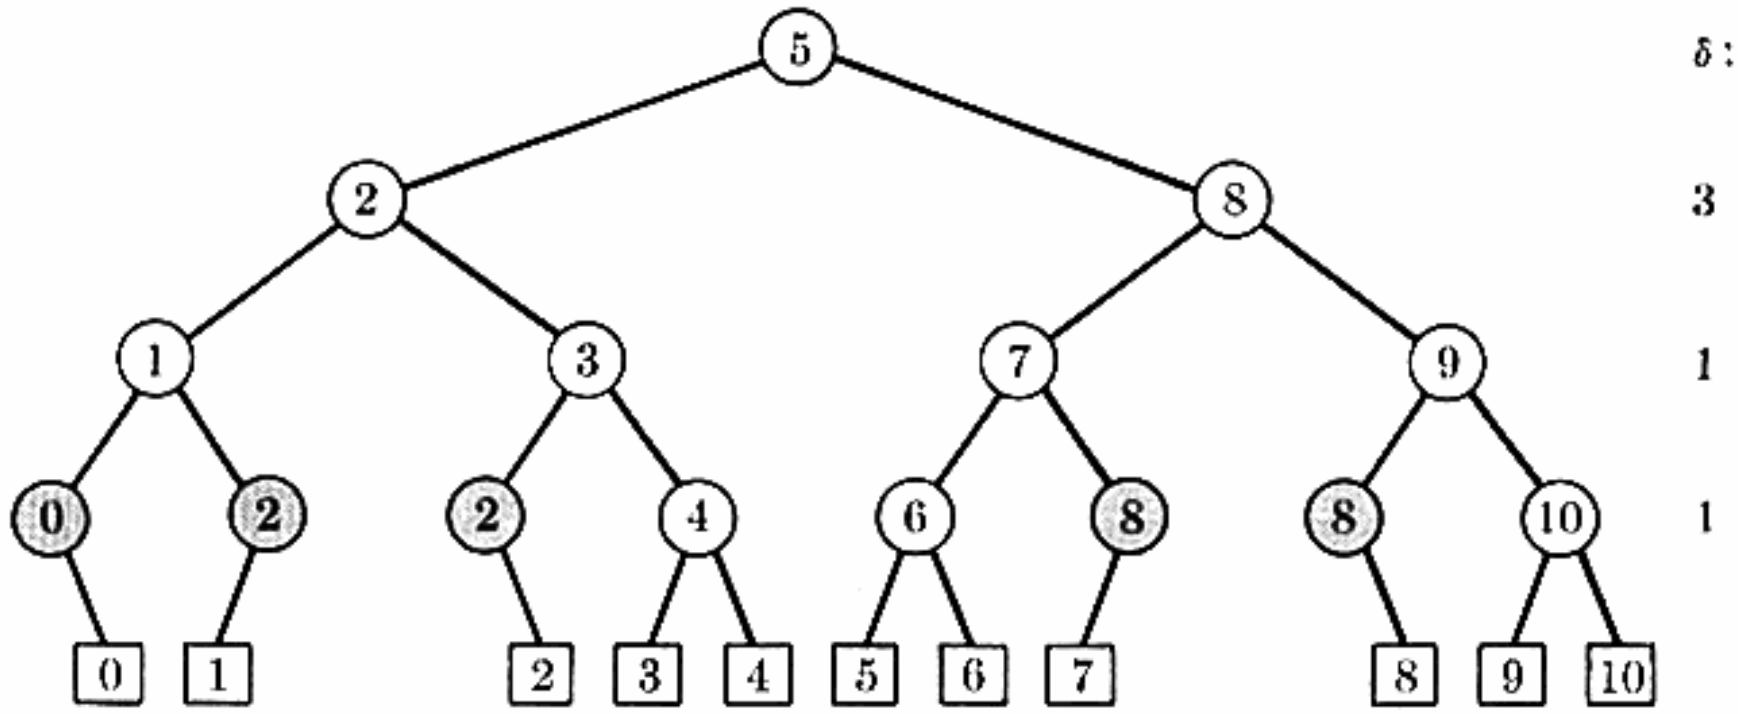

Fig. 6. The binary tree for a "uniform" binary search, when $N = 10$.

Figure 6 shows the corresponding binary tree for the search, when $N = 10$. In an unsuccessful search, the algorithm may make a redundant comparison just before termination; these nodes are shaded in the figure. We may call the search process *uniform* because the difference between the number of a node on level ℓ and the number of its ancestor on level $\ell - 1$ has a constant value δ for all nodes on level ℓ.

The theory underlying Algorithm U can be understood as follows: Suppose that we have an interval of length $n - 1$ to search; a comparison with the middle element (for n even) or with one of the two middle elements (for n odd) leaves us with two intervals of lengths $\lfloor n/2 \rfloor - 1$ and $\lceil n/2 \rceil - 1$. After repeating this process k times, we obtain 2^k intervals, of which the smallest has length $\lfloor n/2^k \rfloor - 1$ and the largest has length $\lceil n/2^k \rceil - 1$. Hence the lengths of two intervals at the same level differ by at most unity; this makes it possible to choose an appropriate "middle" element, without keeping track of the exact lengths.

The principal advantage of Algorithm U is that we need not maintain the value of m at all; we need only refer to a short table of the various δ to use at each level of the tree. Thus the algorithm reduces to the following procedure, which is equally good on binary or decimal computers:

Algorithm C (*Uniform binary search*). This algorithm is just like Algorithm U, but it uses an auxiliary table in place of the calculations involving m. The table entries are

$$\texttt{DELTA}[j] = \left\lfloor \frac{N + 2^{j-1}}{2^j} \right\rfloor = \left(\frac{N}{2^j}\right)\text{rounded}, \quad \text{for} \quad 1 \le j \le \lfloor \log_2 N \rfloor + 2. \tag{6}$$

C1. [Initialize.] Set $i \leftarrow \texttt{DELTA}[1]$, $j \leftarrow 2$.

C2. [Compare.] If $K < K_i$, go to C3; if $K > K_i$, go to C4; and if $K = K_i$, the algorithm terminates successfully.

C3. [Decrease i.] If $\texttt{DELTA}[j] = 0$, the algorithm terminates unsuccessfully. Otherwise, set $i \leftarrow i - \texttt{DELTA}[j]$, $j \leftarrow j + 1$, and go to C2.

C4. [Increase i.] If DELTA[j] $= 0$, the algorithm terminates unsuccessfully. Otherwise, set $i \leftarrow i +$ DELTA[j], $j \leftarrow j + 1$, and go to C2. ▮

Exercise 8 proves that this algorithm refers to the artificial key $K_0 = -\infty$ only when N is even.

Program C (*Uniform binary search*). This program does the same job as Program B, using Algorithm C with rA $\equiv K$, rI1 $\equiv i$, rI2 $\equiv j$, rI3 $\equiv$ DELTA[j].

```
01    START   ENT1  N+1/2      1          C1. Initialize.
02            ENT2  2          1          j ← 2.
03            LDA   K          1
04            JMP   2F         1
05    3H      JE    SUCCESS    C1         Jump if K = K_i.
06            J3Z   FAILURE    C1 − S     Jump if DELTA[j] = 0.
07            DEC1  0,3        C1 − S − A C3. Decrease i.
08    5H      INC2  1          C − 1      j ← j + 1.
09    2H      LD3   DELTA,2    C          C2. Compare.
10            CMPA  KEY,1      C
11            JLE   3B         C          Jump if K ≤ K_i.
12            INC1  0,3        C2         C4. Increase i.
13            J3NZ  5B         C2         Jump if DELTA[j] ≠ 0.
14    FAILURE EQU   *          1 − S      Exit if not in table. ▮
```

In a successful search, this algorithm corresponds to a binary tree with the same internal path length as the tree of Algorithm B, so the average number of comparisons C_N is the same as before. In an unsuccessful search, Algorithm C always makes exactly $\lfloor \log_2 N \rfloor + 1$ comparisons. The total running time of Program C is not quite symmetrical between left and right branches, since $C1$ is weighted more heavily than $C2$, but exercise 9 shows that we have $K < K_i$ roughly as often as $K > K_i$; hence Program C takes approximately

$$\begin{aligned} &(8.5 \log_2 N - 6)u && \text{for a successful search,} \\ &(8.5 \lfloor \log_2 N \rfloor + 12)u && \text{for an unsuccessful search.} \end{aligned} \tag{7}$$

This is more than twice as fast as Program B, without using any special properties of binary computers, even though the running times (5) for Program B assume that MIX has a "shift right binary" instruction.

Another modification of binary search, suggested in 1971 by L. E. Shar, will be still faster on some computers, because it is uniform after the first step, and it requires no table. The first step is to compare K with K_i, where $i = 2^k$, $k = \lfloor \log_2 N \rfloor$. If $K < K_i$, we use a uniform search with the δ's equal to 2^{k-1}, $2^{k-2}, \ldots, 1, 0$. On the other hand, if $K > K_i$ and $N > 2^k$, we reset i to $i' = N + 1 - 2^\ell$, where $\ell = \lfloor \log_2 (N - 2^k) \rfloor + 1$, and pretend that the first comparison was actually $K > K_{i'}$, using a uniform search with the δ's equal to $2^{\ell-1}, 2^{\ell-2}, \ldots, 1, 0$.

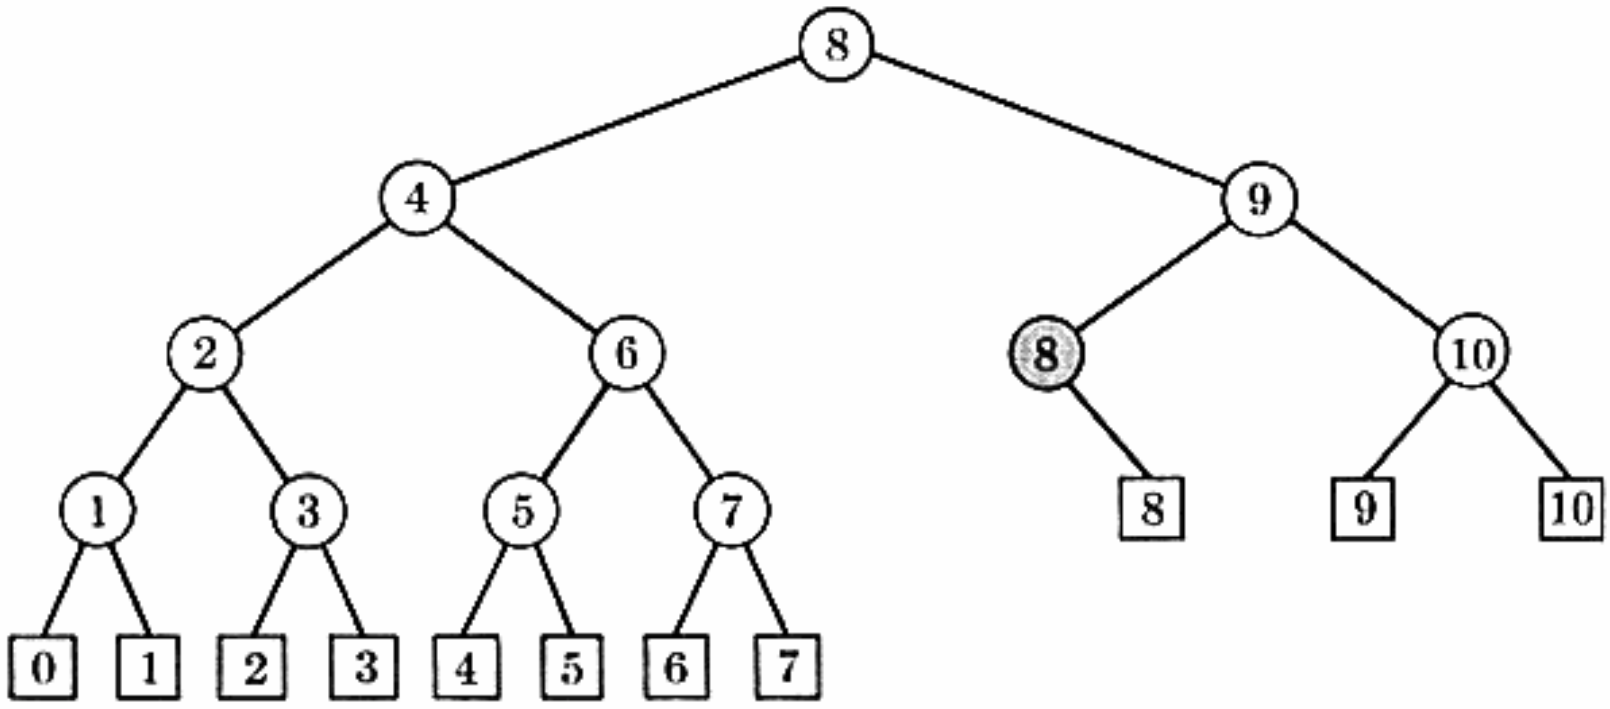

Fig. 7. The binary tree for Shar's almost uniform search, when $N = 10$.

Shar's method is illustrated for $N = 10$ in Fig. 7. Like the previous algorithms, it never makes more than $\lfloor \log_2 N \rfloor + 1$ comparisons; hence it is within one of the best possible average number of comparisons, in spite of the fact that it occasionally goes through several redundant steps in succession (cf. exercise 12).

Still another modification of binary search, which increases the speed of *all* the above methods when N is very large, is discussed in exercise 23. See also exercise 24 for a method that is faster yet!

Fibonaccian search. In the polyphase merge we have seen that the Fibonacci numbers can play a role analogous to the powers of 2. A similar phenomenon occurs in searching, where Fibonacci numbers provide us with an alternative to binary search. The resulting method is preferable on some computers, because it involves only addition and subtraction, not division by 2. The procedure we are about to discuss should be distinguished from an important numerical "Fibonacci search" procedure used to locate the maximum of a unimodal function [cf. *Fibonacci Quarterly* **4** (1966), 265–269]; the similarity of names has led to some confusion.

The Fibonaccian search technique looks very mysterious at first glance, if we simply take the program and try to explain what is happening; it seems to work by magic. But the mystery disappears as soon as the corresponding search tree is displayed. Therefore we shall begin our study of the method by looking at "Fibonacci trees."

Figure 8 shows the Fibonacci tree of order 6. Note that it looks somewhat more like a real-life shrub than the other trees we have been considering, perhaps because many natural processes satisfy a Fibonacci law. In general, the Fibonacci tree of order k has $F_{k+1} - 1$ internal (circular) nodes and F_{k+1} external (square) nodes, and it is constructed as follows:

If $k = 0$ or $k = 1$, the tree is simply $\boxed{0}$.

If $k \geq 2$, the root is $\textcircled{F_k}$; the left subtree is the Fibonacci tree of order $k - 1$; and the right subtree is the Fibonacci tree of order $k - 2$ with all numbers increased by F_k.

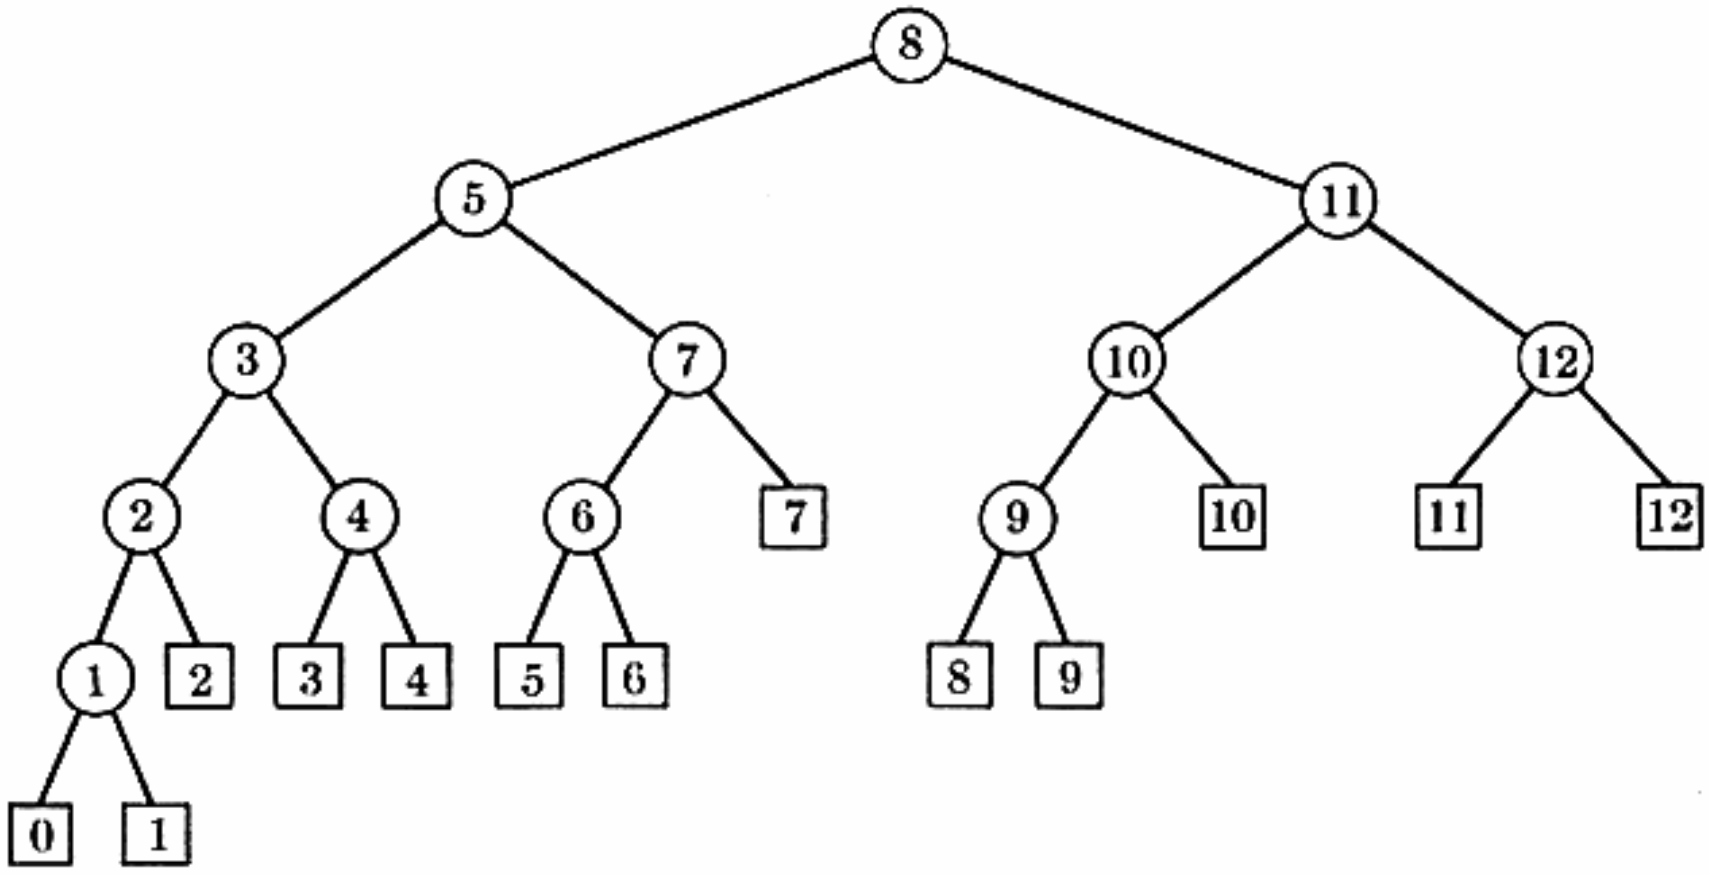

Fig. 8. The Fibonacci tree of order 6.

Note that, except for the external nodes, the numbers on the two sons of each internal node differ from their father's number by the same amount, and this amount is a Fibonacci number. Thus, $5 = 8 - F_4$ and $11 = 8 + F_4$ in Fig. 8. When the difference is F_j, the corresponding Fibonacci difference for the next branch on the left is F_{j-1}, while on the right it skips down to F_{j-2}. For example, $3 = 5 - F_3$ while $10 = 11 - F_2$.

If we combine these observations with an appropriate mechanism for recognizing the external nodes, we arrive at the following method:

Algorithm F (*Fibonaccian search*). Given a table of records $R_1, R_2, \ldots, R_N$ whose keys are in increasing order $K_1 < K_2 < \cdots < K_N$, this algorithm searches for a given argument K.

For convenience in description, this algorithm assumes that $N + 1$ is a perfect Fibonacci number, F_{k+1}. It is not difficult to make the method work for arbitrary N, if a suitable initialization is provided (see exercise 14).

F1. [Initialize.] Set $i \leftarrow F_k$, $p \leftarrow F_{k-1}$, $q \leftarrow F_{k-2}$. (Throughout the algorithm, p and q will be consecutive Fibonacci numbers.)

F2. [Compare.] If $K < K_i$, go to step F3; if $K > K_i$, go to F4; and if $K = K_i$, the algorithm terminates successfully.

F3. [Decrease i.] If $q = 0$, the algorithm terminates unsuccessfully. Otherwise set $i \leftarrow i - q$, and set $(p, q) \leftarrow (q, p - q)$; then return to F2.

F4. [Increase i.] If $p = 1$, the algorithm terminates unsuccessfully. Otherwise set $i \leftarrow i + q$, $p \leftarrow p - q$, then $q \leftarrow q - p$, and return to F2. ∎

The following MIX implementation gains speed by making two copies of the inner loop, one in which p is in rI2 and q in rI3, and one in which the registers are reversed; this simplifies step F3. In fact, the program actually keeps $p - 1$ and $q - 1$ in the registers, instead of p and q, in order to simplify the test "$p = 1$?" in step F4.

Program F (*Fibonaccian search*). rA $\equiv K$, rI1 $\equiv i$, (rI2, rI3) $\equiv p-1$, (rI3, rI2) $\equiv q-1$.

```
                    01  START  LDA   K                          1          F1. Initialize.
                    02         ENT1  F_k                        1          i ← F_k.
                    03         ENT2  F_{k-1}-1                  1          p ← F_{k-1}.
                    04         ENT3  F_{k-2}-1                  1          q ← F_{k-2}.
                    05         JMP   F2A                        1          To step F2.
06  F4A   INC1  1,3          18  F4B   INC1  1,2          C2 − S − A   F4. Increase i.  i ← i + q.
07        DEC2  1,3          19        DEC3  1,2          C2 − S − A   p ← p − q.
08        DEC3  1,2          20        DEC2  1,3          C2 − S − A   q ← q − p.
09  F2A   CMPA  KEY,1        21  F2B   CMPA  KEY,1             C       F2. Compare.
10        JL    F3A          22        JL    F3B              C       To F3 if K < K_i.
11        JE    SUCCESS      23        JE    SUCCESS          C2      Exit if K = K_i.
12        J2NZ  F4A          24        J3NZ  F4B            C2 − S    To F4 if p ≠ 1.
13        JMP   FAILURE      25        JMP   FAILURE          A       Exit if not in table.
14  F3A   DEC1  1,3          26  F3B   DEC1  1,2              C1      F3. Decrease i.  i ← i − q.
15        DEC2  1,3          27        DEC3  1,2              C1      p ← p − q.
16        J3NN  F2B          28        J2NN  F2A              C1      Swap registers if q > 0.
17        JMP   FAILURE      29        JMP   FAILURE      1 − S − A   Exit if not in table.  ∎
```

The running time of this program is analyzed in exercise 18. Figure 8 shows, and the analysis proves, that a left branch is taken somewhat more often than a right branch. Let C, $C1$, and $(C2 - S)$ be the respective number of times steps F2, F3, and F4 are performed. Then we have

$$\begin{aligned} C &= (\text{ave} \quad \phi k/\sqrt{5} + O(1), \quad \max k - 1), \\ C1 &= (\text{ave} \quad k/\sqrt{5} + O(1), \quad \max k - 1), \\ C2 - S &= (\text{ave } \phi^{-1}k/\sqrt{5} + O(1), \quad \max \lfloor k/2 \rfloor). \end{aligned} \tag{8}$$

Thus the left branch is taken about $\phi = 1.618$ times as often as the right branch (a fact which we might have guessed, since each probe divides the remaining interval into two parts, with the left part about ϕ times as large as the right). The total average running time of Program F therefore comes to approximately

$$\begin{aligned} (6\phi k/\sqrt{5} - (2 + 22\phi)/5)\ u &\approx (6.252 \log_2 N - 4.6)u \\ &\quad \text{for a successful search;} \\ (6\phi k/\sqrt{5} + (58/(27\phi))/5)\ u &\approx (6.252 \log_2 N + 5.8)u \\ &\quad \text{for an unsuccessful search.} \end{aligned} \tag{9}$$

This is slightly faster than Program C, although the worst case running time (roughly $8.6 \log_2 N$) is slightly slower.

Interpolation search. Let's forget computers for a moment, and consider how people actually carry out a search. Sometimes everyday life provides us with clues that lead to good algorithms.

Imagine yourself looking up a word in a dictionary. You probably *don't* begin by looking first at the middle page, then looking at the 1/4 or 3/4 point, etc., as in a binary search. It's even less likely that you use a Fibonaccian search!

If the word you want starts with the letter A, you probably begin near the front of the dictionary. In fact, many dictionaries have "thumb-indexes" which

show the starting page for the words beginning with a fixed letter. This thumb-index technique can readily be adapted to computers, and it will speed up the search; such algorithms are explored in Section 6.3.

Yet even after the initial point of search has been found, your actions still are not much like the methods we have discussed. If you notice that the desired word is alphabetically much greater than the words on the page being examined, you will turn over a fairly large chunk of pages before making the next reference. This is quite different from the above algorithms, which make no distinction between "much greater" and "slightly greater."

These considerations suggest an algorithm which might be called "interpolation search": When we know that K lies between K_l and K_u, we can choose the next probe to be about $(K - K_l)/(K_u - K_l)$ of the way between l and u, assuming that the keys are numeric and that they increase in a roughly constant manner throughout the interval.

Unfortunately, computer simulation experiments show that interpolation search does not decrease the number of comparisons enough to compensate for the extra computing time involved, when searching a table stored within a high-speed memory. It has been successful only to a limited extent when applied to *external* searching in peripheral memory devices. (Note that dictionary look-up by hand is essentially an external, not an internal, search.) We shall discuss external searching later.

History and bibliography. The earliest known example of a long list of items that was sorted into order to facilitate searching is the remarkable Babylonian reciprocal table of Inakibit-Anu, dating from about 200 B.C. This clay tablet is apparently the first of a series of three, which contained over 800 multiple-precision sexagesimal numbers and their reciprocals, sorted into lexicographic order. For example, the list included the following sequence of entries:

02 43 50 24	21 58 21 33 45
02 44 01 30	21 56 52 20 44 26 40
02 45 42 03 14 08	21 43 33 12 53 32 50 30 28 07 30
02 45 53 16 48	21 42 05
02 46 04 31 07 30	21 40 36 53 04 38 11 21 28 53 20

The task of sorting 800 entries like this, given the technology available at that time, must have been truly phenomenal. [See D. E. Knuth, *CACM* **15** (1972), 671–677, for further details.]

It is fairly natural to sort numerical values into order, but an order relation between letters or words does not suggest itself so readily. Yet a collating sequence for individual letters was present already in the most ancient alphabets. For example, many of the Biblical psalms have verses which follow a strict alphabetic sequence, the first verse starting with aleph, the second with beth, etc.; this was an aid to memory. Eventually the standard sequence of letters was used by Semitic and Greek peoples to denote numerals; for example, α, β, γ stood for 1, 2, 3, respectively.

But the use of alphabetic order for entire words seems to be a much later invention; it is something we might think is obvious, yet it has to be taught to children, and at some point in history it was necessary to teach it to adults! Several lists from about 300 B.C. have been found on the Aegean Islands, giving the names of people in certain religious cults; these lists have been alphabetized, but only by the first letter, thus representing only the first pass of a left-to-right radix sort. Some Greek papyri from the years 134–135 A.D. contain fragments of ledgers which show the names of taxpayers alphabetized by the first two letters. Apollonius Sophista used alphabetic order on the first two letters, and often on subsequent letters, in his lengthy concordance of Homer's poetry (first century A.D.). A few examples of more perfect alphabetization are known, notably Galen's *Hippocratic Glosses* (c. 200 A.D.), but these were very rare. Thus, words were arranged by their first letter only, in the *Etymologiarum* of St. Isidorus (c. 630 A.D., book x); and the *Corpus Glossary* (c. 725) used only the first two letters of each word. The latter two works were perhaps the largest nonnumerical files of data to be compiled during the Middle Ages.

It is not until Giovanni di Genoa's *Catholicon* (1286) that we find a specific description of true alphabetical order. In his preface, Giovanni explained that

amo	precedes	*bibo*
abeo	precedes	*adeo*
amatus	precedes	*amor*
imprudens	precedes	*impudens*
iusticia	precedes	*iustus*
polisintheton	precedes	*polissenus*

(thereby giving examples of situations in which the ordering is determined by the 1st, 2nd, . . . , 6th letters), "and so in like manner." He remarked that strenuous effort was required to devise these rules. "I beg of you, therefore, good reader, do not scorn this great labor of mine and this order as something worthless."

A detailed study of the development of alphabetic order, up to the time printing was invented, has been made by Lloyd W. Daly, *Collection Latomus* **90** (1967), 100 pp. He found some interesting old manuscripts that were evidently used as worksheets while sorting words by their first letters (see pp. 87–90 of his monograph).

The first dictionary of English, Robert Cawdrey's *Table Alphabeticall* (London, 1604), contains the following instructions:

> Nowe if the word, which thou art desirous to finde, beginne with (a) then looke in the beginning of this Table, but if with (v) looke towards the end. Againe, if thy word beginne with (ca) looke in the beginning of the letter (c) but if with (cu) then looke toward the end of that letter. And so of all the rest. &c.

It is interesting to note that Cawdrey was teaching *himself* how to alphabetize

as he prepared his dictionary; numerous misplaced words appear on the first few pages, but the last part is in nearly perfect alphabetical order!

Binary search was first mentioned by John Mauchly, in what was perhaps the first published discussion of nonnumerical programming methods [*Theory and techniques for the design of electronic digital computers*, ed. by G. W. Patterson, **3** (1946), 22.8–22.9]. The method became "well known" during the 50's, but nobody seems to have worked out the details of what should be done when N does not have the special form $2^n - 1$. [See A. D. Booth, *Nature* **176** (1955), 565; A. I. Dumey, *Computers and Automation* **5** (December, 1956), 7, where binary search is called "Twenty Questions"; Daniel D. McCracken, *Digital Computer Programming* (Wiley, 1957), 201–203; and M. Halpern, *CACM* **1** (February, 1958), 1–3.]

H. Bottenbruch [*JACM* **9** (1962), 214] was apparently the first to publish a binary search algorithm which works for all N. He presented an interesting variation of Algorithm B which avoids a separate test for equality until the very end: Using $i \leftarrow \lceil (l+u)/2 \rceil$ instead of $\lfloor (l+u)/2 \rfloor$ in step B2, he set $l \leftarrow i$ whenever $K \geq K_i$; then $u - l$ decreases at every step. Eventually, when $l = u$, we have $K_l \leq K < K_{l+1}$, and we can test whether or not the search was successful by making one more comparison. (He assumed that $K \geq K_1$ initially.) This idea speeds up the inner loop slightly on many computers, and the same principle can be used with all of the algorithms we have discussed in this section; but the change is desirable only for large N (see exercise 23).

K. E. Iverson [*A Programming Language* (Wiley, 1962), 141] gave the procedure of Algorithm B, but without considering the possibility of an unsuccessful search. D. E. Knuth [*CACM* **6** (1963), 556–558] presented Algorithm B as an example used with an automated flowcharting system. The uniform binary search, Algorithm C, was suggested to the author by A. K. Chandra of Stanford University in 1971.

Fibonaccian searching was invented by David E. Ferguson [*CACM* **3** (1960), 648], but his flowchart and analysis were incorrect. The Fibonacci tree (without labels) had appeared many years earlier, as a curiosity in the first edition of Hugo Steinhaus's popular book *Mathematical Snapshots* (New York: Stechert, 1938), p. 28; he drew it upside down and made it look like a real tree, with right branches twice as long as left branches so that all the leaves occur at the same level.

Interpolation searching was suggested by W. W. Peterson [*IBM J. Res. & Devel.* **1** (1957), 131–132]; he gave a theoretical estimate for the average number of comparisons needed if the keys are randomly selected from a uniform distribution, but the estimate does not seem to agree with actual simulation experiments.

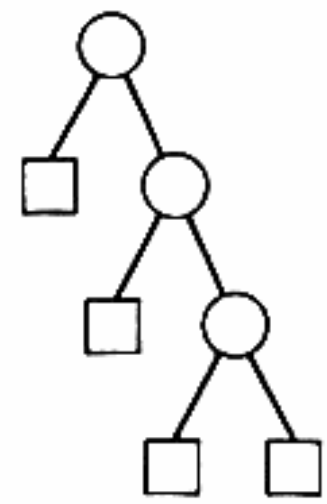
EXERCISES

▶ **1.** [*21*] Prove that if $u < l$ in step B2 of the binary search, we have $u = l - 1$ and

$K_u < K < K_l$. (Assume by convention that $K_0 = -\infty$ and $K_{N+1} = +\infty$, although these artificial keys are never really used by the algorithm so they need not be present in the actual table.)

▸ **2.** [*22*] Would Algorithm B still work properly if we (a) changed step B5 to "$l \leftarrow i$" instead of "$l \leftarrow i + 1$"? (b) changed step B4 to "$u \leftarrow i$" instead of "$u \leftarrow i - 1$"? (c) made both of these changes?

3. [*15*] What searching method corresponds to the tree



?

What is the average number of comparisons made in a successful search? in an unsuccessful search?

4. [*20*] If a search using Program 6.1S (sequential search) takes exactly 638 units of time, how long does it take with Program B (binary search)?

5. [*M24*] For what values of N is Program B actually *slower* than a sequential search (Program 6.1Q′) on the average, assuming that the search is successful?

6. [*28*] (K. E. Iverson.) Exercise 5 suggests that it would be best to have a "hybrid" method, changing from binary search to sequential search when the remaining interval has length less than some judiciously chosen value. Write an efficient MIX program for such a search and determine the best changeover value.

▸ **7.** [*M22*] Would Algorithm U still work properly if we changed step U1 so that (a) both i and m are set equal to $\lfloor N/2 \rfloor$? (b) both i and m are set equal to $\lceil N/2 \rceil$? [*Hint:* Suppose the first step were "Set $i \leftarrow 0$, $m \leftarrow N$ (or $N + 1$), go to U4."]

8. [*M20*] (a) What is the sum $\sum_{0 \le j \le \lfloor \log_2 N \rfloor + 2}$ DELTA[j] of the increments in Algorithm C? (b) What are the minimum and maximum values of i which can occur in step C2?

9. [*M26*] Find exact formulas for the average values of $C1$, $C2$, and A in the frequency analysis of Program C, as a function of N and S.

10. [*20*] Is there any value of $N > 1$ for which Algorithms B and C are exactly equivalent, in the sense that they will both perform the same sequence of comparisons for all search arguments?

11. [*21*] Explain how to write a MIX program for Algorithm C containing approximately $7 \log_2 N$ instructions and having a running time of about $4.5 \log_2 N$ units.

12. [*20*] Draw the binary search tree corresponding to Shar's method when $N = 12$.

13. [*M24*] Tabulate the average number of comparisons made by Shar's method, for $1 \le N \le 16$, considering both successful and unsuccessful searches.

14. [*21*] Explain how to extend Algorithm F so that it will apply for all $N \ge 1$.

15. [*21*] Figure 9 shows the lineal chart of the rabbits in Fibonacci's original rabbit problem (cf. Section 1.2.8). Is there a simple relationship between this and the Fibonacci tree discussed in the text?

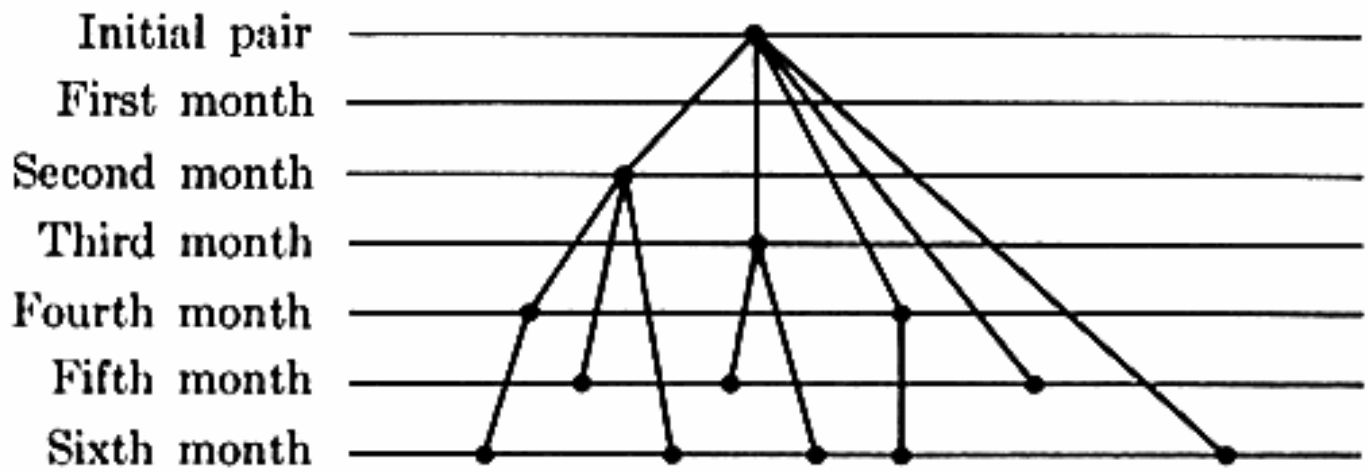


Fig. 9. Pairs of rabbits breeding by Fibonacci's rule.

16. [*M19*] For what values of k does the Fibonacci tree of order k define an optimal search procedure, in the sense that the fewest comparisons are made on the average?

17. [*M21*] From exercise 1.2.8–34 (or exercise 5.4.2–10) we know that every positive integer n has a unique representation as a sum of Fibonacci numbers $n = F_{a_1} + F_{a_2} + \cdots + F_{a_r}$, where $r \geq 1$, $a_j \geq a_{j+1} + 2$ for $1 \leq j < r$, and $a_r \geq 2$. Prove that in the Fibonacci tree of order k, the path from the root to node $\boxed{n}$ has length $k + 1 - r - a_r$.

18. [*M30*] Find exact formulas for the average values of $C1$, $C2$, and A in the frequency analysis of Program F, as a function of k, F_k, F_{k+1}, and S.

19. [*M42*] Carry out a detailed analysis of the average running time of the algorithm suggested in exercise 14.

20. [*M22*] The number of comparisons required in a binary search is approximately $\log_2 N$, and in the Fibonaccian search it is roughly $(\phi/\sqrt{5}) \log_\phi N$. The purpose of this exercise is to show that these formulas are special cases of a more general result.

Let p and q be positive numbers with $p + q = 1$. Consider a search algorithm which, given a table of N numbers in increasing order, starts by comparing the argument with the (pN)th key, and iterates this procedure on the smaller blocks. (The binary search has $p = q = 1/2$; the Fibonacci search has $p = 1/\phi$, $q = 1/\phi^2$.)

If $C(N)$ denotes the average number of comparisons required to search a table of size N, it approximately satisfies the relations

$$C(1) = 0; \qquad C(N) = 1 + pC(pN) + qC(qN) \qquad \text{for} \qquad N > 1.$$

This happens because there is probability p (roughly) that the search reduces to a pN-element search, and probability q that it reduces to a qN-element search, after the first comparison. When N is large, we may ignore the small-order effect caused by the fact that pN and qN aren't exactly integers.

a) Show that $C(N) = \log_b N$ satisfies these relations exactly, for a certain choice of b. For binary and Fibonaccian search, this value of b agrees with the formulas derived earlier.

b) A man argues as follows: "With probability p, the size of the interval being scanned in this algorithm is divided by $1/p$; with probability q, the interval size is divided by $1/q$. Therefore the interval is divided by $p \cdot (1/p) + q \cdot (1/q) = 2$ on the average, so the algorithm is exactly as good as the binary search, regardless of p and q." Is there anything wrong with his argument?

21. [*20*] Draw the binary tree corresponding to interpolation search when $N = 10$.

22. [*M47*] Derive formulas which properly estimate the average number of iterations needed in the interpolation search applied to random data.

▶**23.** [*25*] The binary search algorithm of H. Bottenbruch, mentioned at the close of this section, avoids testing for equality until the very end of the search. (During the algorithm we know that $K_l \le K < K_{u+1}$, and the case of equality is not examined until $l = u$.) Such a trick would make Program B run a little bit faster for large N, since the "JE" instruction could be removed from the inner loop. (However, the idea wouldn't really be practical since $\log_2 N$ is usually small; we would need $N > 2^{36}$ in order to compensate for the extra iteration necessary!)

Show that *every* search algorithm corresponding to a binary tree can be adapted to a search algorithm that uses two-way branching ($<$ vs. $\ge$) at the internal nodes of the tree, in place of the three-way branching ($<$, $=$, or $>$) used in the text's discussion. In particular, show how to modify Algorithm C in this way.

▶**24.** [*23*] The complete binary tree is a convenient way to represent a minimum-path-length tree in consecutive locations. (Cf. Section 2.3.4.5.) Devise an efficient search method based on this representation. [*Hint:* Is it possible to use multiplication by 2 instead of division by 2 in a binary search?]

▶**25.** [*M25*] Suppose that a binary tree has a_k internal nodes and b_k external nodes on level k, for $k = 0, 1, \ldots$. (The root is at level zero.) Thus in Fig. 8 we have $(a_0, a_1, \ldots, a_6) = (1, 2, 4, 4, 1, 0)$ and $(b_0, b_1, \ldots, b_6) = (0, 0, 0, 4, 7, 2)$. (a) Show that there is a simple algebraic relationship which connects the generating functions $A(z) = \sum_k a_k z^k$ and $B(z) = \sum_k b_k z^k$. (b) The probability distribution for a successful search in a binary tree has the generating function $g(z) = zA(z)/N$, and for an unsuccessful search the generating function is $h(z) = B(z)/(N+1)$. (Thus in the text's notation we have $C_N = \text{mean}(g)$, $C'_N = \text{mean}(h)$, and Eq. (2) gives a relation between these quantities.) Find a relation between $\text{var}(g)$ and $\text{var}(h)$.

26. [*22*] Show that the Fibonacci tree is related to polyphase merge sorting on three tapes.

27. [*M30*] (H. S. Stone and John Linn.) Consider a search process which uses k processors simultaneously, and which is based solely on comparisons of keys. Thus at every step of the search, k indices $i_1, \ldots, i_k$ are specified, and we perform k simultaneous comparisons; if $K = K_{i_j}$ for some j, the search terminates successfully, otherwise the search proceeds to the next step based on the 2^k possible outcomes $K < K_{i_j}$ or $K > K_{i_j}$, $1 \le j \le n$.

Prove that such a process must always take at least approximately $\log_{k+1} N$ steps on the average, as $N \to \infty$, assuming that each key of the table is equally likely as a search argument. (Hence the potential increase in speed over 1-processor binary search is only a factor of $\log_2 (k+1)$, not the factor of k we might expect. In this sense it is more efficient to assign each processor to a different, independent search problem, instead of making them cooperate on a single search.)

6.2.2. Binary Tree Searching

In the preceding section, we learned that an implicit binary tree structure makes it easier to understand the behavior of binary search and Fibonaccian search. For a given value of N, the tree corresponding to binary search achieves

the theoretical minimum number of comparisons that are necessary to search a table by means of key comparisons. But the methods of the preceding section are appropriate mainly for fixed-size tables, since the sequential allocation of records makes insertions and deletions rather expensive. If the table is dynamically changing, we might spend more time maintaining it than we save in binary-searching it.

The use of an *explicit* binary tree structure makes it possible to insert and delete records quickly, as well as to search the table efficiently. As a result, we essentially have a method which is useful both for searching and for sorting. This gain in flexibility is achieved by adding two link fields to each record of the table.

Techniques for searching a growing table are often called *symbol table algorithms*, because assemblers and compilers and other system routines generally use such methods to keep track of user-defined symbols. For example, the key of each record within a compiler might be a symbolic identifier denoting a variable in some FORTRAN or ALGOL program, and the rest of that record might contain information about the type of that variable and its storage allocation. Or the key might be a symbol in a MIXAL program, with the rest of the record containing the equivalent of that symbol. The tree search and insertion routines to be described in this section are quite efficient for use as symbol table algorithms, especially in applications where it is desirable to print out a list of the symbols in alphabetic order. Other symbol table algorithms are described in Sections 6.3 and 6.4.

Figure 10 shows a binary search tree containing the names of eleven signs

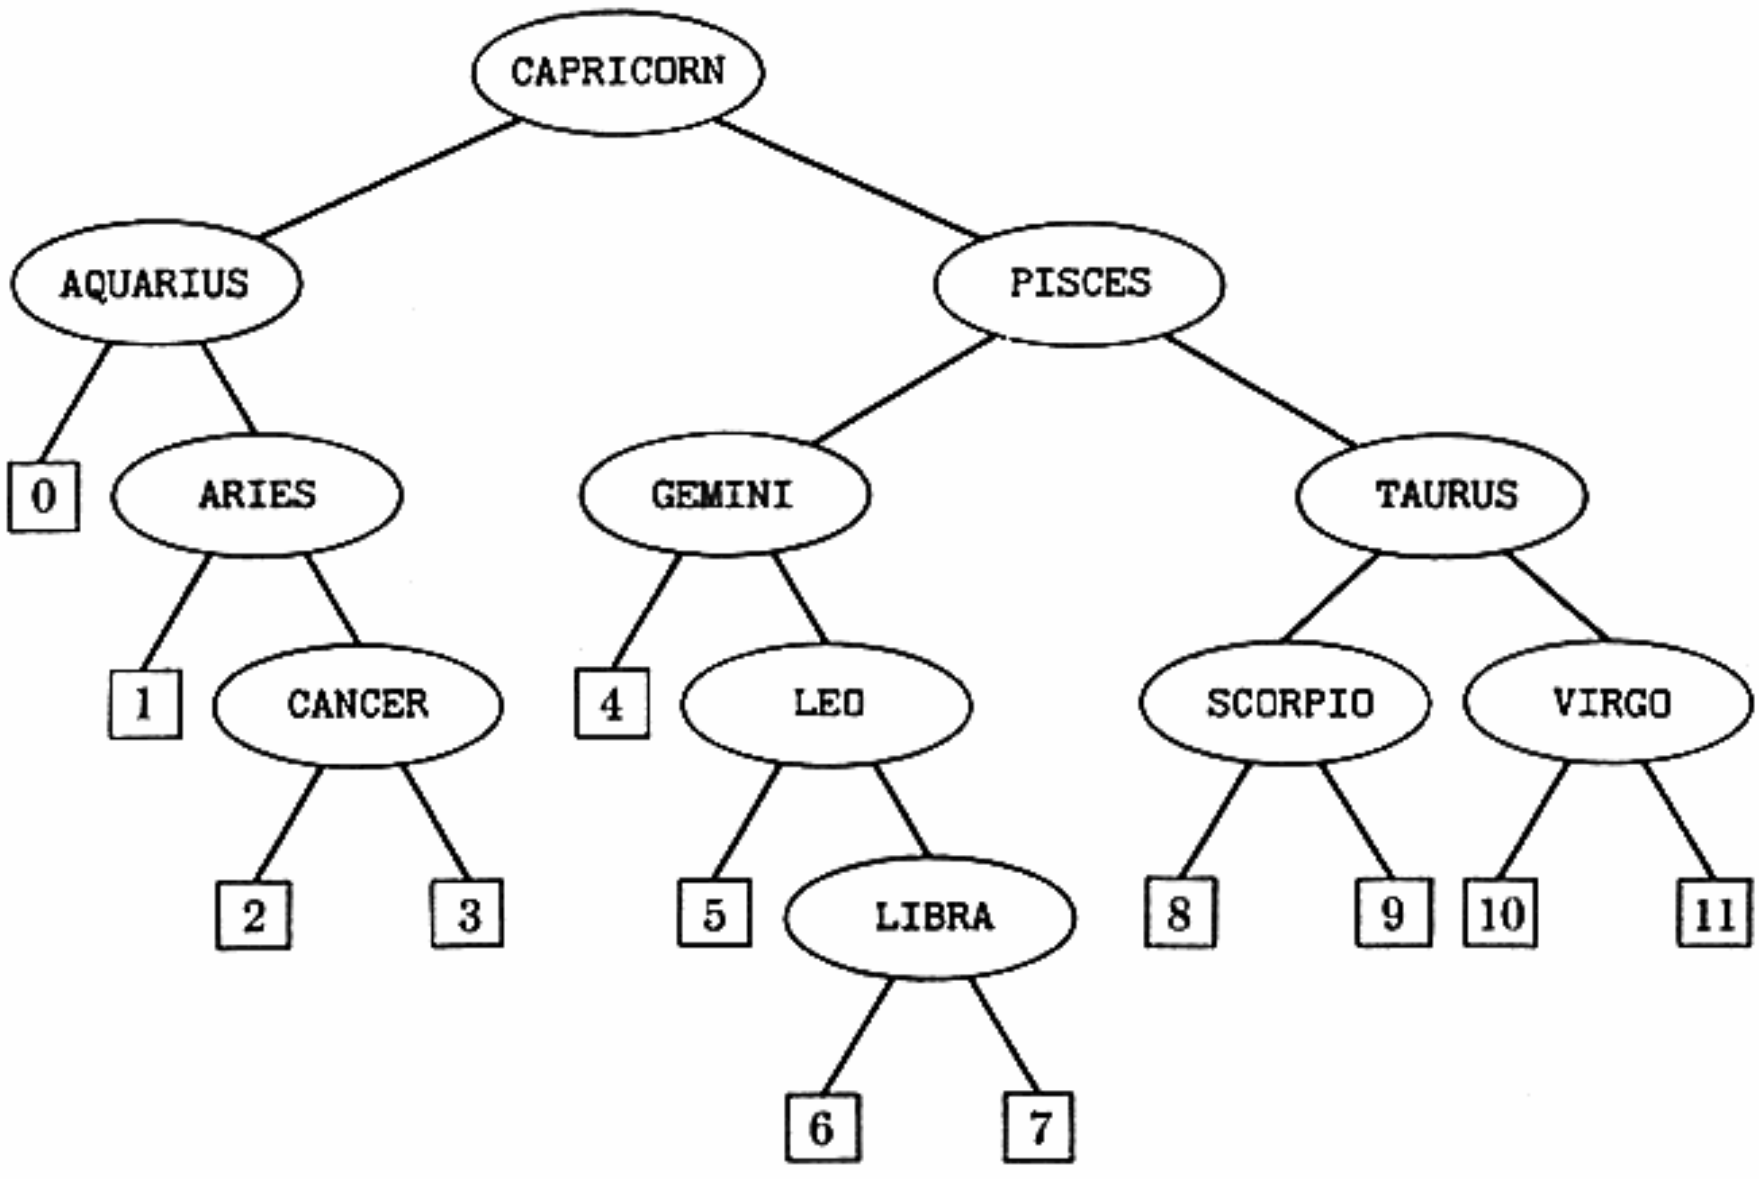

Fig. 10. A binary search tree.

of the zodiac. If we now search for the twelfth name, SAGITTARIUS, starting at the root or apex of the tree, we find it is greater than CAPRICORN, so we move to the right; it is greater than PISCES, so we move right again; it is less than TAURUS, so we move left; and it is less than SCORPIO, so we arrive at external node $\boxed{8}$. The search was unsuccessful; we can now *insert* SAGITTARIUS at the place the search ended, by linking it into the tree in place of the external node $\boxed{8}$. In this way the table can grow without the necessity of moving any of the existing records. Figure 10 was formed by starting with an empty tree and successively inserting the keys CAPRICORN, AQUARIUS, PISCES, ARIES, TAURUS, GEMINI, CANCER, LEO, VIRGO, LIBRA, SCORPIO, in this order.

All of the keys in the left subtree of the root in Fig. 10 are alphabetically less than CAPRICORN, and all keys in the right subtree are alphabetically greater. A similar statement holds for the left and right subtrees of every node. It follows that the keys appear in strict alphabetic sequence from left to right,

AQUARIUS, ARIES, CANCER, CAPRICORN, GEMINI, LEO, . . . , VIRGO

if we traverse the tree in *symmetric order* (cf. Section 2.3.1), since symmetric order is based on traversing the left subtree of each node just before that node, then traversing the right subtree.

The following algorithm spells out the searching and insertion processes in detail.

Algorithm T (*Tree search and insertion*). Given a table of records which form a binary tree as described above, this algorithm searches for a given argument K. If K is not in the table, a new node containing K is inserted into the tree in the appropriate place.

The nodes of the tree are assumed to contain at least the following fields:

KEY(P) = key stored in NODE(P);
LLINK(P) = pointer to left subtree of NODE(P);
RLINK(P) = pointer to right subtree of NODE(P).

Null subtrees (the external nodes in Fig. 10) are represented by the null pointer Λ. The variable ROOT points to the root of the tree. For convenience, we assume that the tree is not empty (i.e., ROOT $\neq \Lambda$).

T1. [Initialize.] Set P $\leftarrow$ ROOT. (The pointer variable P will move down the tree.)

T2. [Compare.] If $K <$ KEY(P), go to T3; if $K >$ KEY(P), go to T4; and if $K =$ KEY(P), the search terminates successfully.

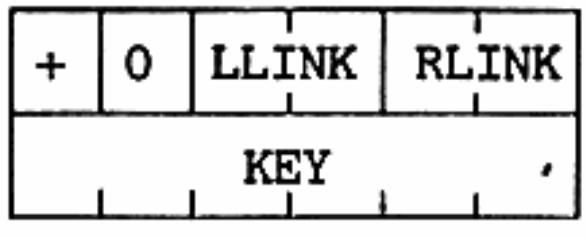
T3. [Move left.] If LLINK(P) $\neq \Lambda$, set P $\leftarrow$ LLINK(P) and go back to T2. Otherwise go to T5.

T4. [Move right.] If RLINK(P) $\neq \Lambda$, set P $\leftarrow$ RLINK(P) and go back to T2.

T5. [Insert into tree.] (The search is unsuccessful; we will now put K into the

tree.) Set Q ⇐ AVAIL, the address of a new node. Set KEY(Q) ← K, LLINK(Q) ← RLINK(Q) ← Λ. (In practice, other fields of the new node should also be initialized.) If K was less than KEY(P), set LLINK(P) ← Q, otherwise set RLINK(P) ← Q. (At this point we could set P ← Q and terminate the algorithm successfully.) ∎

This algorithm lends itself to a convenient machine language implementation. We may assume, for example, that the tree nodes have the form



(1)

followed perhaps by additional words of INFO. Using an AVAIL list for the free storage pool, as in Chapter 2, we can write the following MIX program:

Program T (*Tree search and insertion*). rA ≡ K, rI1 ≡ P, rI2 ≡ Q.

```
01    LLINK   EQU   2:3
02    RLINK   EQU   4:5
03    START   LDA   K                 1          T1. Initialize.
04            LD1   ROOT              1          P ← ROOT.
05            JMP   2F                1
06    4H      LD2   0,1(RLINK)        C2         T4. Move right.  Q ← RLINK(P).
07            J2Z   5F                C2         To T5 if Q = Λ.
08    1H      ENT1  0,2               C − 1      P ← Q.
09    2H      CMPA  1,1               C          T2. Compare.
10            JG    4B                C          To T4 if K > KEY(P).
11            JE    SUCCESS           C1         Exit if K = KEY(P).
12            LD2   0,1(LLINK)        C1 − S     T3. Move left.  Q ← LLINK(P).
13            J2NZ  1B                C1 − S     To T2 if Q ≠ Λ.
14    5H      LD2   AVAIL             1 − S      T5. Insert into tree.
15            J2Z   OVERFLOW          1 − S
16            LDX   0,2(RLINK)        1 − S
17            STX   AVAIL             1 − S      Q ⇐ AVAIL.
18            STA   1,2               1 − S      KEY(Q) ← K.
19            STZ   0,2               1 − S      LLINK(Q) ← RLINK(Q) ← Λ.
20            JL    1F                1 − S      Was K < KEY(P)?
21            ST2   0,1(RLINK)          A        RLINK(P) ← Q.
22            JMP   *+2                 A
23    1H      ST2   0,1(LLINK)        1 − S − A  LLINK(P) ← Q.
24    DONE    EQU   *                 1 − S      Exit after insertion. ∎
```

The first 13 lines of this program do the search; the last 11 lines do the insertion. The running time for the searching phase is $(7C + C1 - 3S + 4)u$, where

C = number of comparisons made;
$C1$ = number of times $K \le$ KEY(P);
S = 1 if the search is successful, 0 otherwise.

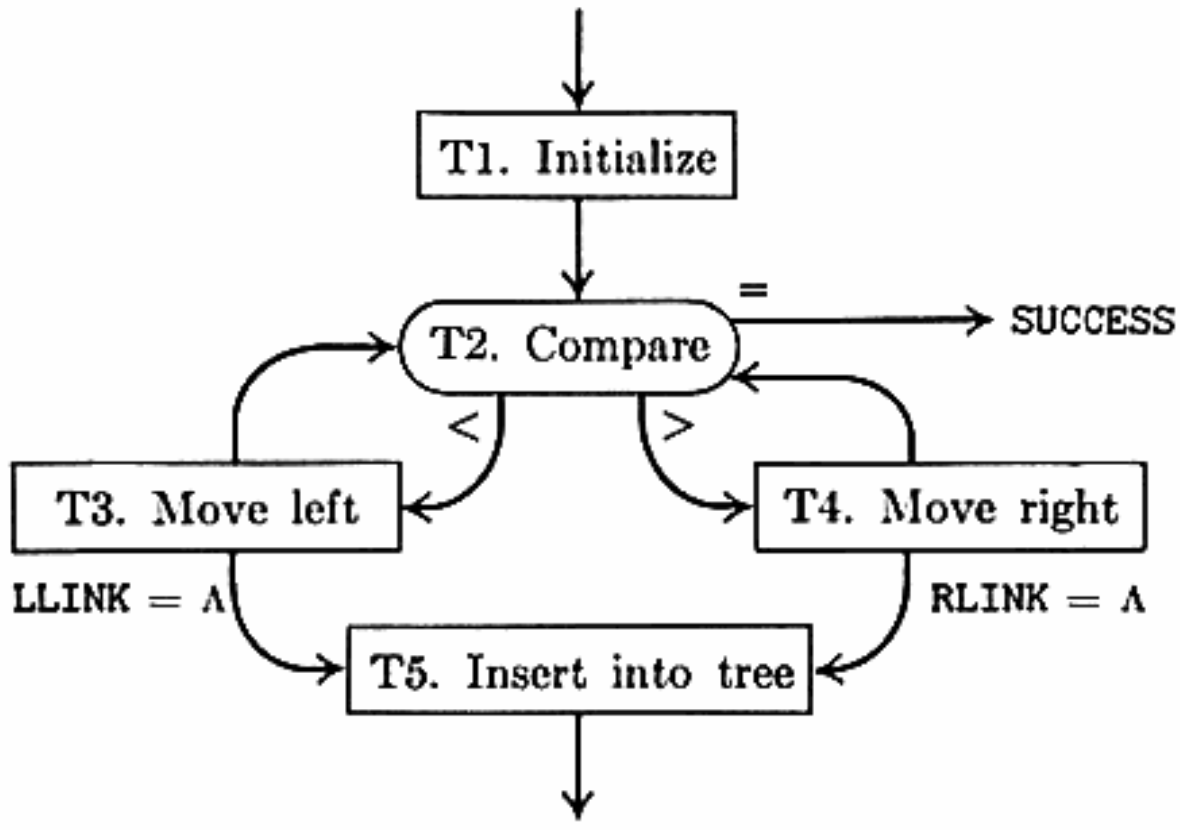


Fig. 11. Tree search and insertion.

On the average we have $C1 = \frac{1}{2}(C + S)$, since $C1 + C2 = C$ and $C1 - S \approx C2$; so the running time is about $(7.5C - 2.5S + 4)u$. This compares favorably with the binary search algorithms which use an implicit tree (cf. Program 6.2.1C). By duplicating the code as in Program 6.2.1F we could eliminate line 08 of Program T, reducing the running time to $(6.5C - 2.5S + 5)u$. If the search is unsuccessful, the insertion phase of the program costs an extra $14u$ or $15u$.

Algorithm T can be conveniently adapted to *variable-length keys* and variable-length records. For example, if we allocate the available space sequentially, in a last-in-first-out manner, we can easily create nodes of varying size; the first word of (1) could indicate the size. Since this is an efficient use of storage, symbol table algorithms based on trees are often especially attractive for use in compilers, assemblers, and loaders.

But what about the worst case? Programmers are often skeptical of Algorithm T when they first see it. If the keys of Fig. 10 had been entered into the tree in alphabetic order AQUARIUS, . . . , VIRGO instead of the calendar order CAPRICORN, . . . , SCORPIO, the algorithm would have built a degenerate tree which essentially specifies a *sequential* search. (All LLINKS would be null.) Similarly, if the keys come in the uncommon order

AQUARIUS, VIRGO, ARIES, TAURUS, CANCER, SCORPIO,

CAPRICORN, PISCES, GEMINI, LIBRA, LEO

we obtain a "zigzag" tree which is just as bad. (Try it!)

On the other hand, the particular tree in Fig. 10 requires only $3\frac{2}{11}$ comparisons, on the average, for a successful search; this is just a little higher than the minimum possible average number of comparisons, 3, achievable in the best possible binary tree.

When we have a fairly well-balanced tree, the search time is roughly proportional to $\log N$, but when we have a degenerate tree, the search time is

roughly proportional to N. Exercise 2.3.4.5–5 proves that the average search time would be roughly proportional to $\sqrt{N}$ if we considered each N-node binary tree to be equally likely. What behavior can we really expect from Algorithm T?

Fortunately, it can be proved that tree search will require only about $2 \ln N \approx 1.386 \log_2 N$ comparisons, if the keys are inserted into the tree in random order; well-balanced trees are common, and degenerate trees are very rare.

There is a surprisingly simple proof of this fact. Let us assume that each of the $N!$ possible orderings of the N keys is an equally likely sequence of insertions for building the tree. The number of comparisons needed to find a key is exactly one more than the number of comparisons that were needed when that key was entered into the tree. Therefore if C_N is the average number of comparisons involved in a successful search and C'_N is the average number in an unsuccessful search, we have

$$C_N = 1 + \frac{C'_0 + C'_1 + \cdots + C'_{N-1}}{N}. \tag{2}$$

But the relation between internal and external path length tells us that

$$C_N = \left(1 + \frac{1}{N}\right) C'_N - 1; \tag{3}$$

this is Eq. 6.2.1–2. Putting this together with (2) yields

$$(N+1)C'_N = 2N + C'_0 + C'_1 + \cdots + C'_{N-1}. \tag{4}$$

This recurrence is easy to solve. Subtracting the equation

$$NC'_{N-1} = 2(N-1) + C'_0 + C'_1 + \cdots + C'_{N-2},$$

we obtain

$$(N+1)C'_N - NC'_{N-1} = 2 + C'_{N-1},$$

$$C'_N = C'_{N-1} + 2/(N+1).$$

Since $C'_0 = 0$, this means that

$$C'_N = 2H_{N+1} - 2. \tag{5}$$

Applying (3) and simplifying yields the desired result

$$C_N = 2\left(1 + \frac{1}{N}\right) H_N - 3. \tag{6}$$

Exercises 6–8 below give more detailed information; it is possible to compute the exact probability distribution of C_N and C'_N, not merely the average values.

Tree insertion sorting. Algorithm T was developed for searching, but it can also be used as the basis of an internal *sorting* algorithm; in fact, we can view it as a natural generalization of list insertion, Algorithm 5.2.1L. When properly programmed, its average running time will be only a little slower than some of the best algorithms we discussed in Chapter 5. After the tree has been constructed for all keys, a symmetric tree traversal (Algorithm 2.3.1T) will visit the records in sorted order.

A few precautions are necessary, however. Note that something different needs to be done if $K = \texttt{KEY(P)}$ in step T2, since we are sorting instead of searching. One solution is to treat $K = \texttt{KEY(P)}$ exactly as if $K > \texttt{KEY(P)}$; this leads to a stable sorting method. (Note, however, that equal keys will not necessarily be adjacent in the tree, they will only be adjacent in symmetric order.) If many duplicate keys are present, this method will cause the tree to get badly unbalanced, and the sorting will slow down. Another idea is to keep a list, for each node, of all records having the same key; this requires another link field, but it will make the sorting faster when a lot of equal keys occur.

Thus if we are interested only in sorting, not in searching, Algorithm L isn't bad; but there are better ways to sort. On the other hand, if we have an application that combines searching and sorting, the tree method can be warmly recommended.

It is interesting to note that there is a strong relation between the analysis of tree insertion sorting and the analysis of partition exchange ("quicksort"), although the methods are superficially dissimilar. If we successively insert N keys into an initially empty tree, we make the same average number of comparisons between keys as Algorithm 5.2.2Q does, with minor exceptions. For example, in tree insertion every key gets compared with K_1, and then every key less than K_1 gets compared with the first key less than K_1, etc.; in quicksort, every key gets compared to the first partitioning element K, and then every key less than K gets compared to a particular element less than K, etc. The average number of comparisons made in both cases is NC_N. (However, Algorithm 5.2.2Q actually makes a few more comparisons, in order to speed up the inner loop.)

Deletions. Sometimes we want to make the computer forget one of the table entries it knows. It is easy to delete a "leaf" node (one in which both subtrees are empty), or to delete a node in which either LLINK or RLINK $= \Lambda$; but when both LLINK and RLINK are non-null pointers, we have to do something special, since we can't point two ways at once.

For example, consider Fig. 10 again; how can we delete CAPRICORN? One solution is to delete the *next* node, which always has a null LLINK, then reinsert it in place of the node we really wanted to delete. For example, in Fig. 10 we could delete GEMINI, then replace CAPRICORN by GEMINI. This operation preserves the essential left-to-right order of the table entries. The following algorithm gives a detailed description of one general way to do this.

Algorithm D (*Tree deletion*). Let Q be a variable which points to a node of a binary search tree represented as in Algorithm T. This algorithm deletes that node, leaving a binary search tree. (In practice, we will have either Q ≡ ROOT or Q ≡ LLINK(P) or RLINK(P) in some node of the tree. This algorithm resets the value of Q in memory, to reflect the deletion.)

D1. [Is RLINK null?] Set T ← Q. If RLINK(T) = Λ, set Q ← LLINK(T) and go to D4.

D2. [Find successor.] Set R ← RLINK(T). If LLINK(R) = Λ, set LLINK(R) ← LLINK(T), Q ← R, and go to D4.

D3. [Find null LLINK.] Set S ← LLINK(R). Then if LLINK(S) ≠ Λ, set R ← S and repeat this step until LLINK(S) = Λ. (At this point S will be equal to Q$, the symmetric successor of Q.) Finally, set LLINK(S) ← LLINK(T), LLINK(R) ← RLINK(S), RLINK(S) ← RLINK(T), Q ← S.

D4. [Free the node.] Set AVAIL ⇐ T (i.e., return the deleted node to the free storage pool). ▮

The reader may wish to try this algorithm by deleting AQUARIUS, CANCER, and CAPRICORN from Fig. 10; each case is slightly different. An alert reader may have noticed that no special test has been made for the case RLINK(T) ≠ Λ, LLINK(T) = Λ; we will defer the discussion of this case until later, since the algorithm as it stands has some very interesting properties.

Since Algorithm D is quite unsymmetrical between left and right, it stands to reason that a long sequence of random deletions and insertions will make the tree get way out of balance, so that the efficiency estimates we have made will be invalid. But actually the trees do not degenerate at all!

Theorem H (T. N. Hibbard, 1962). *After a random element is deleted from a random tree by Algorithm D, the resulting tree is still random.*

[Nonmathematical readers, please skip to (10).] This statement of the theorem is, of course, very vague. We can summarize the situation more precisely as follows: Let $\mathfrak{I}$ be a tree of n elements, and let $P(\mathfrak{I})$ be the probability that $\mathfrak{I}$ occurs if its keys are inserted in random order by Algorithm T. Some trees are more probable than others. Let $Q(\mathfrak{I})$ be the probability that $\mathfrak{I}$ will occur if $n + 1$ elements are inserted in random order by Algorithm T and then one of these elements is chosen at random and deleted by Algorithm D. In calculating $P(\mathfrak{I})$, we assume that the $n!$ permutations of the keys are equally likely; in calculating $Q(\mathfrak{I})$, we assume that the $(n + 1) \cdot (n + 1)!$ permutations of keys and selections of the key to delete are equally likely. The theorem states that $P(\mathfrak{I}) = Q(\mathfrak{I})$ for all $\mathfrak{I}$.

Proof. We are faced with the fact that permutations are equally probable, not trees, and therefore we shall prove the result by considering *permutations* as the random objects. We shall define a deletion from a permutation, and then we will prove that "a random element deleted from a random permutation leaves a random permutation."

Let $a_1a_2 \ldots a_{n+1}$ be a permutation of $\{1, 2, \ldots, n+1\}$; we want to define the operation of deleting a_i, so as to obtain a permutation $b_1b_2 \ldots b_n$ of $\{1, 2, \ldots, n\}$. This operation should correspond to Algorithms T and D, so that if we start with the tree constructed from the sequence of insertions $a_1, a_2, \ldots, a_{n+1}$ and delete a_i, renumbering the keys from 1 to n, we obtain the tree constructed from $b_1b_2 \ldots b_n$.

Fortunately it is not hard to define such a deletion operation. There are two cases:

Case 1: $a_i = n + 1$, or $a_i + 1 = a_j$ for some $j < i$. (This is essentially the condition "RLINK(a_i) = Λ.") Remove a_i from the sequence, and subtract unity from each element greater than a_i.

Case 2: $a_i + 1 = a_j$ for some $j > i$. Replace a_i by a_j, remove a_j from its original place, and subtract unity from each element greater than a_i.

For example, suppose we have the permutation 4 6 1 3 5 2. If we circle the element which is to be deleted, we have

$$\textcircled{4}6\ 1\ 3\ 5\ 2 = 4\ 5\ 1\ 3\ 2 \qquad 4\ 6\ 1\ \textcircled{3}\ 5\ 2 = 3\ 5\ 1\ 4\ 2$$
$$4\ \textcircled{6}\ 1\ 3\ 5\ 2 = 4\ 1\ 3\ 5\ 2 \qquad 4\ 6\ 1\ 3\ \textcircled{5}\ 2 = 4\ 5\ 1\ 3\ 2$$
$$4\ 6\ \textcircled{1}\ 3\ 5\ 2 = 3\ 5\ 1\ 2\ 4 \qquad 4\ 6\ 1\ 3\ 5\ \textcircled{2} = 3\ 5\ 1\ 2\ 4$$

Since there are $(n + 1) \cdot (n + 1)!$ possible deletion operations, the theorem will be established if we can show that every permutation of $\{1, 2, \ldots, n\}$ is the result of exactly $(n + 1)^2$ deletions.

Let $b_1b_2 \ldots b_n$ be a permutation of $\{1, 2, \ldots, n\}$. We shall define $(n + 1)^2$ deletions, one for each pair i, j with $1 \leq i, j \leq n + 1$, as follows:

If $i < j$, the deletion is

$$b'_1 \ldots b'_{i-1}\,\textcircled{b_i}\,b'_{i+1} \ldots b'_{j-1}(b_i + 1)b'_j \ldots b'_n. \tag{7}$$

Here, as below, b'_k stands for either b_k or $b_k + 1$, depending on whether or not b_k is less than the circled element. This deletion corresponds to Case 2.

If $i > j$, the deletion is

$$b'_1 \ldots b'_{i-1}\,\textcircled{b_j}\,b'_i \ldots b'_n; \tag{8}$$

this deletion fits the definition of Case 1.

Finally, if $i = j$, we have another Case 1 deletion, namely

$$b'_1 \ldots b'_{i-1}\,\textcircled{$n+1$}\,b'_i \ldots b'_n. \tag{9}$$

As an example, let $n = 4$ and consider the 25 deletions which map into 3 1 4 2:

	$i=1$	$i=2$	$i=3$	$i=4$	$i=5$
$j=1$	⑤3 1 4 2	4③1 5 2	4 1③5 2	4 1 5③2	4 1 5 2③
$j=2$	③4 1 5 2	3⑤1 4 2	4 2①5 3	4 2 5①3	4 2 5 3①
$j=3$	③1 4 5 2	4①2 5 3	3 1⑤4 2	3 1 5④2	3 1 5 2④
$j=4$	③1 5 4 2	4①5 2 3	3 1④5 2	3 1 4⑤2	4 1 5 3②
$j=5$	③1 5 2 4	4①5 3 2	3 1④2 5	4 1 5②3	3 1 4 2⑤

The circled element is always in position i, and for fixed i we have clearly constructed $n+1$ different deletions; hence $(n+1)^2$ different deletions have been constructed for each permutation $b_1 b_2 \ldots b_n$. Since only $(n+1)^2 n!$ deletions are possible, we must have found all of them. ∎

The proof of Theorem H not only tells us about the result of deletions, it also helps us analyze the running time in an average deletion. Exercise 12 shows that we can expect to execute step D2 slightly less than half the time, on the average, when deleting a random element from a random table.

Let us now consider how often the loop in step D3 needs to be performed: Suppose that we are deleting a node on level l, and that the *external* node immediately following in symmetric order is on level k. For example, if we are deleting CAPRICORN from Fig. 10, we have $l=0$ and $k=3$ since node $\boxed{4}$ is on level 3. If $k=l+1$, we have RLINK(T) $=\Lambda$ in step D1; and if $k>l+1$, we will set S $\leftarrow$ LLINK(R) exactly $k-l-2$ times in step D3. The average value of l is (internal path length)$/N$; the average value of k is (external path length $-$ distance to leftmost external node)$/N$. The distance to the leftmost external node is the number of left-to-right minima in the insertion sequence, so it has the average value H_N by the analysis of Section 1.2.10. Since external path length minus internal path length is $2N$, the average value of $k-l-2$ is $-H_N/N$. Adding to this the average number of times that $k-l-2$ is -1, we see that *the operation* S $\leftarrow$ LLINK(R) *in step D3 is performed only*

$$\frac{1}{2}+\frac{\frac{1}{2}-H_N}{N} \tag{10}$$

times, on the average, in a random deletion. This is reassuring, since the worst case can be pretty slow (see exercise 11).

As mentioned above, Algorithm D does not test for the case LLINK(T) $=\Lambda$, although this is one of the easy cases for deletion. We could add a new step between D1 and D2, namely,

D1½. [Is LLINK null?] If LLINK(T) $=\Lambda$, set Q $\leftarrow$ RLINK(T) and go to D4.

Exercise 14 shows that Algorithm D with this extra step always leaves a tree

that is at least as good as the original Algorithm D, in the path-length sense, and sometimes the result is even better. Thus, a sequence of insertions and deletions using this modification of Algorithm D will result in trees which are actually *better* than the theory of random trees would predict: the average computation time for search and insertion will tend to decrease as time goes on.

Frequency of access. So far we have assumed that each key was equally likely as a search argument. In a more general situation, let p_k be the probability that we will search for the kth element inserted, where $p_1 + \cdots + p_N = 1$. Then a straightforward modification of Eq. (2), if we retain the assumption of random order so that the shape of the tree stays random, shows that the average number of comparisons in a successful search will be

$$1 + \sum_{1\le k\le N} p_k(2H_k - 2) = 2 \sum_{1\le k\le N} p_k H_k - 1. \tag{11}$$

(Cf. Eq. (5).)

For example, if the probabilities obey Zipf's law, Eq. 6.1–8, the average number of comparisons reduces to

$$H_N - 1 + H_N^{(2)}/H_N \tag{12}$$

if we insert the keys in decreasing order of importance. (See exercise 18.) This is about half as many comparisons as predicted by the equal-frequency analysis, and it is less comparisons than we would make using binary search.

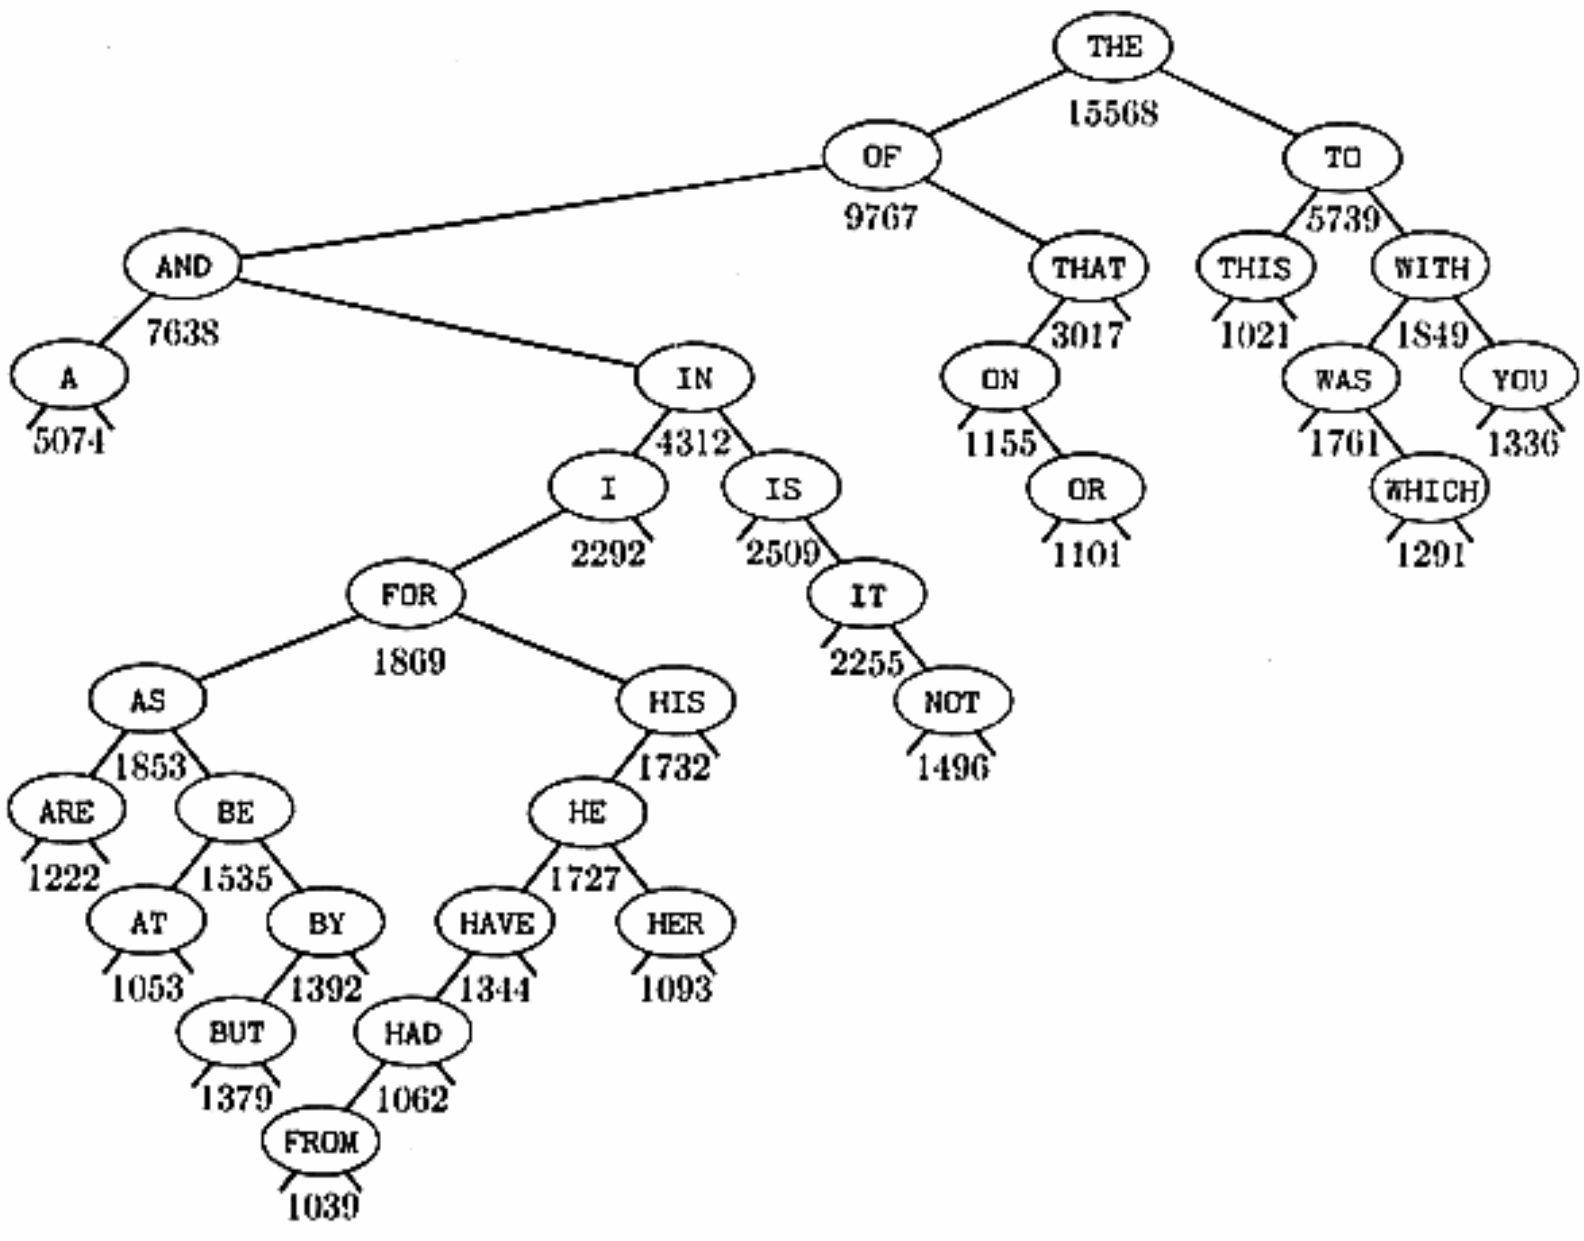

Fig. 12. The 31 most common English words, inserted in decreasing order of frequency.

For example, Fig. 12 shows the tree which results when the most common 31 words of English are entered in decreasing order of frequency. The relative frequency is shown with each word [cf. *Cryptanalysis* by H. F. Gaines (New York: Dover, 1956), p. 226]. The average number of comparisons for a successful search in this tree is 4.042; the corresponding binary search, using Algorithm 6.2.1B or C, would require 4.393 comparisons.

Optimum binary search trees. These considerations make it natural to ask about the best possible tree for searching a table of keys with given frequencies. For example, the optimum tree for the 31 most common English words is shown in Fig. 13; it requires only 3.437 comparisons for an average successful search.

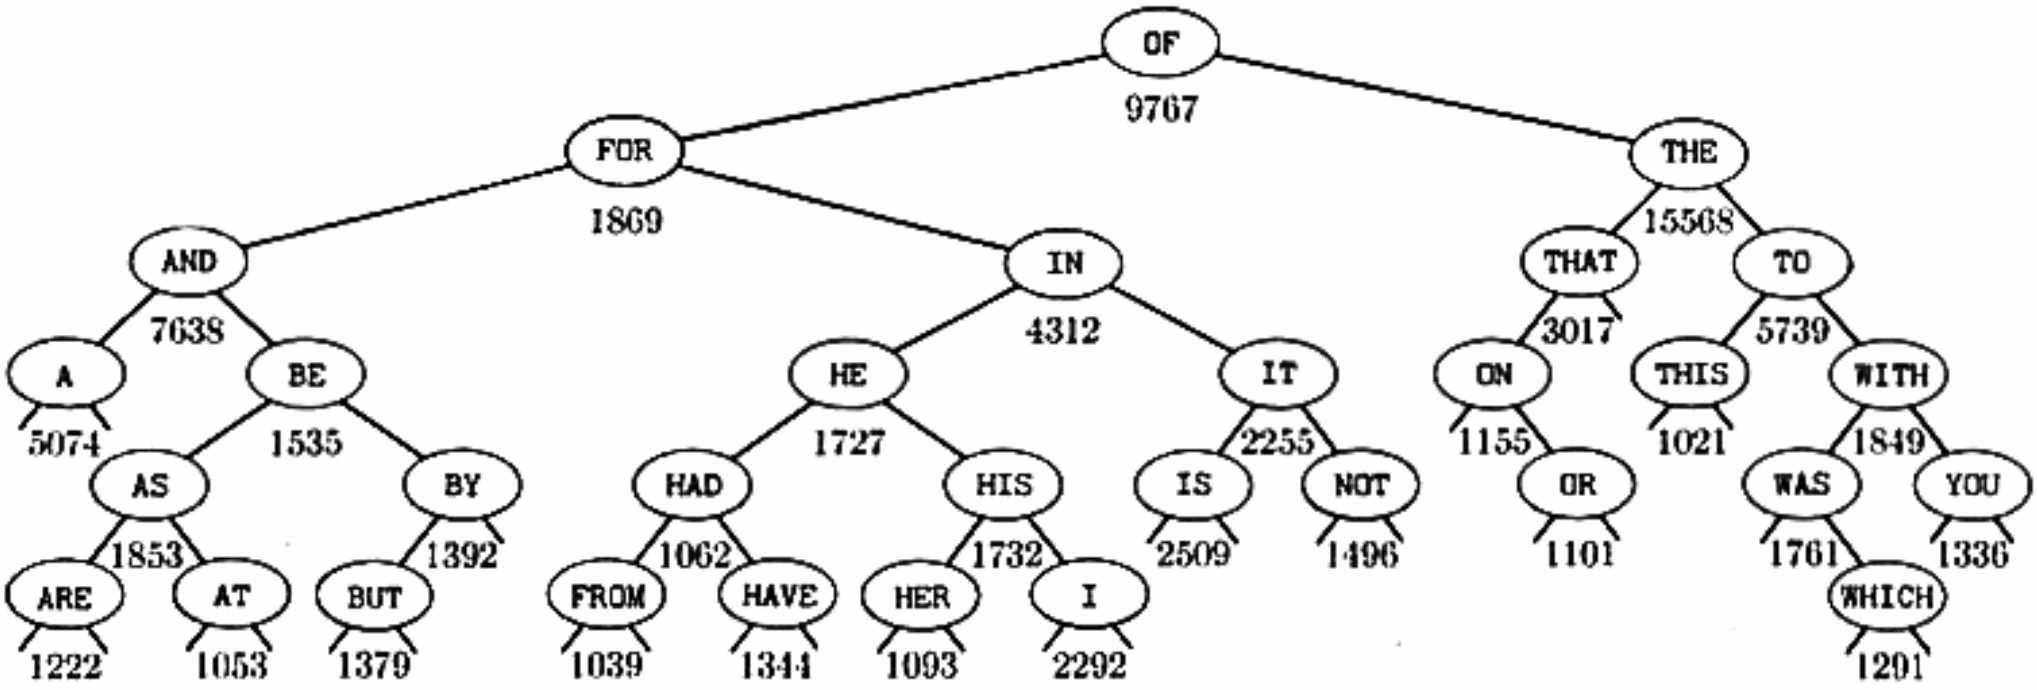

Fig. 13. Optimum search tree for the 31 most common English words.

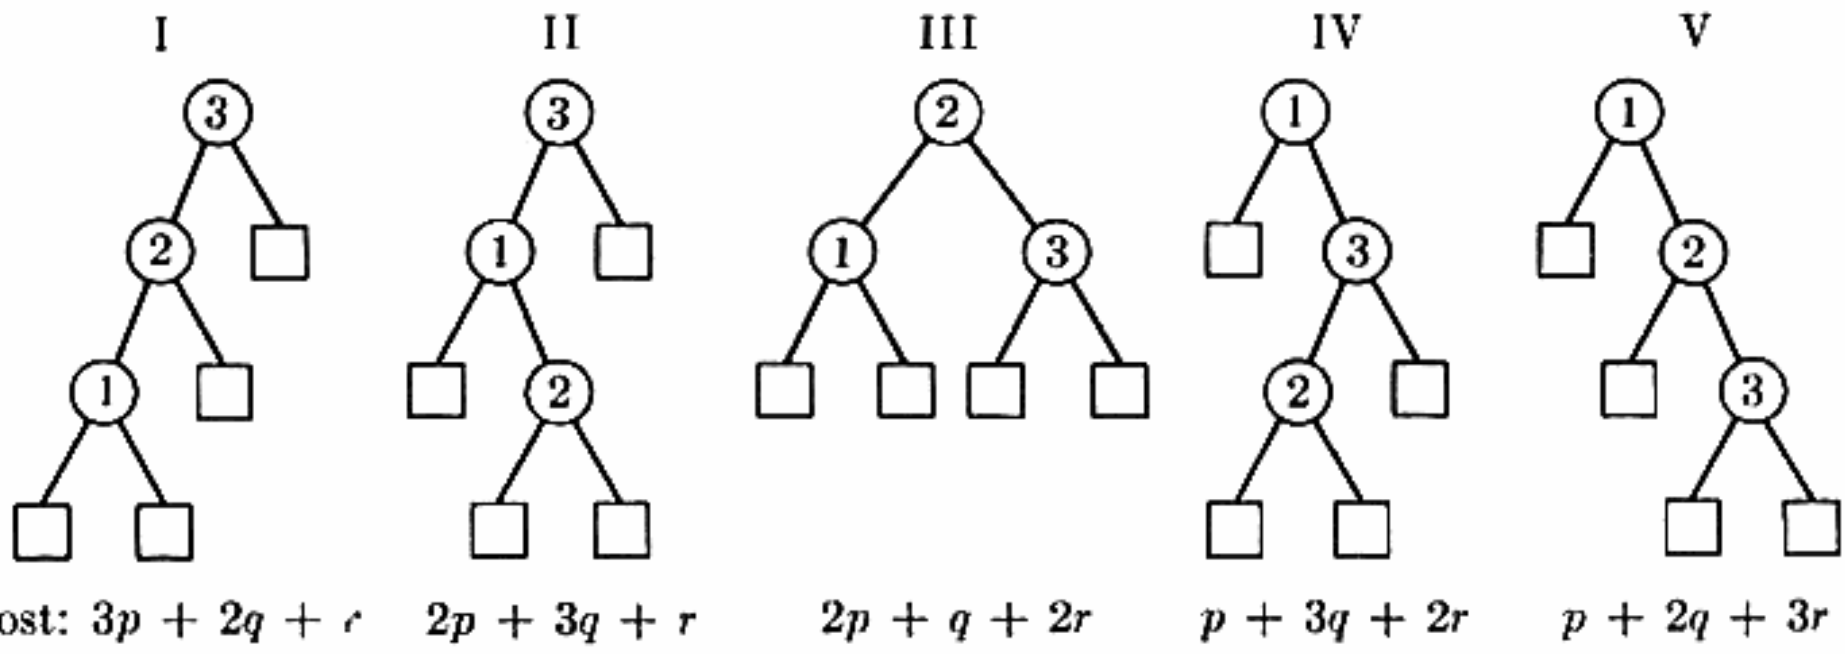
Let us now explore the problem of finding the optimum tree. When $N = 3$, for example, let us assume that the keys $K_1 < K_2 < K_3$ have respective probabilities p, q, r. There are five possible trees:



(13)

Figure 14 shows the ranges of p, q, r for which each tree is optimum; the balanced tree is best about 45 percent of the time, if we choose p, q, r at random (see exercise 21).

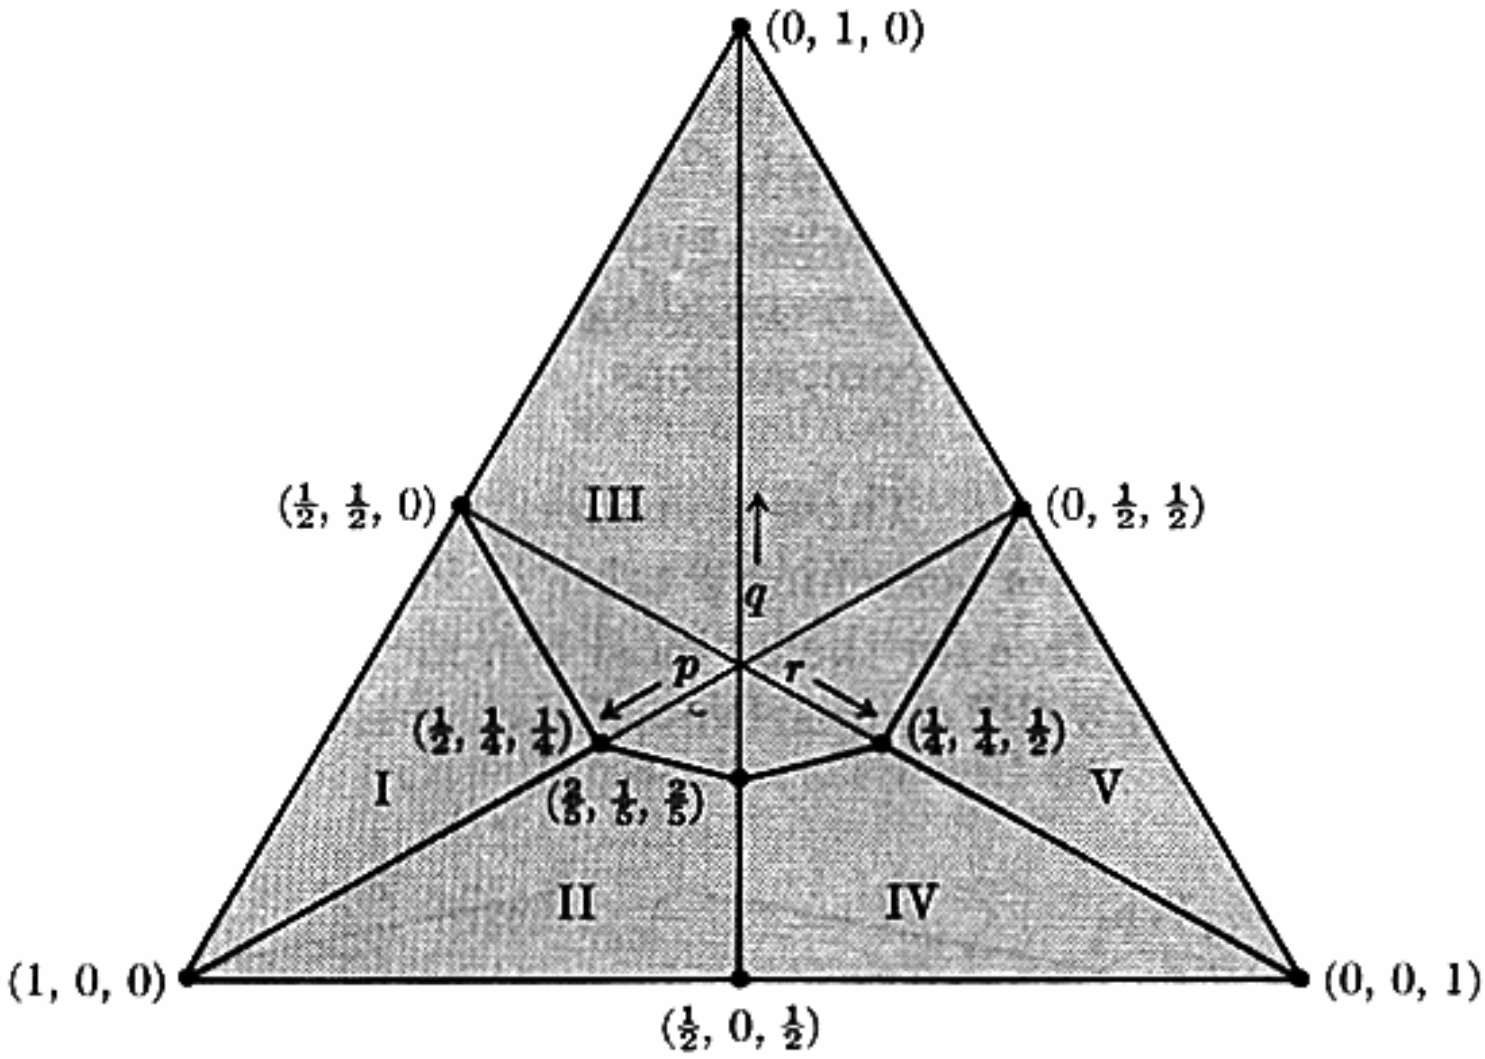


Fig. 14. If the relative frequencies of (K_1, K_2, K_3) are (p, q, r), this graph shows which of the five trees in (13) is best. The fact that $p + q + r = 1$ makes the graph two-dimensional although there are three coordinates.

Unfortunately, when N is large there are

$$\binom{2N}{N} \Big/ (N+1) \approx 4^N/(\sqrt{\pi}\, N^{3/2})$$

binary trees, so we can't just try them all and see which is best. Let us therefore study the properties of optimum binary search trees more closely, in order to discover a better way to find them.

So far we have considered only the probabilities for a successful search; in practice, the unsuccessful case must usually be considered as well. For example, the 31 words in Fig. 13 account for only about 36 percent of typical English text; the other 64 percent will certainly influence the structure of the optimum search tree.

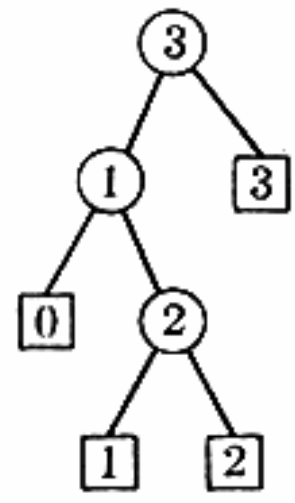
Therefore let us set the problem up in the following way: We are given $2n + 1$ probabilities $p_1, p_2, \ldots, p_n$ and $q_0, q_1, \ldots, q_n$, where

p_i = probability that K_i is the search argument;
q_i = probability that the search argument lies between K_i and K_{i+1}.

(By convention, q_0 is the probability that the search argument is less than K_1, and q_n is the probability that the search argument is greater than K_n.) Thus, $p_1 + p_2 + \cdots + p_n + q_0 + q_1 + \cdots + q_n = 1$, and we want to find a binary tree which minimizes the expected number of comparisons in the search, namely

$$\sum_{1 \le j \le n} p_j(\text{level}(\textcircled{j}) + 1) + \sum_{0 \le k \le n} q_k \,\text{level}(\boxed{k}), \tag{14}$$

where (j) is the jth internal node in symmetric order and [k] is the $(k+1)$st external node, and where the root has level zero. Thus the expected number of comparisons for the binary tree



(15)

is $2q_0 + 2p_1 + 3q_1 + 3p_2 + 3q_2 + p_3 + q_3$. Let us call this the *cost* of the tree; and let us say that a minimum-cost tree is *optimum*. In this definition there is no need to require that the p's and q's sum to unity, we can ask for a minimum-cost tree with any given sequence of "weights" $(p_1, \ldots, p_n; q_0, \ldots, q_n)$.

We have studied Huffman's procedure for constructing trees with minimum weighted path length, in Section 2.3.4.5; but that method requires all the p's to be zero, and the tree it produces will usually not have the external node weights $(q_0, \ldots, q_n)$ in the proper symmetric order from left to right. Therefore we need another approach.

The principle which saves us is that *all subtrees of an optimum tree are optimum.* For example if (15) is an optimum tree for the weights $(p_1, p_2, p_3; q_0, q_1, q_2, q_3)$, then the left subtree of the root must be optimum for $(p_1, p_2; q_0, q_1, q_2)$; any improvement to a subtree leads to an improvement in the whole tree.

This principle suggests a computation procedure which systematically finds larger and larger optimum subtrees. We have used much the same idea in Section 5.4.9 to construct optimum merge patterns; the general approach is known as "dynamic programming," and we shall consider it further in Chapter 7.

Let $c(i, j)$ be the cost of an optimum subtree with weights $(p_{i+1}, \ldots, p_j; q_i, \ldots, q_j)$; and let $w(i, j) = p_{i+1} + \cdots + p_j + q_i + \cdots + q_j$ be the sum of all those weights; $c(i, j)$ and $w(i, j)$ are defined for $0 \le i \le j \le n$. It follows that

$$\begin{aligned} c(i, i) &= 0, \\ c(i, j) &= w(i, j) + \min_{i \le k < j} \big(c(i, k-1) + c(k, j)\big), \qquad \text{for} \quad i < j, \end{aligned} \tag{16}$$

since the minimum possible cost of a tree with root (k) is $w(i, j) + c(i, k-1) + c(k, j)$. When $i < j$, let $R(i, j)$ be the set of all k for which the minimum is achieved in (16); this set specifies the possible roots of the optimum trees.

Equation (16) makes it possible to evaluate $c(i, j)$ for $j - i = 1, 2, 3, \ldots, n$; there are about $\frac{1}{2}n^2$ such values, and the minimization operation is carried out for about $\frac{1}{6}n^3$ values of k. This means we can determine an optimum tree in $O(n^3)$ units of time, using $O(n^2)$ cells of memory.

A factor of n can actually be removed from the running time if we make use of a "monotonicity" property. Let $r(i, j)$ denote an element of $R(i, j)$; we need not compute the entire set $R(i, j)$, a single representative is sufficient. Once we have found $r(i, j-1)$ and $r(i+1, j)$, the result of exercise 27 proves that we may always assume that

$$r(i, j-1) \le r(i, j) \le r(i+1, j) \tag{17}$$

when the weights are nonnegative. This limits the search for the minimum, since only $r(i+1, j) - r(i, j-1) + 1$ values of k need to be examined in (16) instead of $j - i$. The total amount of work when $j - i = d$ is now bounded by the telescoping series

$$\sum_{\substack{d \le j \le n \\ i = j-d}} (r(i+1, j) - r(i, j-1) + 1)$$
$$= r(n-d+1, n) - r(0, d-1) + n - d + 1 < 2n,$$

hence the total running time is reduced to $O(n^2)$.

The following algorithm describes this procedure in detail.

Algorithm K (*Find optimum binary search trees*). Given $2n + 1$ nonnegative weights $(p_1, \ldots, p_n; q_0, \ldots, q_n)$, this algorithm constructs binary trees $t(i, j)$ which have minimum cost for the weights $(p_{i+1}, \ldots, p_j; q_i, \ldots, q_j)$ in the sense defined above. Three arrays are computed, namely

$c[i, j]$,	for	$0 \le i \le j \le n$,	the cost of $t(i, j)$;
$r[i, j]$,	for	$0 \le i \le j \le n$,	the root of $t(i, j)$;
$w[i, j]$,	for	$0 \le i \le j \le n$,	the total weight of $t(i, j)$.

The results of the algorithm are specified by the r array: If $i = j$, $t(i, j)$ is null; else its left subtree is $t(i, r[i, j] - 1)$ and its right subtree is $t(r[i, j], j)$.

K1. [Initialize.] For $0 \le i \le n$, set $c[i, i] \leftarrow 0$ and $w[i, i] \leftarrow q_i$ and $w[i, j] \leftarrow w[i, j-1] + p_j + q_j$ for $j = i+1, \ldots, n$. Then for $1 \le j \le n$ set $c[j-1, j] \leftarrow w[j-1, j]$ and $r[j-1, j] \leftarrow j$. (This determines all the 1-node optimum trees.)

K2. [Loop on d.] Do step K3 for $d = 2, 3, \ldots, n$, then terminate the algorithm.

K3. [Loop on j.] (We have already determined the optimum trees of less than d nodes. This step determines all the d-node optimum trees.) Do step K4 for $j = d, d+1, \ldots, n$.

K4. [Find $c[i, j]$, $r[i, j]$.] Set $i \leftarrow j - d$. Then set

$$c[i, j] \leftarrow w[i, j] + \min_{r[i, j-1] \le k \le r[i+1, j]} (c[i, k-1] + c[k, j]),$$

and set $r[i, j]$ to a value of k for which the minimum occurs. (Exercise 22 proves that $r[i, j-1] \le r[i+1, j]$.) ∎

As an example of Algorithm K, consider Fig. 15, which is based on a "keyword-in-context" (KWIC) indexing application. The titles of all articles in the first ten volumes of the ACM *Journal* were sorted to prepare a concordance in which there is one line for every word of every title. However, certain words like "THE" and "EQUATION" were felt to be sufficiently uninformative that they were left out of the index. These special words and their frequency of occurrence are shown in the internal nodes of Fig. 15. Note that a title such as "On the solution of an equation for a certain new problem" would be so uninformative, it wouldn't appear in the index at all! The idea of KWIC indexing is due to H. P. Luhn, *Amer. Documentation* **11** (1960), 288–295. (See W. W. Youden, *JACM* **10** (1963), 583–646, where the full KWIC index appears.)

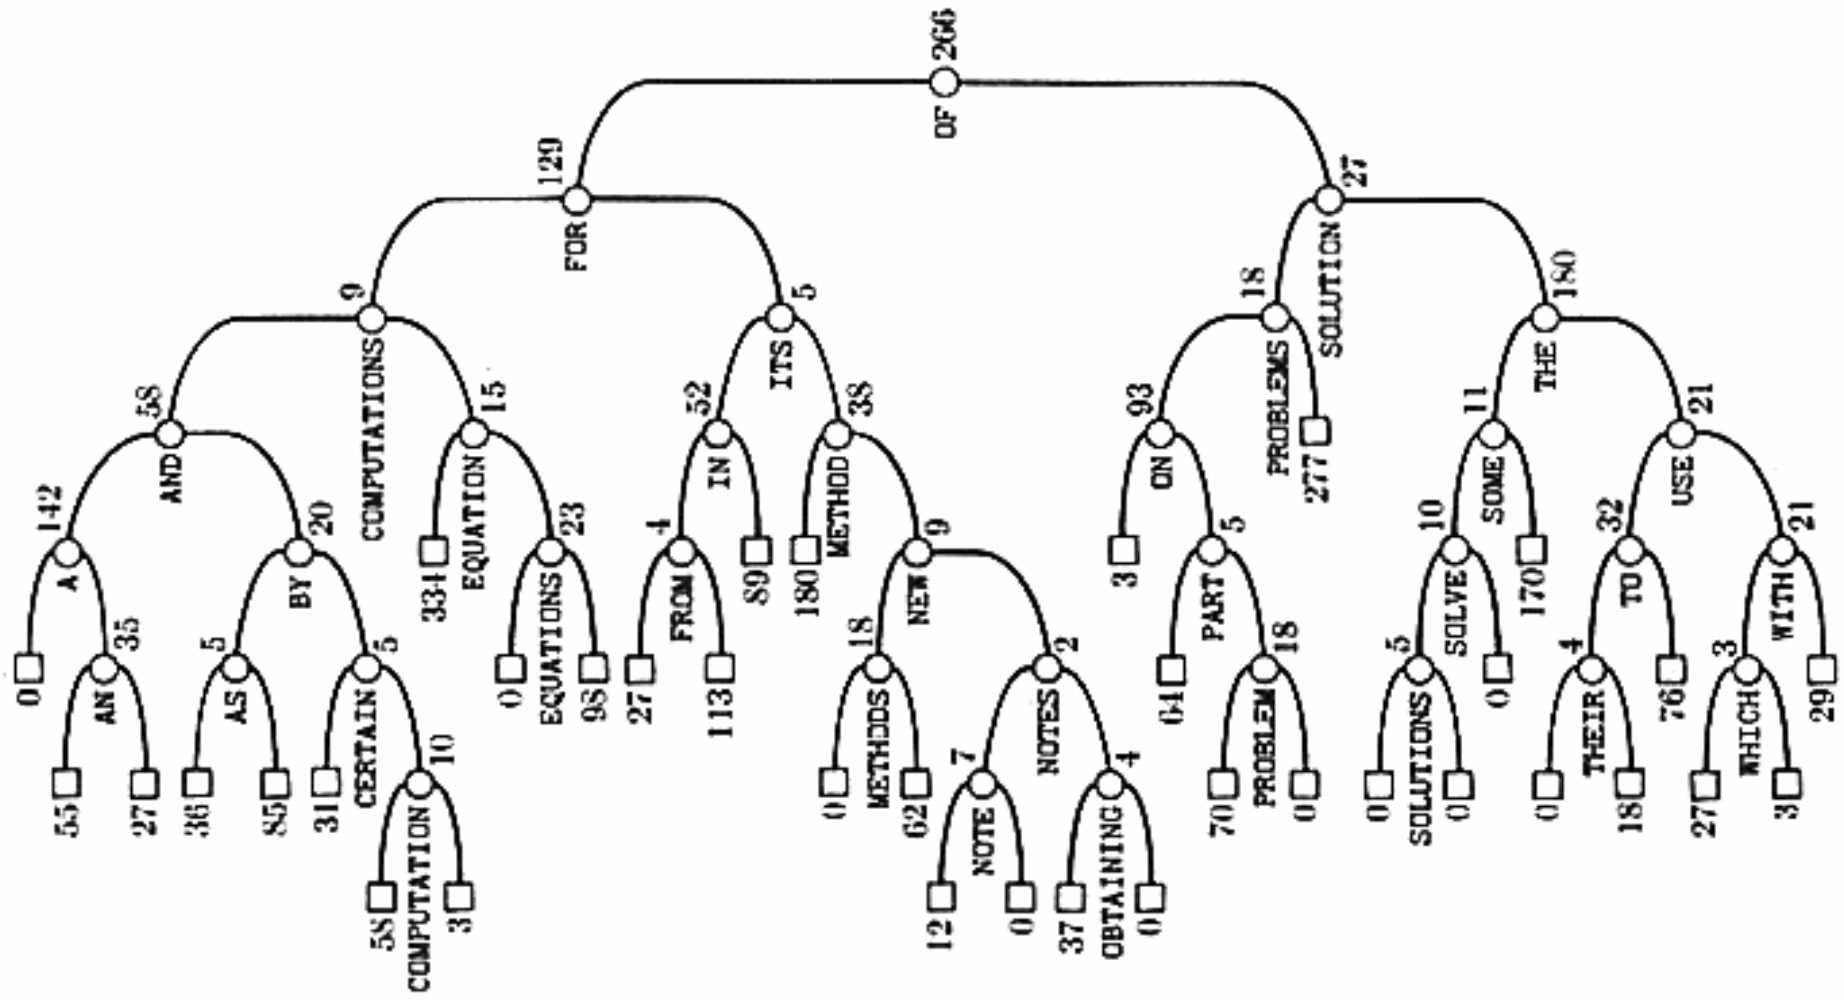


Fig. 15. An optimum binary search tree for a KWIC indexing application.

When preparing a KWIC index file for sorting, we might want to use a binary search tree in order to test whether or not each particular word is to be indexed. The other words fall between two of the unindexed words, with the frequencies shown in the external nodes of Fig. 15; thus, exactly 277 words which are alphabetically between "PROBLEMS" and "SOLUTION" appeared in the *JACM* titles during 1954–1963.

Figure 15 shows the optimum tree obtained by Algorithm K, with $n = 35$. The computed values of $r[0, j]$ for $j = 1, 2, \ldots, 35$ are (1, 1, 2, 3, 3, 3, 3, 8, 8, 8, 8, 8, 8, 11, 11, . . . , 11, 21, 21, 21, 21, 21, 21); the values of $r[i, 35]$ for $i = 0, 1, \ldots, 34$ are (21, 21, . . . , 21, 25, 25, 25, 25, 25, 25, 26, 26, 26, 30, 30, 30, 30, 30, 30, 30, 33, 33, 33, 35, 35).

The "betweenness frequencies" q_j have a noticeable effect on the optimum tree structure; Fig. 16(a) shows the optimum tree that would have been obtained with the q_j set to zero. Similarly, the internal frequencies p_i are important: Fig. 16(b) shows the optimum tree when the p_i are set to zero. Considering

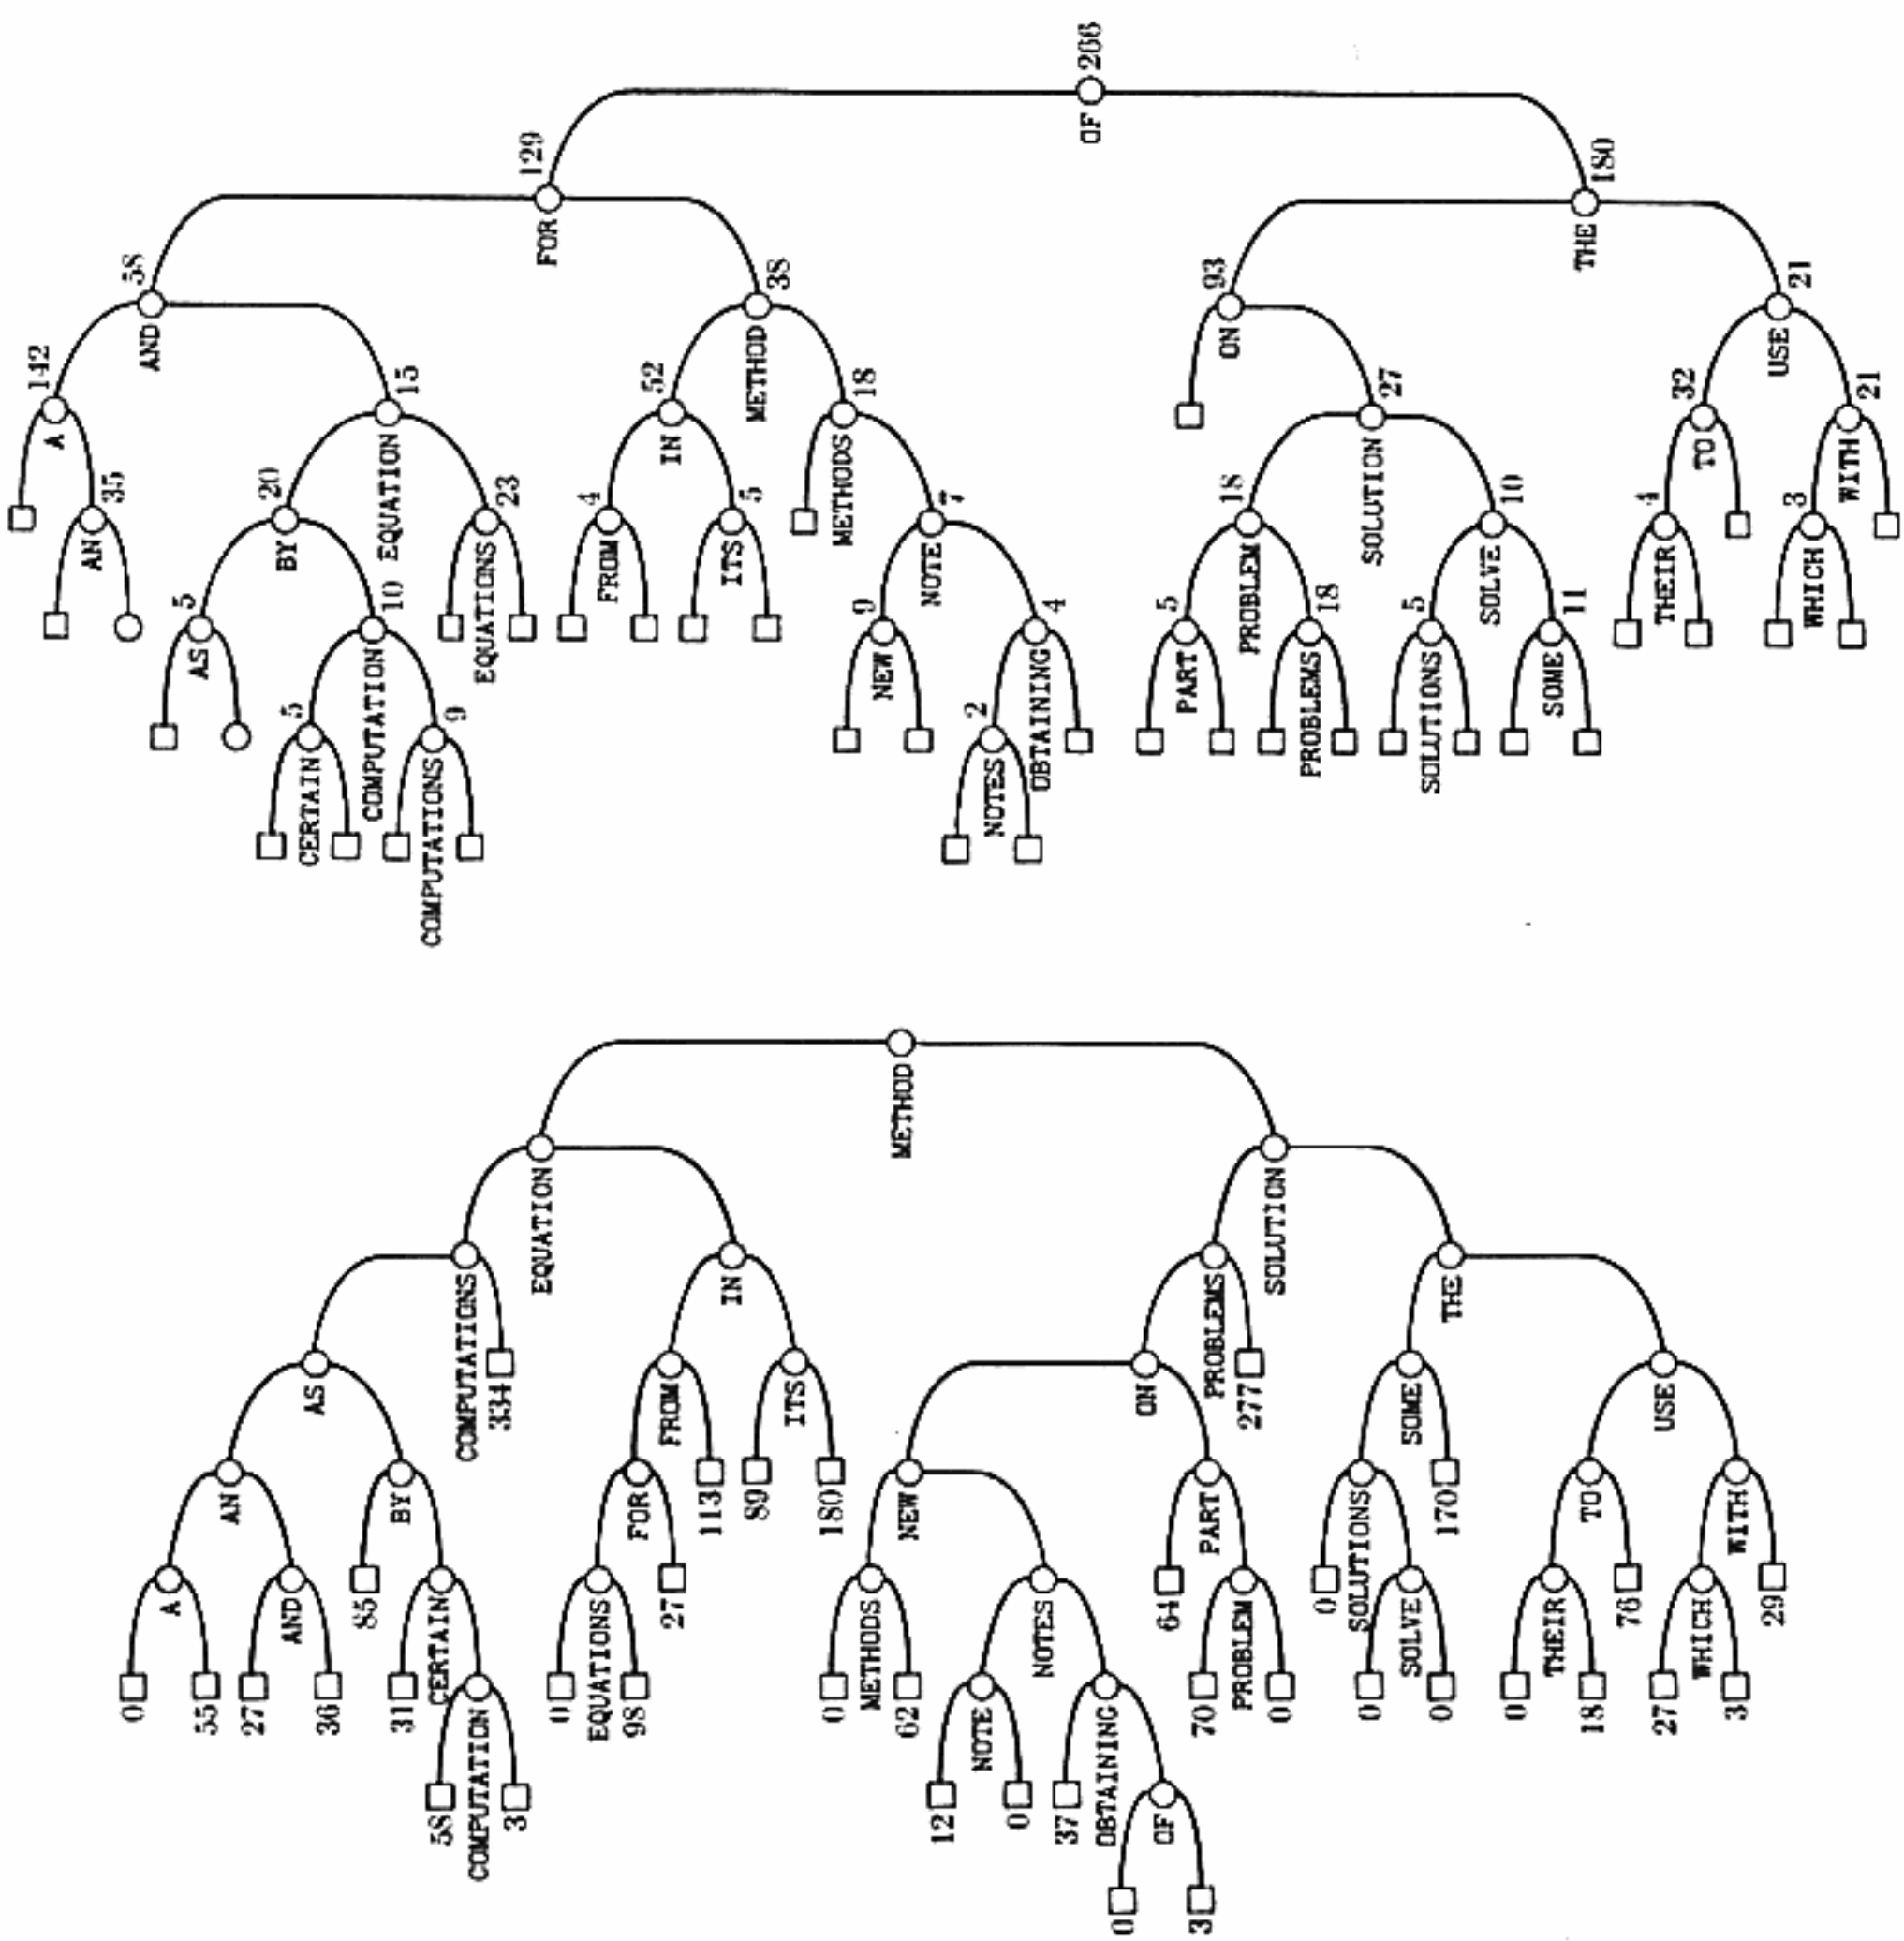

Fig. 16. Optimum binary search trees based on half of the data of Fig. 15; (a) external frequencies suppressed, (b) internal frequencies suppressed.

the full set of frequencies, the tree of Fig. 15 requires only 4.75 comparisons, on the average, while the trees of Fig. 16 require, respectively, 5.29 and 5.32. (A straight binary search would have been better than the trees of Fig. 16, in this example.)

Since Algorithm K requires time and space proportional to n^2, it becomes impractical to use it when n is very large. Of course we may not really want to use binary search trees for large n, in view of the other search techniques to be discussed later in this chapter; but let's assume anyway that we want to find an optimum or nearly optimum tree when n is large.

We have seen that the idea of inserting the keys in order of decreasing frequency can tend to make a fairly good tree, on the average; but it can also

be very bad (see exercise 20), and it is not usually very near the optimum, since it makes no use of the q_j weights. Another approach is to choose the root k so that the weights $w(0, k-1)$ and $w(k, n)$ of the resulting subtrees are as near to being equal as possible. This approach also fails, because it may choose a node with very small p_k to be the root.

A fairly satisfactory procedure can be obtained by combining these two methods, as suggested by W. A. Walker and C. C. Gotlieb [*Graph Theory and Computing* (Academic Press, 1972)]: Try to equalize the left-hand and right-hand weights, but be prepared to move the root a few steps to the left or right to find a node with relatively large p_k. Figure 17 shows why this method is reasonable: If we plot $c(0, k-1) + c(k, n)$ as a function of k, for the KWIC data of Fig. 15, we see that the result is quite sensitive to the magnitude of p_k.

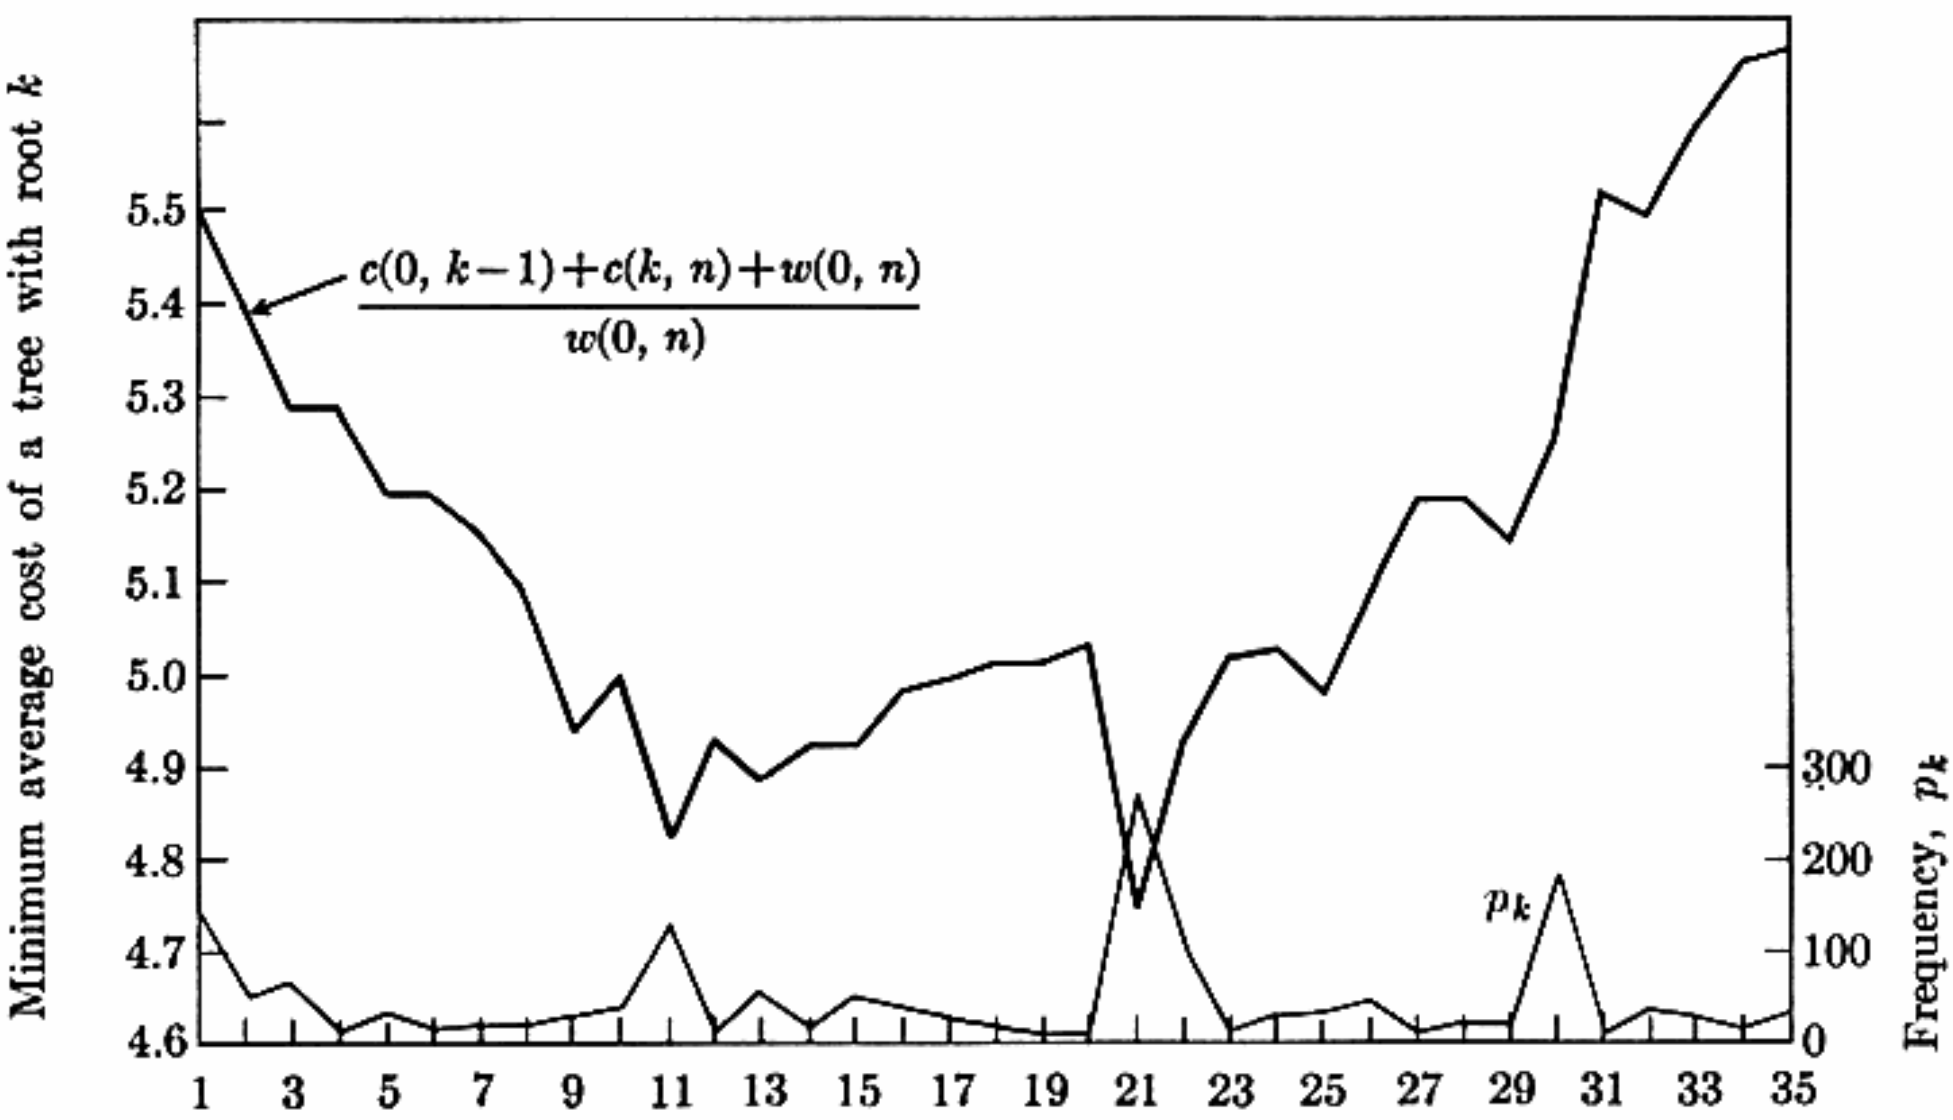

Fig. 17. Behavior of the cost as a function of the root, k.

A "top-down" method such as this can be used for large n to choose the root and then to work on the left and the right subtrees. When we get down to a sufficiently small subtree we can apply Algorithm K. The resulting method yields fairly good trees (reportedly within 2 or 3 percent of the optimum), and it requires only $O(n)$ units of space, $O(n \log n)$ units of time.

***The Hu-Tucker algorithm.** In the special case that all the p's are zero, T. C. Hu and A. C. Tucker have discovered a remarkable "bottom-up" way to construct optimum trees; if appropriate data structures are used, their method requires $O(n)$ units of space and $O(n \log n)$ units of time, and it constructs a tree which is *really* optimum (not just approximately so).

The Hu-Tucker algorithm can be described as follows.

• PHASE 1, Combination. Start with the "working sequence" of weights written inside of *external* nodes,

$$\boxed{q_0} \quad \boxed{q_1} \quad \boxed{q_2} \quad \cdots \quad \boxed{q_n} . \tag{18}$$

Then repeatedly combine two weights q_i and q_j for $i < j$ into a single weight $q_i + q_j$, deleting the node containing q_j from the working sequence and replacing the node containing q_i by the *internal* node

$$\textcircled{q_i + q_j} . \tag{19}$$

This combination is to be done on the unique pair of weights (q_i, q_j) satisfying the following rules:

i) No external nodes occur between q_i and q_j. (This is the most important rule which distinguishes the algorithm from Huffman's method.)

ii) The sum $q_i + q_j$ is minimum over all (q_i, q_j) satisfying rule (i).

iii) The index i is minimum over all (q_i, q_j) satisfying rules (i), (ii).

iv) The index j is minimum over all (q_i, q_j) satisfying rules (i), (ii), (iii).

• PHASE 2, Level assignment. When Phase 1 ends, there is a single node left in the working sequence. Mark it with level number 0. Then undo the steps of Phase 1 in reverse order, marking level numbers of the corresponding tree; if (19) has level l, the nodes containing q_i and q_j which formed it are marked with level $l + 1$.

• PHASE 3, Recombination. Now we have the working sequence of external nodes and levels

$$\underset{l_1}{\boxed{q_0}} \quad \underset{l_2}{\boxed{q_1}} \quad \underset{l_3}{\boxed{q_2}} \quad \cdots \quad \underset{l_n}{\boxed{q_n}} .$$

The internal nodes used in Phases 1 and 2 are now discarded, we shall create new ones by combining weights (q_i, q_j) according to the following new rules:

i′) The nodes containing q_i and q_j must be adjacent in the working sequence.

ii′) The levels l_i and l_j must both be the maximum among all remaining levels.

iii′) The index i must be minimum over all (q_i, q_j) satisfying (i′), (ii′).

The new node (19) is assigned level $l_i - 1$. The binary tree formed during this phase has minimum weighted path length over all binary trees whose external nodes are weighted $q_0, q_1, \ldots, q_n$ from left to right.

Figure 18 shows an example of this algorithm; the weights q_i are the relative frequencies of the letters ␣, A, B, . . . , Z in English text. During Phase 1, the

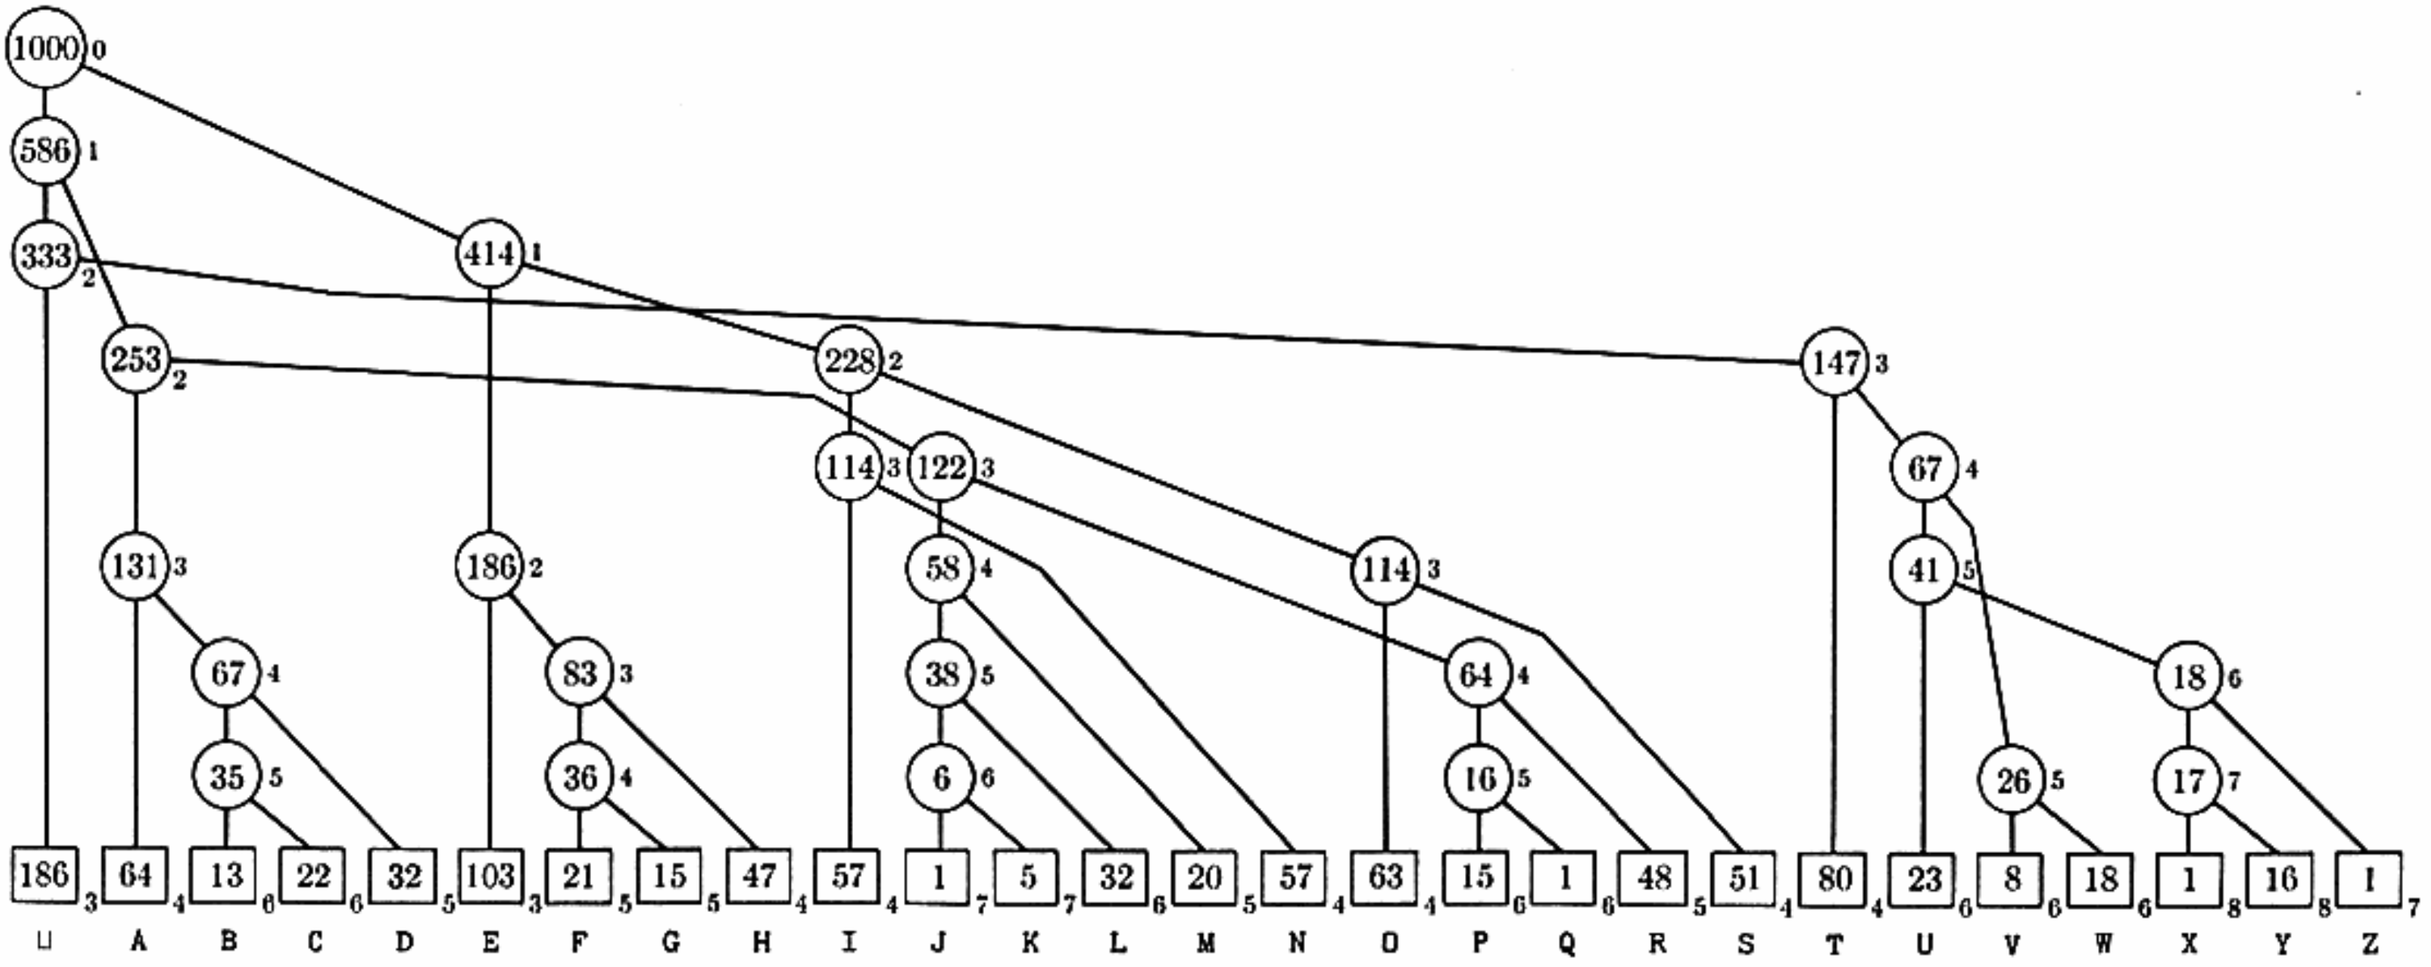

Fig. 18. The Hu-Tucker algorithm applied to alphabetic frequency data: Phases 1 and 2.

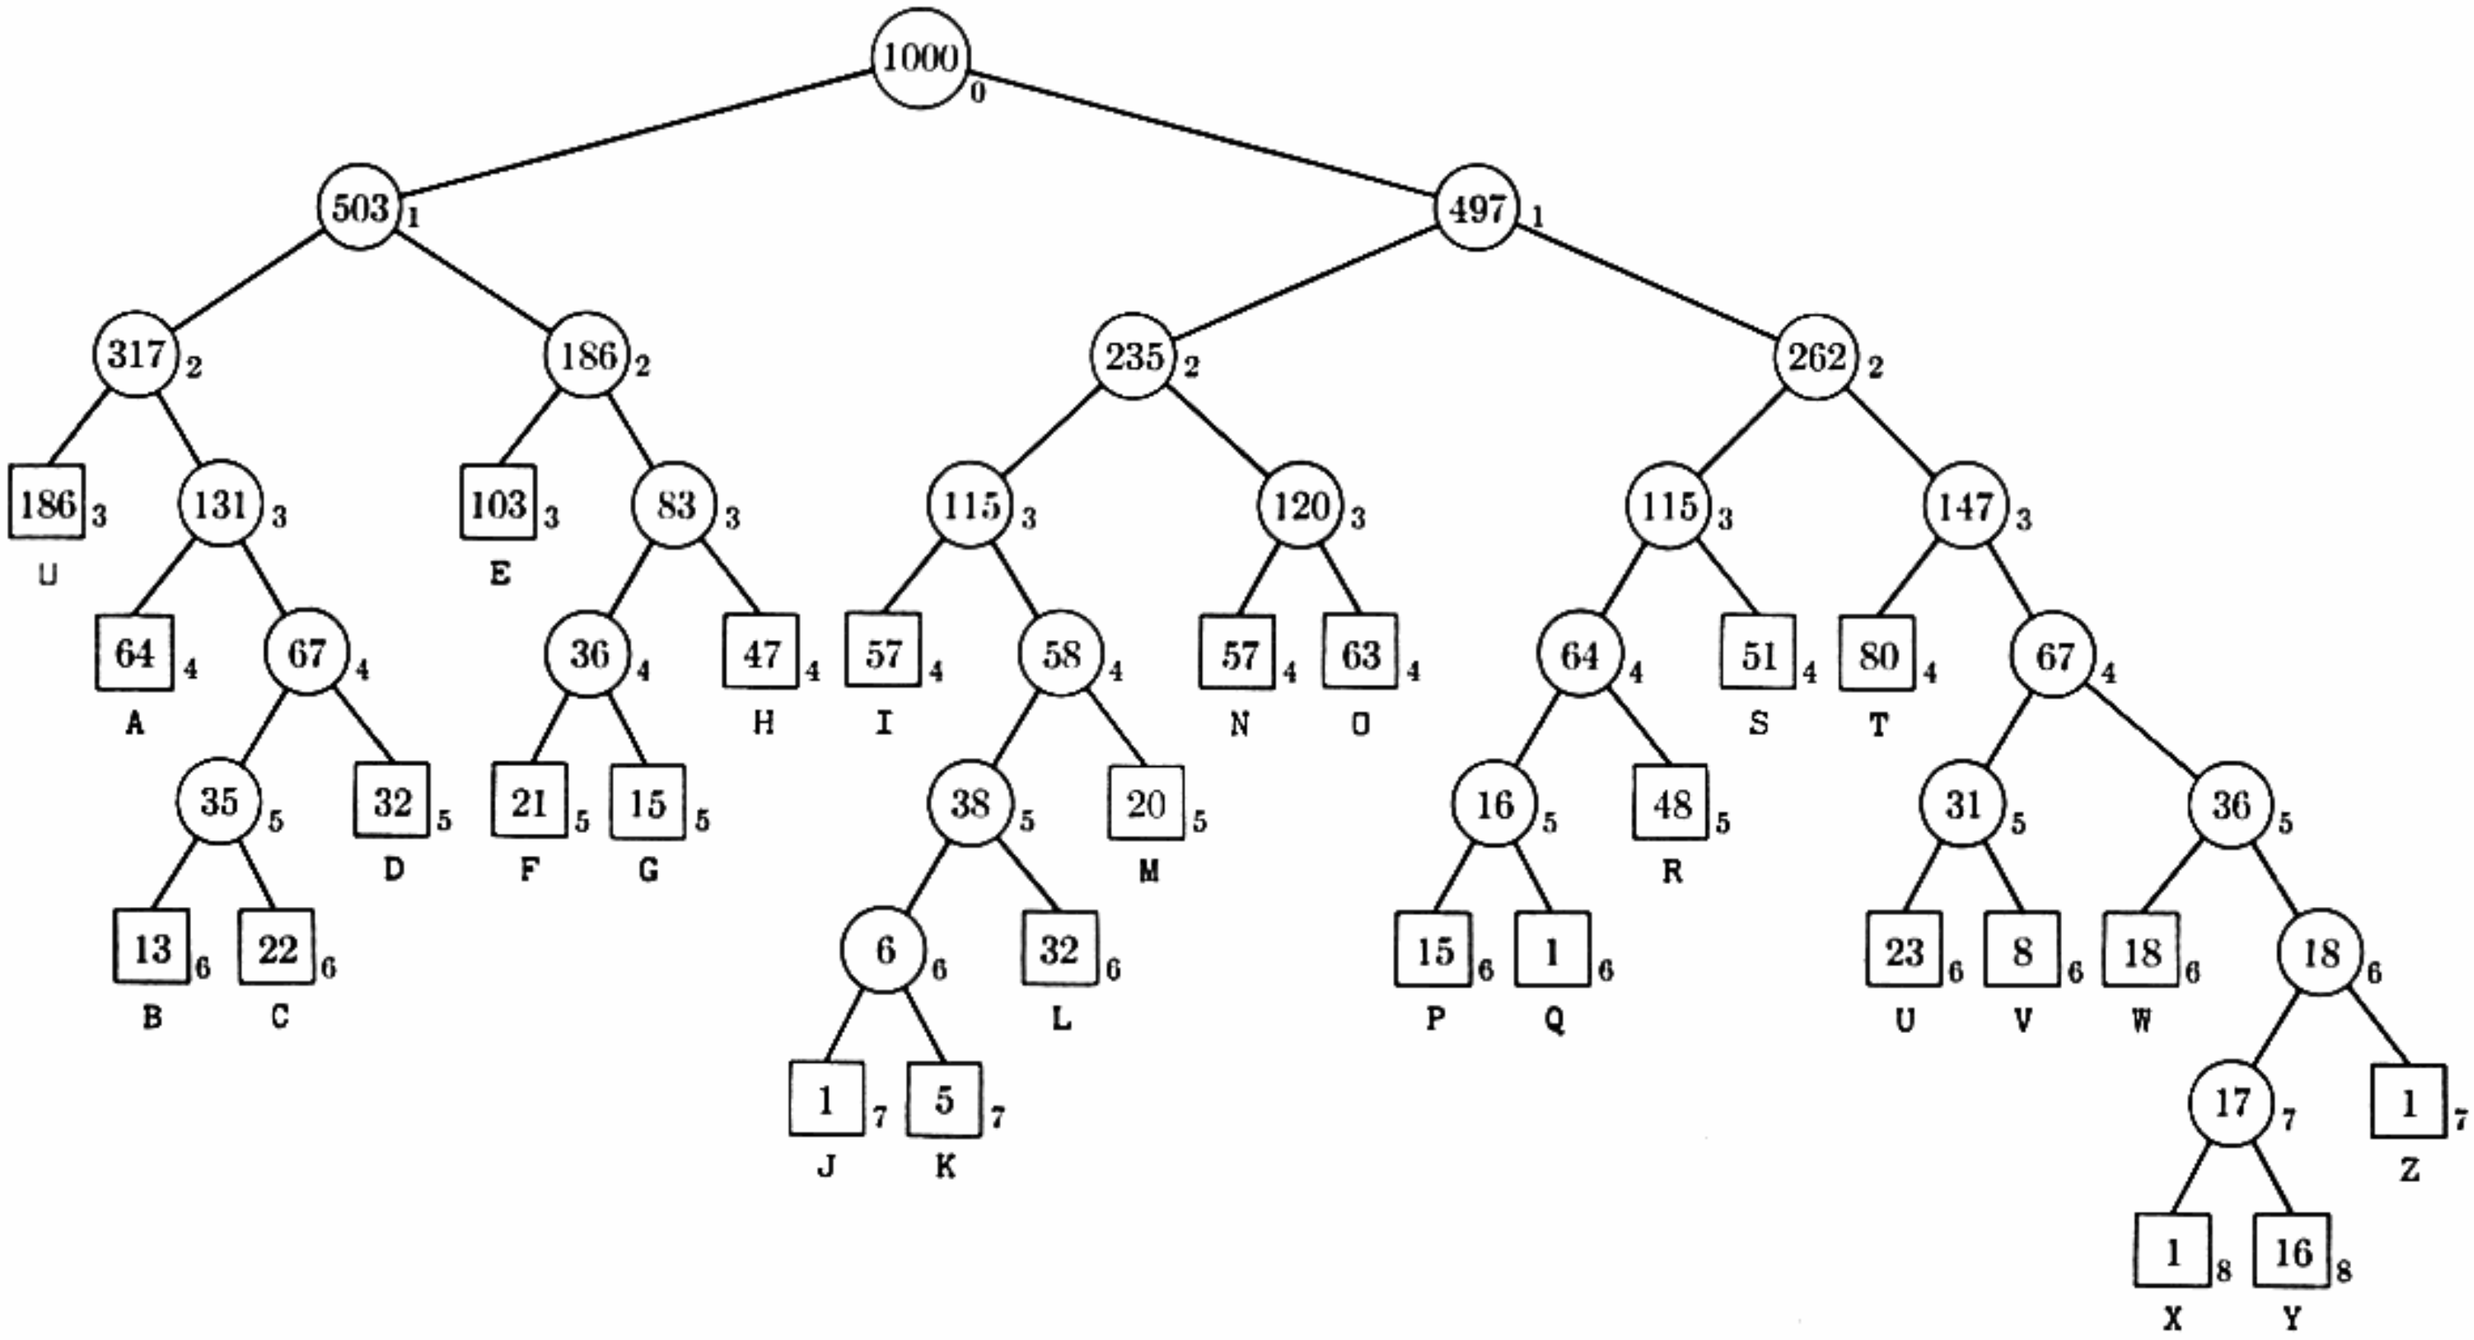

Fig. 19. The Hu-Tucker algorithm applied to alphabetic frequency data: Phase 3.

first node formed is (6), combining the J and K frequencies; then the node (16) is formed (combining P and Q), then

$$(17),\ (18),\ (26),\ (35),\ (36),\ (38),\ (41),\ (58),\ (64),\ (67),\ (67),\ (83);$$

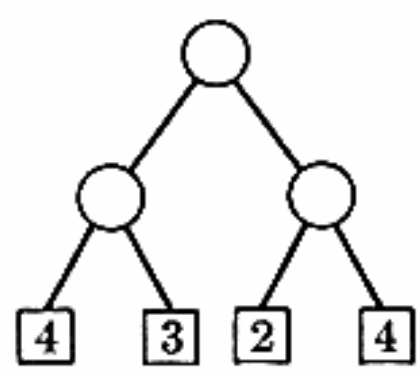
at this point we have the working sequence

$$\boxed{186}\ \boxed{64}\ (67)\ \boxed{103}\ (83)\ \boxed{57}\ (58)\ \boxed{57}\ \boxed{63}\ (64)\ \boxed{51}\ \boxed{80}\ (67). \tag{20}$$

Rule (i) allows us to combine nonadjacent weights only if they are separated by internal nodes; so we can combine $57 + 57$, then $63 + 51$, then $58 + 64$, etc.

The level numbers assigned during Phase 2 appear at the right of each node in Fig. 18. The recombination during Phase 3 now yields the tree shown in Fig. 19; note that things must be associated differently in this tree than in Fig. 18, because Fig. 18 does not preserve the left-to-right ordering. But Fig. 19 has the same cost as Fig. 18, since the external nodes appear at the same levels in both trees.

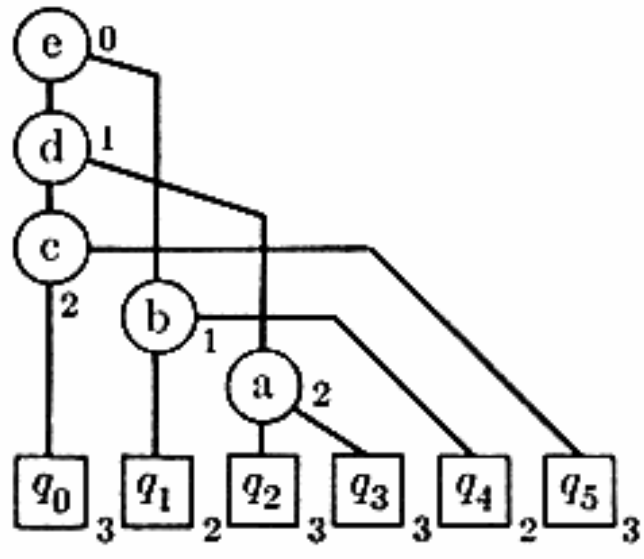
Consider a simple example where the weights are 4, 3, 2, 4; the unique optimum tree is easily shown to be



(21)

This example shows that the two smallest weights, 2 and 3, should *not* always be combined in an optimum tree, even when they are adjacent; some recombination phase is needed.

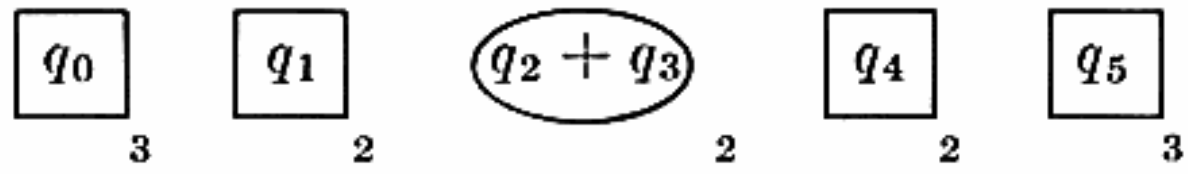
It is beyond the scope of this book to give a proof that the Hu-Tucker algorithm is valid; no simple proof is known, and it is quite possible that no simple proof will ever be found! In order to illustrate the inherent complexities of the situation, note that Phase 3 must combine all nodes into a single tree, and this is not obviously possible. For example, suppose that Phases 1 and 2 were to construct the tree



(22)

by combining nodes (a), (b), (c), (d), (e) in this order; this accords with rule

(i). Then Phase 3 will get stuck after forming



because the two level-3 nodes are not adjacent! Rule (i) does not by itself guarantee that Phase 3 will be able to proceed, and it is necessary to prove that configurations like (22) will *never* be constructed during Phase 1.

When implementing the Hu-Tucker algorithm, we can maintain priority queues for the sets of node weights which are not separated by external nodes. For example, (20) could be represented by priority queues containing, respectively,

$$\begin{array}{cccccccc} 64 & 64 & 57 & 57 & 57 & 51 & 51 & 67 \\ 186 & 67 & 83 & 57 & 63 & 63 & 80 & 80 \\ & 103 & 103 & 58 & & 64 & & \end{array} \qquad (23)$$

plus information about which of these is external, and an indication of left-to-right order for breaking ties by rules (iii) and (iv). Another "master" priority queue can keep track of the sums of the two least elements in the other queues. The creation of the new node $57 + 57$ causes three of the above priority queues to be merged. When priority queues are represented as leftist trees (cf. Section 5.2.3), each combination step of Phase 1 requires at most $O(\log n)$ operations; thus $O(n \log n)$ operations suffice as $n \to \infty$. Of course for small n it will be more efficient to use a comparatively straightforward $O(n^2)$ method of implementation.

The optimum binary tree in Fig. 19 has an interesting application to coding theory as well as to searching: Using 0 to stand for a left branch in the tree and 1 to stand for a right branch, we obtain the following variable-length codewords:

␣	000	I	1000	R	11001
A	0010	J	1001000	S	1101
B	001100	K	1001001	T	1110
C	001101	L	100101	U	111100
D	00111	M	10011	V	111101
E	010	N	1010	W	111110
F	01100	O	1011	X	11111100
G	01101	P	110000	Y	11111101
H	0111	Q	110001	Z	1111111

(24)

Thus a message like "RIGHT ON" would be encoded by the string

110011000011010111111000010111010.

Note that decoding from left to right is easy, in spite of the variable length of the codewords, because the tree structure tells us when one codeword ends and another begins. This method of coding preserves the alphabetical order of messages, and it uses an average of about 4.2 bits per letter. Thus the code could be used to compress data files, without destroying lexicographic order of alphabetic information. (The figure of 4.2 bits per letter is minimum over all binary tree codes, although it could be reduced to 4.1 bits per letter if we disregarded the alphabetic ordering constraint. A further reduction, preserving alphabetic order, could be achieved if pairs of letters instead of single letters were encoded.)

An interesting asymptotic bound on the minimum weighted path length of search trees has been derived by E. N. Gilbert and E. F. Moore:

Theorem G. *If* $p_1 = p_2 = \cdots = p_n = 0$, *the weighted path length of an optimum binary search tree lies between*

$$\sum_{0\le i\le n} q_i \log_2 (Q/q_i) \qquad \textit{and} \qquad 2Q + \sum_{0\le i\le n} q_i \log_2 (Q/q_i),$$

where $Q = \sum_{0\le i\le n} q_i$.

Proof. To get the lower bound, we use induction on n. If $n > 0$ the weighted external path length is at least

$$Q + \sum_{0\le i<k} q_i \log_2 (Q_1/q_i) + \sum_{k\le i\le n} q_i \log_2 ((Q - Q_1)/q_i) \ge \sum_{0\le i\le n} q_i \log_2 (Q/q_i) + f(Q_1),$$

for some k, where

$$Q_1 = \sum_{0\le i<k} q_i,$$

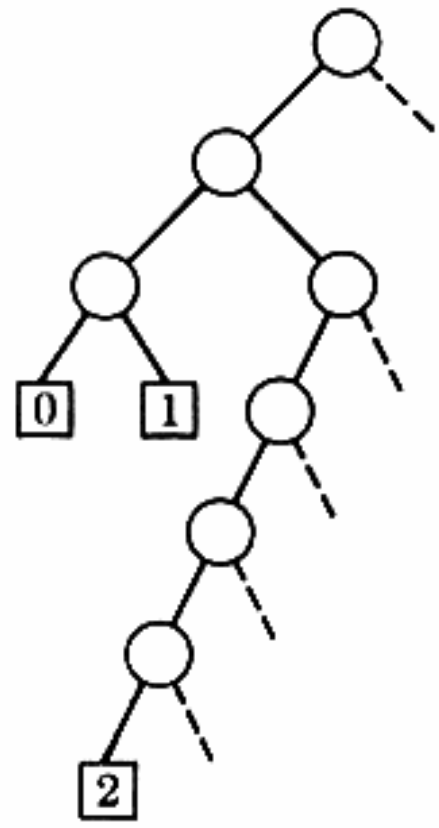
and

$$f(Q_1) = Q + Q_1 \log_2 Q_1 + (Q - Q_1) \log_2 (Q - Q_1) - Q \log_2 Q.$$

The function $f(Q_1)$ is nonnegative, and it takes its minimum value 0 when $Q_1 = \frac{1}{2}Q$.

To get the upper bound, we may assume that $Q = 1$. Let $e_0, \ldots, e_n$ be integers such that $2^{-e_i} \le q_i < 2^{1-e_i}$, for $0 \le i \le n$. Construct codewords C_i of 0's and 1's, by using the most significant $e_i + 1$ binary digits of the fraction $\sum_{0\le k<i} q_k + \frac{1}{2}q_i$, expressed in binary notation. Exercise 35 proves that C_i is never an initial substring of C_j when $i \ne j$; it follows that we can construct a binary search tree corresponding to these codewords. For example when the q's are the letter frequencies of Fig. 19, this construction gives $C_0 = 0001$,

$C_1 = 00110$, $C_2 = 01000001$, $C_3 = 0100011$, etc.; the tree begins



(25)

(Redundant bits at the right end of the codes can often be removed.) The weighted path length of the binary tree constructed by this general procedure is

$$\leq \sum_{0\leq i\leq n} (e_i + 1)q_i < \sum_{0\leq i\leq n} q_i(2 + \log(1/q_i)). \quad \blacksquare$$

The first part of the above proof is readily extended to show that the weighted path length of *every* binary tree must be at least $\sum_{0\leq i\leq n} q_i \log_2 (Q/q_i)$, whether or not the weights are required to be in order from left to right. (This fundamental result is due to Claude Shannon.) Therefore the left-to-right constraint does not raise the cost of the minimum tree by more than the cost of two extra levels, i.e., twice the total weight.

History and bibliography. The tree search methods of this section were discovered independently by several people during the 1950's. In an unpublished memorandum dated August, 1952, A. I. Dumey described a primitive form of tree insertion:

"Consider a drum with 2^n item storages in it, each having a binary address. Follow this program:

"1. Read in the first item and store it in address 2^{n-1}, i.e., at the halfway storage place.

"2. Read in the next item. Compare it with the first.

"3. If it is larger, put it in address $2^{n-1} + 2^{n-2}$. If it is smaller, put it at 2^{n-2}. . . ."

Another early form of tree insertion was introduced by D. J. Wheeler, who actually allowed multiway branching similar to what we shall discuss in Section 6.2.4; and a binary tree insertion technique was also independently devised by C. M. Berners-Lee [see *Comp. J.* **2** (1959), 5].

The first published descriptions of tree insertion were by P. F. Windley [*Comp. J.* **3** (1960), 84–88], A. D. Booth and A. J. T. Colin [*Information and Control* **3** (1960), 327–334], and Thomas N. Hibbard [*JACM* **9** (1962), 13–28]. All three of these authors seem to have developed the method independently of one another, and all three authors gave somewhat different proofs of the average number of comparisons (6). The three authors also went on to treat different aspects of the algorithm: Windley gave a detailed discussion of tree insertion sorting; Booth and Colin discussed the effect of preconditioning by making the first $2^n - 1$ elements form a perfectly balanced tree (see exercise 4); Hibbard introduced the idea of deletion and showed the connection between the analysis of tree insertion and the analysis of quicksort.

The idea of *optimum* binary search trees was first developed for the special case $p_1 = \cdots = p_n = 0$, in the context of alphabetic binary encodings like (24). A very interesting paper by E. N. Gilbert and E. F. Moore [*Bell System Tech. J.* **38** (1959), 933–968] discussed this problem and its relation to other coding problems. Gilbert and Moore observed, among other things, that an optimum tree could be constructed in $O(n^3)$ steps, using a method like Algorithm K but without the monotonicity relation (17). K. E. Iverson [*A Programming Language* (Wiley, 1962), 142–144] independently considered the *other* case, when all the q's are zero. He suggested that an optimum tree would be obtained if the root is chosen so as to equalize the left and right subtree probabilities as much as possible; unfortunately we have seen that this idea doesn't work. D. E. Knuth [*Acta Informatica* **1** (1971), 14–25, 270] subsequently considered the case of general p and q weights and proved that the algorithm could be reduced to $O(n^2)$ steps; he also presented an example from a compiler application, where the keys in the tree are "reserved words" in an ALGOL-like language. T. C. Hu had been studying his own algorithm for the $p = 0$ case for several years; a rigorous proof of the validity of that algorithm was difficult to find because of the complexity of the problem, but he eventually obtained a proof jointly with A. C. Tucker in 1969 [*SIAM J. Applied Math.* **21** (1971), 514–532].

EXERCISES

1. [*15*] Algorithm T has been stated only for nonempty trees. What changes should be made so that it works properly for the empty tree too?

2. [*2*] Modify Algorithm T so that it works with *right-threaded* trees. (Cf. Section 2.3.1; symmetric traversal is easier in such trees.)

▸ **3.** [*20*] In Section 6.1 we saw that a slight change to the sequential search Algorithm 6.1S made it faster (Algorithm 6.1Q). Can a similar trick be used to speed up Algorithm T?

4. [*M24*] (A. D. Booth and A. J. T. Colin.) Given N keys in random order, suppose that we use the first $2^n - 1$ to construct a perfectly balanced tree, placing 2^k keys on level k for $0 \leq k < n$; then we use Algorithm T to insert the remaining keys. What is the average number of comparisons in a successful search? [*Hint:* Modify Eq. (2).]

▸ **5.** [*M25*] There are 11! = 39,916,800 different orders in which the names CAPRICORN, AQUARIUS, etc. could have been inserted into a binary search tree. (a) How many of these arrangements will produce Fig. 10? (b) How many of these arrangements will produce a degenerate tree, in which LLINK or RLINK is Λ in each node?

6. [*M26*] Let P_{nk} be the number of permutations $a_1a_2 \ldots a_n$ of $\{1, 2, \ldots, n\}$ such that, if Algorithm T is used to insert $a_1, a_2, \ldots, a_n$ successively into an initially empty tree, exactly k comparisons are made when a_n is inserted. (In this problem, we will ignore the comparisons made when $a_1, \ldots, a_{n-1}$ were inserted. In the notation of the text, we have $C'_{n-1} = (\sum kP_{nk})/n!$, since this is the average number of comparisons made in an unsuccessful search of a tree containing $n - 1$ elements.)

a) Prove that $P_{n+1,k} = 2P_{n,k-1} + (n - 1)P_{n,k}$. [*Hint:* Consider whether or not a_{n+1} falls below a_n in the tree.]

b) Find a simple formula for the generating function $G_n(z) = \sum_k P_{nk}z^k$, and use your formula to express P_{nk} in terms of Stirling numbers.

c) What is the *variance* of C'_{n-1}?

7. [*M30*] (S. R. Arora and W. T. Dent.) After n elements have been inserted into an initially empty tree, in random order, what is the average number of comparisons needed to find the mth largest element?

8. [*M38*] Let $p(n, k)$ be the probability that k is the total internal path length of a tree built by Algorithm T from n randomly ordered keys. (The internal path length is the number of comparisons made by tree insertion sorting as the tree is being built.) (a) Find a recurrence relation which defines the corresponding generating function. (b) Compute the variance of this distribution. [Several of the exercises in Section 1.2.7 may be helpful here!]

9. [*41*] We have proved that tree search and insertion requires only about $2 \ln N$ comparisons when the keys are inserted in random order; but in practice, the order may not be random. Make empirical studies to see how suitable tree insertion really is for symbol tables within a compiler and/or assembler. Do the identifiers used in typical large programs lead to fairly well-balanced binary search trees?

▸ **10.** [*22*] Suppose that a programmer is not interested in the sorting property of this algorithm, but he expects the input will come in with nonrandom order. Discuss methods by which he can still use the tree search by making the input "appear to be" in random order.

11. [*20*] What is the maximum number of times S ← LLINK(R) can be performed in step D3 when deleting a node from a tree of size N?

12. [*M22*] When making a random deletion from a random tree of N items, how often does step D1 go to D4, on the average? (See the proof of Theorem H.)

▸ **13.** [*M23*] If the root of a random tree is deleted by Algorithm D, is the resulting tree still random?

▸ **14.** [*22*] Prove that the path length of the tree produced by Algorithm D with step D1½ added is never more than the path length of the tree produced without that step. Find a case where step D1½ actually decreases the path length.

15. [*M47*] When the new step D1½ added to Algorithm D, exactly how much is the average running time of Algorithm T affected after a long sequence of insertions and deletions?

▶**16.** [*25*] Is the deletion operation *commutative*? That is, if Algorithm D is used to delete X and then Y, is the resulting tree the same as if Algorithm D is used to delete Y and then X?

17. [*25*] Show that if the roles of left and right are completely reversed in Algorithm D, it is easy to extend the algorithm so that it deletes a given node from a *right-threaded* tree, preserving the necessary threads. (Cf. exercise 2.)

18. [*M21*] Show that Zipf's law yields (12).

19. [*M23*] What is the approximate average number of comparisons, (11), when the input probabilities satisfy the "80-20" law defined in Eqs. 6.1–11, 12?

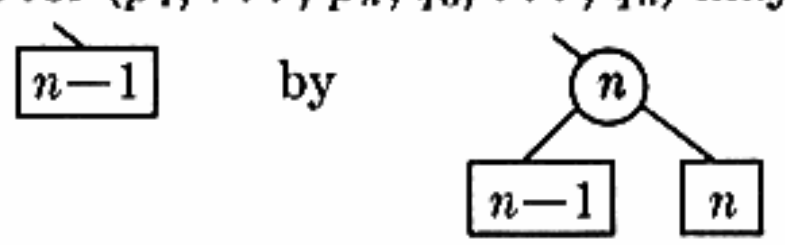
20. [*M20*] Suppose we have inserted keys into a tree in order of decreasing frequency $p_1 \geq p_2 \geq \cdots \geq p_N$. Can this tree be substantially worse than the optimum search tree?

21. [*M20*] If p, q, r are probabilities chosen at random, subject to the condition that $p + q + r = 1$, what are the probabilities that trees I, II, III, IV, V of (13) are optimal, respectively? (Consider the relative areas of the regions in Fig. 14.)

22. [*M20*] Prove that $r[i, j-1]$ is never greater than $r[i+1, j]$ when step K4 of Algorithm K is performed.

▶**23.** [*M23*] Find an optimum binary search tree for the case $n = 40$, with weights $p_1 = 5$, $p_2 = p_3 = \cdots = p_{40} = 1$, $q_0 = q_1 = \cdots = q_{40} = 0$. (Don't use a computer.)

24. [*M25*] Given that $p_n = q_n = 0$ and that the other weights are nonnegative, prove that an optimum tree for $(p_1, \ldots, p_n; q_0, \ldots, q_n)$ may be obtained by replacing



in any optimum tree for $(p_1, \ldots, p_{n-1}; q_0, \ldots, q_{n-1})$.

25. [*M20*] Let A and B be nonempty sets of real numbers, and define $A \leq B$ if the following property holds:

$$(a \in A, \quad b \in B, \quad \text{and} \quad b < a) \qquad \text{implies} \qquad (a \in B \quad \text{and} \quad b \in A).$$

(a) Prove that this relation is transitive on nonempty sets. (b) Prove or disprove: $A \leq B$ if and only if $A \leq A \cup B \leq B$.

26. [*M22*] Let $(p_1, \ldots, p_n; q_0, \ldots, q_n)$ be nonnegative weights, where $p_n + q_n = x$. Prove that as x varies from 0 to ∞, while $(p_1, \ldots, p_{n-1}; q_0, \ldots, q_{n-1})$ are held constant, the cost $c(0, n)$ of an optimum binary search tree is a "convex, continuous, piece-wise linear" function of x with integer slopes. In other words, prove that there exist positive integers $l_0 > l_1 > \cdots > l_m$ and real constants $0 = x_0 < x_1 < \cdots < x_m < x_{m+1} = \infty$ and $y_0 < y_1 < \cdots < y_m$ such that $c(0, n) = y_h + l_h x$ when $x_h \leq x \leq x_{h+1}$, for $0 \leq h \leq m$.

27. [*M33*] The object of this exercise is to prove that the sets of roots $R(i, j)$ of optimum binary search trees satisfy

$$R(i, j-1) \leq R(i, j) \leq R(i+1, j), \qquad \text{for} \qquad j - i \geq 2,$$

in terms of the relation defined in exercise 25, whenever the weights $(p_1, \ldots, p_n; q_0, \ldots, q_n)$ are nonnegative. The proof is by induction on $j - i$; our task is to prove

that $R(0, n-1) \le R(0, n)$, assuming that $n \ge 2$ and that the above relation holds for $j - i < n$. [By left-right symmetry it follows that $R(0, n) \le R(1, n)$.]

a) Prove that $R(0, n-1) \le R(0, n)$ if $p_n = q_n = 0$. (See exercise 24.)

b) Let $p_n + q_n = x$. In the notation of exercise 26, let R_h be the set $R(0, n)$ of optimum roots when $x_h < x < x_{h+1}$, and let R'_h be the set of optimum roots when $x = x_h$. Prove that

$$R'_0 \le R_0 \le R'_1 \le R_1 \le \cdots \le R'_m \le R_m.$$

Hence by part (a) and exercise 25 we have $R(0, n-1) \le R(0, n)$ for all x.
[*Hint:* Consider the case $x = x_h$, and assume that both the trees

are optimum, with $s < r$ and $l \ge l'$. Use the induction hypothesis to prove that there is an optimum tree with root (r) such that $\boxed{n}$ is at level l', and an optimum tree with root (s) such that $\boxed{n}$ is at level l.]

28. [*24*] Use some macro-assembly language to define a "optimum binary search" macro, whose parameter is a nested specification of an optimum binary tree.

29. [*40*] What is the *worst* possible binary search tree for the 31 most common English words, using the frequency data of Fig. 12?

30. [*M46*] Prove or disprove that the costs of optimum binary search trees satisfy $c(i, j) + c(i+1, j-1) \ge c(i, j-1) + c(i+1, j)$.

31. [*M20*] (a) If the weights $(q_0, \ldots, q_5)$ in (22) are (2, 3, 1, 1, 3, 2), respectively, what is the weighted path length of the tree? (b) What is the weighted path length of the *optimum* binary search tree having this sequence of weights?

▸ **32.** [*M22*] (T. C. Hu and A. C. Tucker.) Prove that the new node weights $q_i + q_j$ formed during Phase 1 of the Hu-Tucker algorithm are created in nondecreasing order.

33. [*M41*] In order to find the binary search tree which minimizes the running time of Program T, we should minimize the quantity $7C + C1$ instead of simply minimizing the number of comparisons C. Develop an algorithm which finds optimum binary search trees when different costs are associated with left and right branches in the tree. (Incidentally when the right cost is twice the left cost, and the node frequencies are all equal, the Fibonacci trees turn out to be optimum. Cf. L. E. Stanfel, *JACM* **17** (1970), 508–517.)

34. [*41*] Write a computer program for the Hu-Tucker algorithm, using $O(n)$ units of storage and $O(n \log n)$ units of time.

35. [*M23*] Show that the codewords constructed in the proof of Theorem G have the property that C_i never begins with C_j when $i \ne j$.

36. [*M26*] Generalizing the upper bound of Theorem G, prove that the cost of any optimum binary search tree with nonnegative weights must be less than

$$2S + q_0 \log_2 (S/q_0) + \sum_{1 \le i \le n} (p_i + q_i) \log_2 (S/(p_i + q_i)),$$

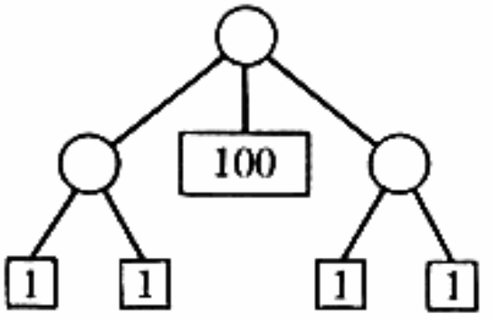
where $S = q_0 + \sum_{1 \le i \le n} (p_i + q_i)$ is the total weight.

▸ **37.** [*M25*] (T. C. Hu and K. C. Tan.) Let $n+1 = 2^m + k$, where $0 \le k \le 2^m$. There are $\binom{2^m}{k}$ binary trees in which all external nodes appear on levels m and $m+1$. Show that, among all these trees, we obtain one with the minimum weighted path length for the weight sequence $(q_0, \ldots, q_n)$ if we apply the Hu-Tucker algorithm to the weights $(M + q_0, \ldots, M + q_n)$ for sufficiently large M.

38. [*M35*] (K. C. Tan.) Prove that, among all sets of probabilities $(p_1, \ldots, p_n; q_0, \ldots, q_n)$ with $p_1 + \cdots + p_n + q_0 + \cdots + q_n = 1$, the most expensive minimum-cost tree occurs when $p_i = 0$ for all i, $q_j = 0$ for all even j, and $q_j = 1/\lceil n/2 \rceil$ for all odd j. [*Hint:* Given arbitrary probabilities $(p_1, \ldots, p_n; q_0, \ldots, q_n)$, let $c_0 = q_0$, $c_i = p_i + q_i$ for $1 \le i \le n$, and $S(0) = \emptyset$; and for $1 \le r \le \lceil n/2 \rceil$ let $S(r) = S(r-1) \cup \{i, j\}$, where $c_i + c_j$ is minimum over all $i < j$ such that $i, j \notin S(r-1)$ and $k \in S(r-1)$ for all $i < k < j$. Construct the binary tree T with the external nodes of $S(n + 1 - 2^q)$ on level $q+1$ and the other external nodes on level q, where $q = \lfloor \log_2 n \rfloor$. Prove that the cost of this tree is $\le f(n)$, where $f(n)$ is the cost of the optimum search tree for the stated "worst" probabilities.]

39. [*M30*] (C. K. Wong and Shi-Kuo Chang.) Consider a scheme whereby a binary search tree is constructed by Algorithm T, except that whenever the number of nodes reaches a number of the form $2^n - 1$ the tree is reorganized into a perfectly-balanced uniform tree, with 2^k nodes on level k for $0 \le k < n$. Prove that the number of comparisons made while constructing such a tree is $N \log_2 N + O(N)$ on the average. (It is not difficult to show that the amount of time needed for the reorganizations is $O(N)$.)

40. [*M50*] Can the Hu-Tucker algorithm be generalized to find optimum trees where each node has degree at most t? For example, when $t = 3$ and the sequence of weights is (1, 1, 100, 1, 1) the optimum tree is



6.2.3. Balanced Trees

The tree insertion algorithm we have just learned will produce good search trees, when the input data is random, but there is still the annoying possibility that a degenerate tree will occur. Perhaps we could devise an algorithm which keeps the tree optimum at all times; but unfortunately that seems to be very difficult. Another idea is to keep track of the total path length, and to completely reorganize the tree whenever its path length exceeds $5N \log_2 N$, say. But this approach might require about $\sqrt{N/2}$ reorganizations as the tree is being built.

A very pretty solution to the problem of maintaining a good search tree was discovered in 1962 by two Russian mathematicians, G. M. Adel'son-Vel'skiĭ and E. M. Landis [*Doklady Akademiia Nauk SSSR* **146** (1962), 263–266; English translation in *Soviet Math.* **3**, 1259–1263]. Their method requires only two extra bits per node, and it never uses more than $O(\log N)$ operations to search

the tree or to insert an item. In fact, we shall see that their approach also leads to a general technique that is good for representing arbitrary *linear lists* of length N, so that each of the following operations can be done in only $O(\log N)$ units of time:

i) Find an item having a given key.
ii) Find the kth item, given k.
iii) Insert an item at a specified place.
iv) Delete a specified item.

If we use sequential allocation for linear lists, operations (i) and (ii) are efficient but operations (iii) and (iv) take order N steps; on the other hand, if we use linked allocation, operations (iii) and (iv) are efficient but operations (i) and (ii) take order N steps. A tree representation of linear lists can do *all four* operations in $O(\log N)$ steps. And it is also possible to do other standard operations with comparable efficiency, so that, for example, we can concatenate a list of M elements with a list of N elements in $O(\log(M + N))$ steps.

The method for achieving all this involves what we shall call "balanced trees." The preceding paragraph is an advertisement for balanced trees, which makes them sound like a universal panacea that makes all other forms of data representation obsolete; but of course we ought to have a balanced attitude about balanced trees! In applications which do not involve all four of the above operations, we may be able to get by with substantially less overhead and simpler programming. Furthermore, there is no advantage to balanced trees unless N is reasonably large; thus if we have an efficient method that takes $20 \log_2 N$ units of time and an inefficient method that takes $2N$ units of time, we should use the inefficient method unless N is greater than 1024. On the other hand, N shouldn't be too large, either; balanced trees are appropriate chiefly for *internal* storage of data, and we shall study better methods for external direct-access files in Section 6.2.4. Since internal memories seem to be getting larger and larger as time goes by, balanced trees are becoming more and more important.

The *height* of a tree is defined to be its maximum level, the length of the longest path from the root to an external node. A binary tree is called *balanced* if the height of the left subtree of every node never differs by more than ± 1 from the height of its right subtree. Figure 20 shows a balanced tree with 17 internal nodes and height 5; the *balance factor* within each node is shown as $+$, $\cdot$, or $-$ according as the right subtree height minus the left subtree height is $+1$, 0, or -1. The Fibonacci tree in Fig. 8 (Section 6.2.1) is another balanced binary tree of height 5, having only 12 internal nodes; most of the balance factors in that tree are -1. The zodiac tree in Fig. 10 (Section 6.2.2) is *not* balanced, because the height restriction on subtrees fails at both the `AQUARIUS` and `GEMINI` nodes.

This definition of balance represents a compromise between *optimum* binary trees (with all external nodes required to be on two adjacent levels) and *arbitrary*

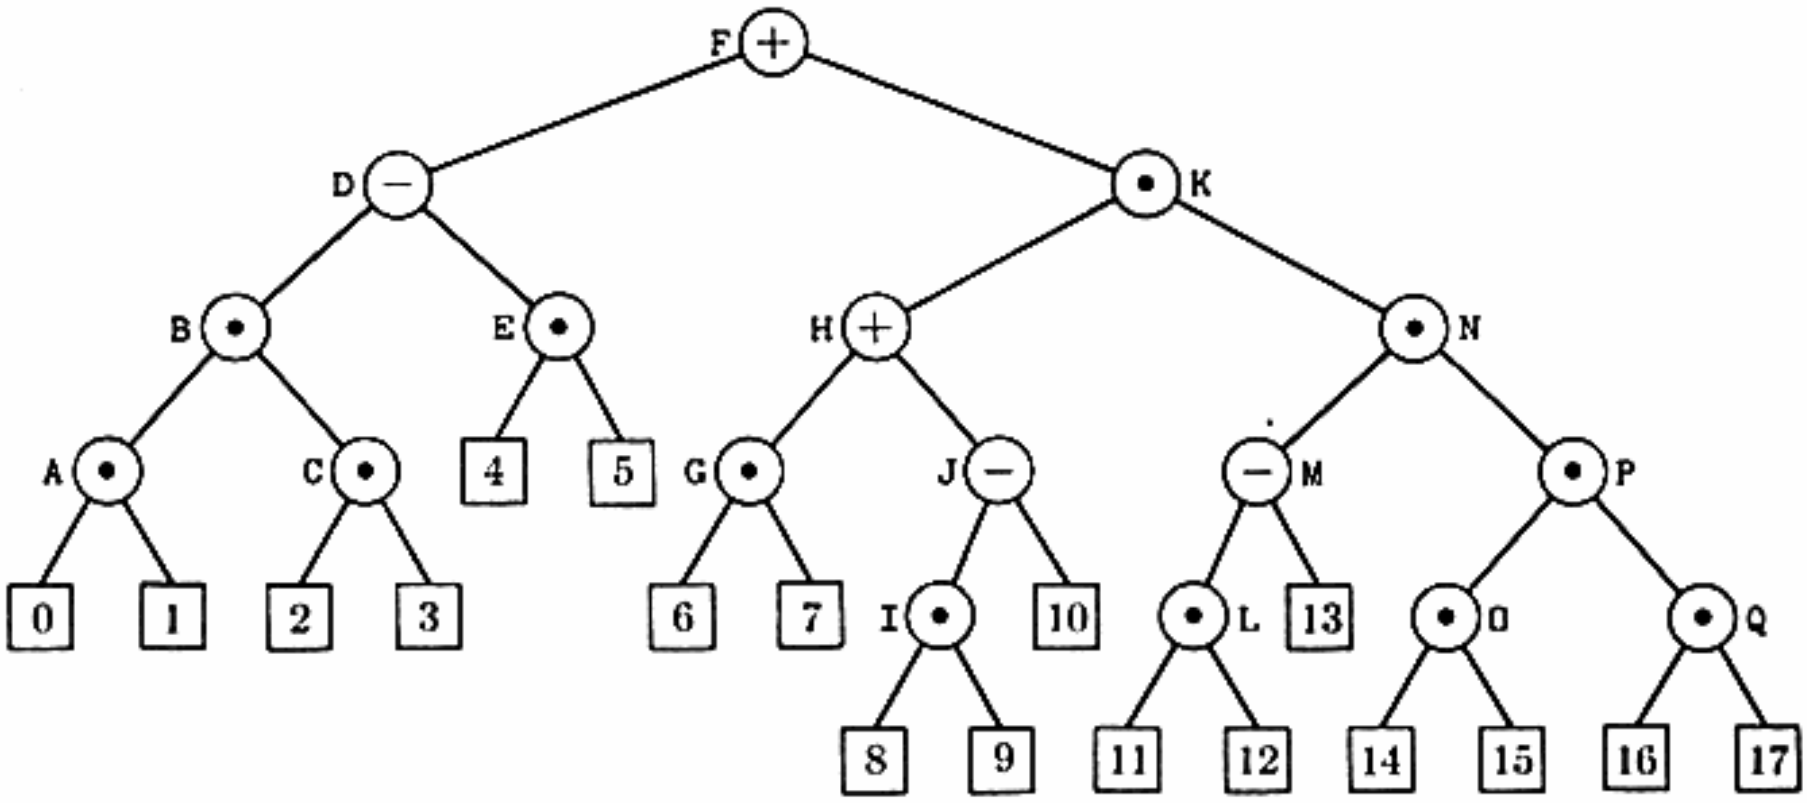


Fig. 20. A balanced binary tree.

binary trees (unrestricted). It is therefore natural to ask how far from optimum a balanced tree can be. The answer is that its search paths will never be more than 45 percent longer than the optimum:

Theorem A (Adel'son-Vel'skiĭ and Landis). *The height of a balanced tree with* N *internal nodes always lies between* $\log_2 (N + 1)$ *and* $1.4404 \log_2 (N + 2) - 0.328$.

Proof. A binary tree of height h obviously cannot have more than 2^h external nodes; so $N + 1 \leq 2^h$, that is, $h \geq \lceil \log_2 (N + 1) \rceil$ in any binary tree.

In order to find the maximum value of h, let us turn the problem around and ask for the minimum number of nodes possible in a balanced tree of height h. Let T_h be such a tree with fewest possible nodes; then one of the subtrees of the root, say the left subtree, has height $h - 1$, and the other subtree has height $h - 1$ or $h - 2$. Since we want T_h to have the minimum number of nodes, we may assume that the left subtree of the root is T_{h-1}, and that the right subtree is T_{h-2}. This argument shows that the *Fibonacci tree* of order $h + 1$ has the fewest possible nodes among all possible balanced trees of height h. (See the definition of Fibonacci trees in Section 6.2.1.) Thus

$$N \geq F_{h+2} - 1 > \phi^{h+2}/\sqrt{5} - 2,$$

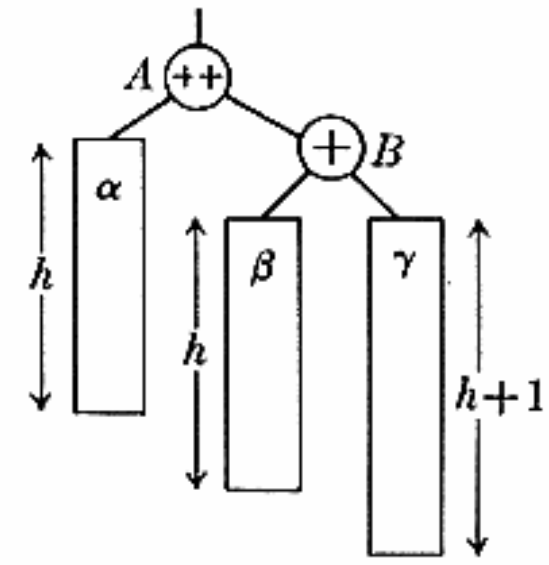
and the stated result follows as in the corollary to Theorem 4.5.3F. ∎

The proof of this theorem shows that a search in a balanced tree will require more than 25 comparisons only if the tree contains at least $F_{27} - 1 = 196{,}417$ nodes.

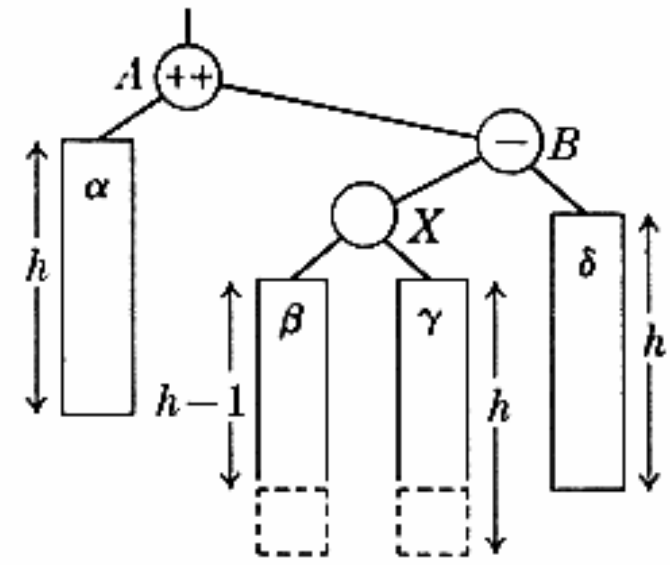
Consider now what happens when a new node is inserted into a balanced tree using tree insertion (Algorithm 6.2.2T). In Fig. 20, the tree will still be balanced if the new node takes the place of [4], [5], [6], [7], [10], or [13], but some adjustment will be needed if the new node falls elsewhere. The problem arises when we have a node with a balance factor of +1 whose right subtree got higher after the insertion; or, dually, if the balance factor is −1 and the left

subtree got higher. It is not difficult to see that there are essentially only two cases which cause trouble:

Case 1



Case 2

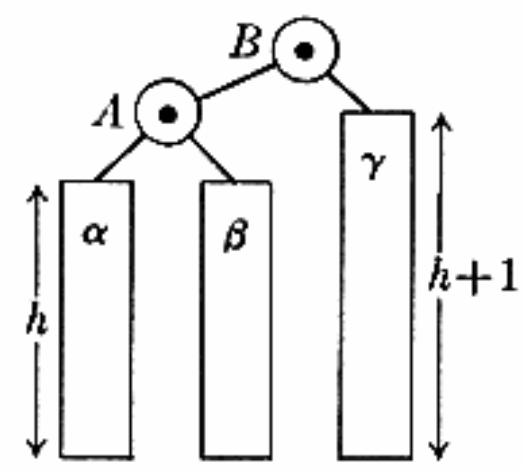


(1)

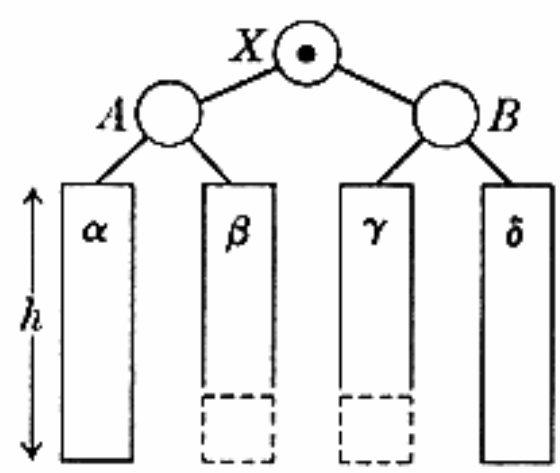
(Two other essentially identical cases occur if we reflect these diagrams, interchanging left and right.) In these diagrams the large rectangles α, β, γ, δ represent subtrees having the respective heights shown. Case 1 occurs when a new element has just increased the height of node B's right subtree from h to $h + 1$, and Case 2 occurs when the new element has increased the height of B's left subtree. In the second case, we have either $h = 0$ (so that X itself was the new node), or else node X has two subtrees of respective heights $(h - 1, h)$ or $(h, h - 1)$.

Simple transformations will restore balance in both of the above cases, while preserving the symmetric order of the tree nodes:

Case 1



Case 2



(2)

In Case 1 we simply "rotate" the tree to the left, attaching β to A instead of B. This transformation is like applying the associative law to an algebraic formula, replacing $\alpha(\beta\gamma)$ by $(\alpha\beta)\gamma$. In Case 2 we use a double rotation, first rotating (X, B) right, then (A, X) left. In both cases only a few links of the tree need to be changed. Furthermore, the new trees have height $h + 2$, which is exactly the height that was present before the insertion; hence the rest of the tree (if any) that was originally above node A always remains balanced.

For example, if we insert a new node into position 17 of Fig. 20 we obtain the balanced tree shown in Fig. 21, after a single rotation (Case 1). Note that several of the balance factors have changed.

The details of this insertion procedure can be worked out in several ways. At first glance an auxiliary stack seems to be necessary, in order to keep track of which nodes will be affected, but the following algorithm gains some speed by avoiding the need for a stack in a slightly tricky way.

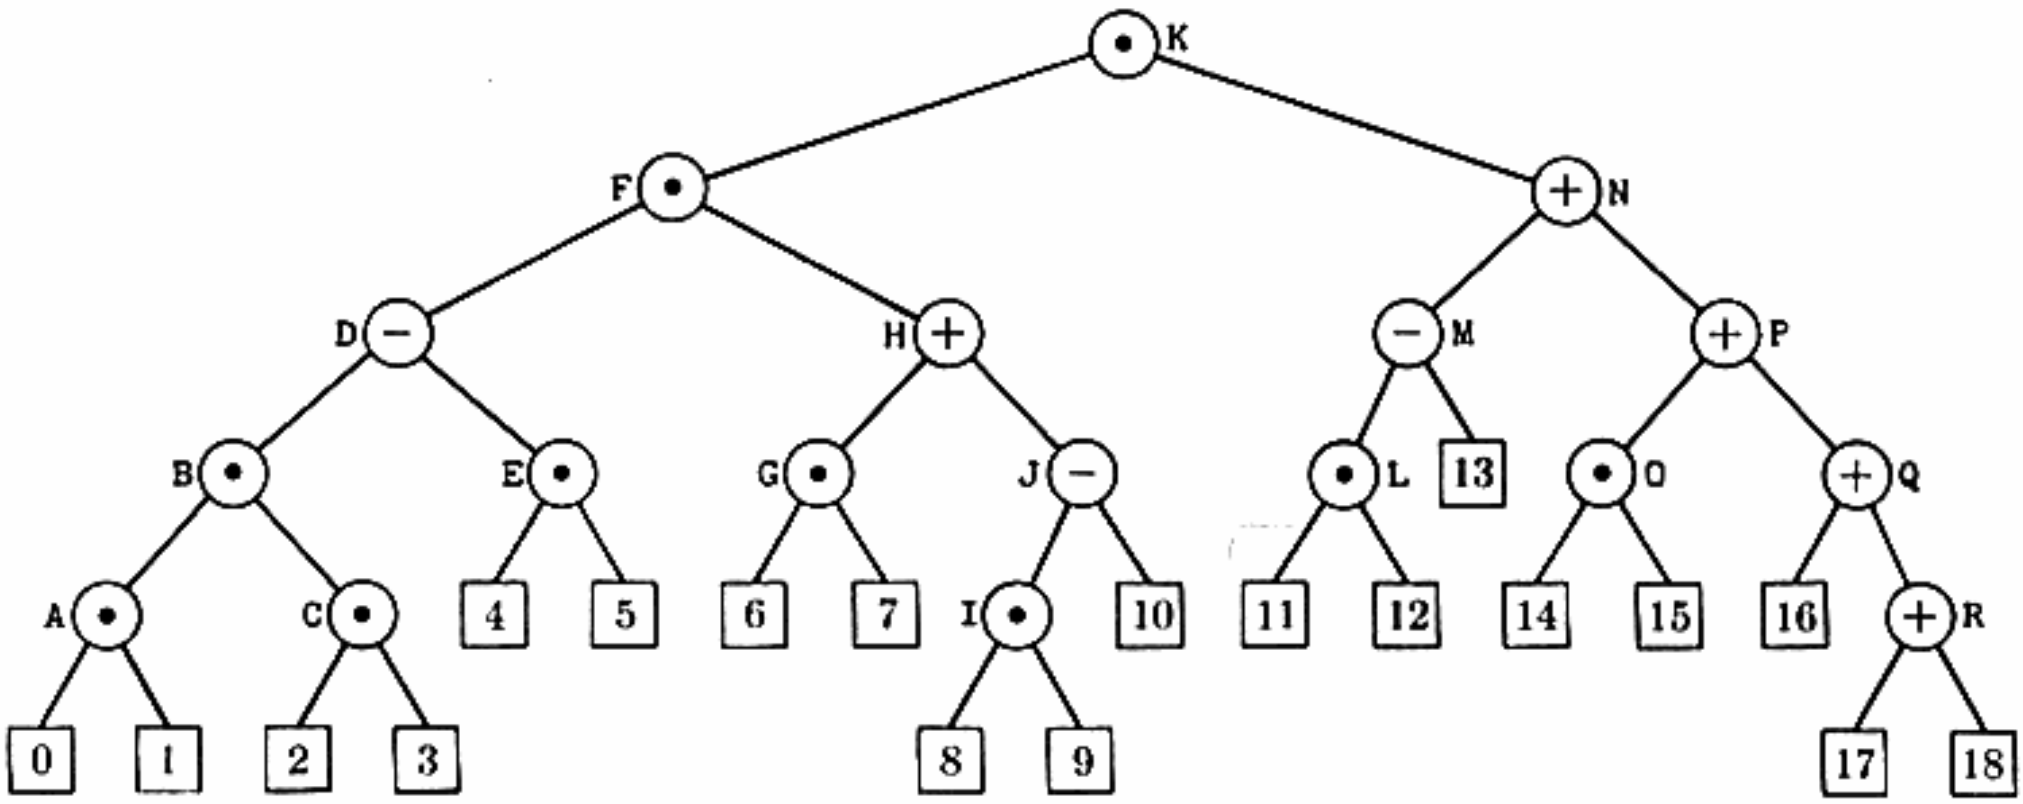


Fig. 21. The tree of Fig. 20, rebalanced after a new key R has been inserted.

Algorithm A (*Balanced tree search and insertion*). Given a table of records which form a balanced binary tree as described above, this algorithm searches for a given argument K. If K is not in the table, a new node containing K is inserted into the tree in the appropriate place and the tree is rebalanced if necessary.

The nodes of the tree are assumed to contain KEY, LLINK, and RLINK fields as in Algorithm 6.2.2T. We also have a new field

$$\texttt{B(P)} = \text{balance factor of } \texttt{NODE(P)},$$

the height of the right subtree minus the height of the left subtree; this field always contains either $+1$, 0 or -1. A special header node also appears at the top of the tree, in location HEAD; the value of RLINK(HEAD) is a pointer to the root of the tree, and LLINK(HEAD) is used to keep track of the overall height of the tree. (Knowledge of the height is not really necessary for this algorithm, but it is useful in the concatenation procedure discussed below.) We assume that the tree is *nonempty*, i.e., that $\texttt{RLINK(HEAD)} \neq \Lambda$.

For convenience in description, the algorithm uses the notation LINK(a, P) as a synonym for LLINK(P) if $a = -1$, and for RLINK(P) if $a = +1$.

A1. [Initialize.] Set T $\leftarrow$ HEAD, S $\leftarrow$ P $\leftarrow$ RLINK(HEAD). (The pointer variable P will move down the tree; S will point to the place where rebalancing may be necessary, and T always points to the father of S.)

A2. [Compare.] If $K <$ KEY(P), go to A3; if $K >$ KEY(P), go to A4; and if $K =$ KEY(P), the search terminates successfully.

A3. [Move left.] Set Q $\leftarrow$ LLINK(P). If Q $= \Lambda$, set Q $\Leftarrow$ AVAIL and LLINK(P) $\leftarrow$ Q and go to step A5. Otherwise if B(Q) $\neq 0$, set T $\leftarrow$ P and S $\leftarrow$ Q. Finally set P $\leftarrow$ Q and return to step A2.

A4. [Move right.] Set Q $\leftarrow$ RLINK(P). If Q $= \Lambda$, set Q $\Leftarrow$ AVAIL and RLINK(P) $\leftarrow$ Q and go to step A5. Otherwise if B(Q) $\neq 0$, set T $\leftarrow$ P and S $\leftarrow$ Q. Finally set P $\leftarrow$ Q and return to step A2. (The last part of this step may be combined with the last part of step A3.)

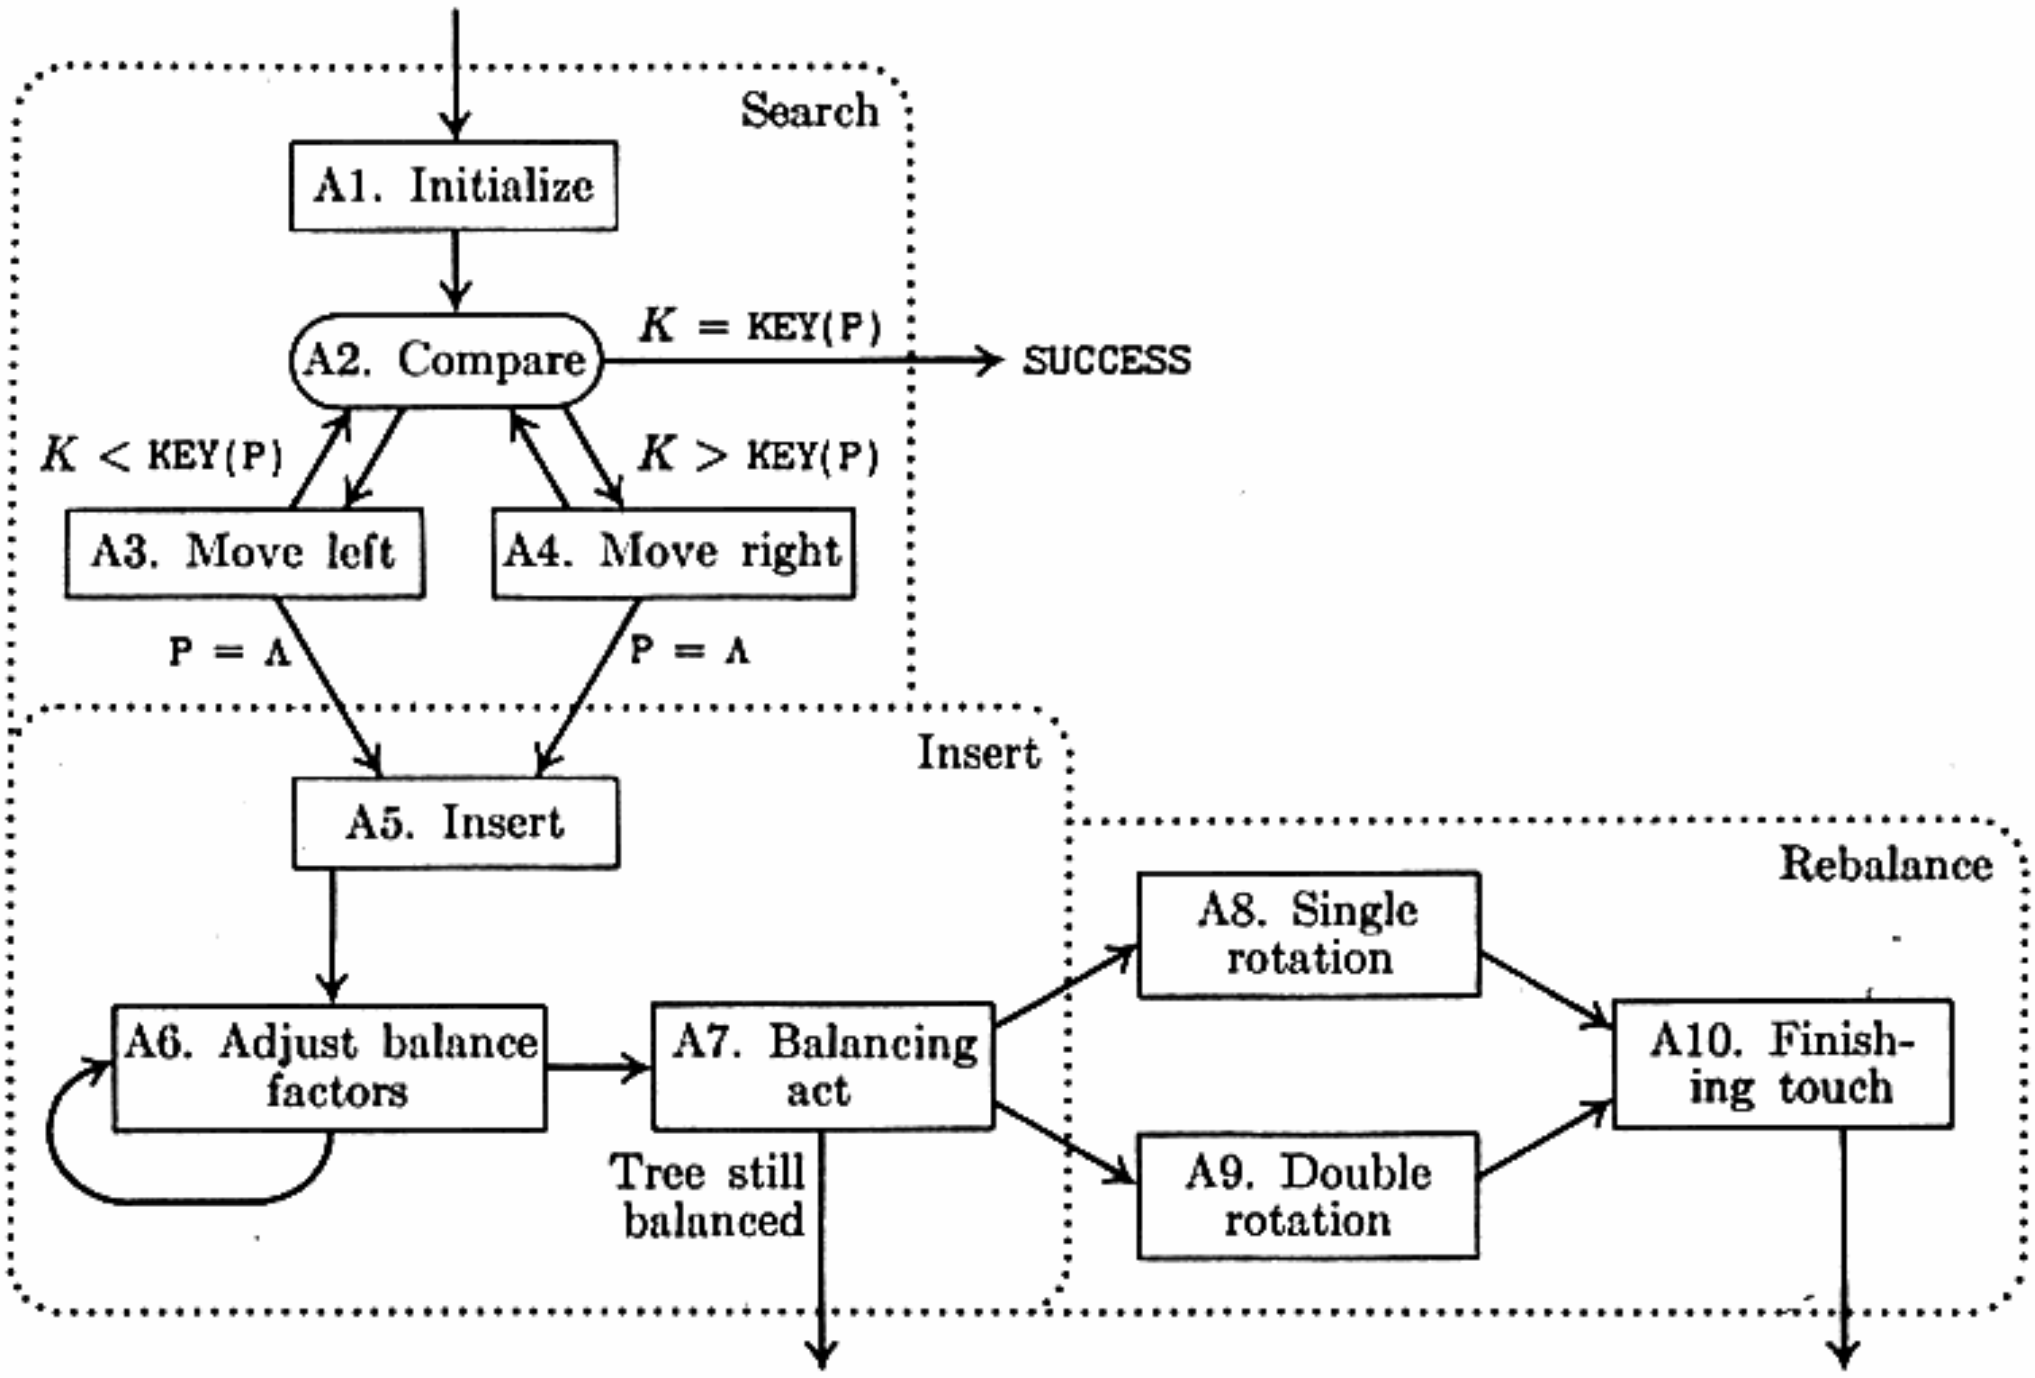

Fig. 22. Balanced tree search and insertion.

A5. [Insert.] (We have just linked a new node, NODE(Q), into the tree, and its fields need to be initialized.) Set KEY(Q) ← K, LLINK(Q) ← RLINK(Q) ← Λ, B(Q) ← 0.

A6. [Adjust balance factors.] (Now the balance factors on nodes between S and Q need to be changed from zero to ±1.) If $K <$ KEY(S), set R ← P ← LLINK(S), otherwise set R ← P ← RLINK(S). Then repeatedly do the following operation zero or more times until P = Q: If $K <$ KEY(P) set B(P) ← −1 and P ← LLINK(P); if $K >$ KEY(P), set B(P) ← +1 and P ← RLINK(P). (If $K =$ KEY(P), then P = Q and we may go on to the next step.)

A7. [Balancing act.] If $K <$ KEY(S) set $a \leftarrow -1$, otherwise set $a \leftarrow +1$. Several cases now arise:

i) If B(S) = 0 (the tree has grown higher), set B(S) ← a, LLINK(HEAD) ← LLINK(HEAD) + 1, and terminate the algorithm.

ii) If B(S) = $-a$ (the tree has gotten more balanced), set B(S) ← 0 and terminate the algorithm.

iii) If B(S) = a (the tree has gotten out of balance), go to step A8 if B(R) = a, to A9 if B(R) = $-a$.

(Case (iii) corresponds to the situations depicted in (1) when $a = +1$; S and R point, respectively, to nodes A and B, and LINK($-a$, S) points to α, etc.)

A8. [Single rotation.] Set P ← R, LINK(a, S) ← LINK($-a$, R), LINK($-a$, R) ← S, B(S) ← B(R) ← 0. Go to A10.

A9. [Double rotation.] Set P ← LINK($-a$, R), LINK($-a$ R) ← LINK(a, P), LINK(a, P) ← R, LINK(a, S) ← LINK($-a$, P), LINK($-a$, P) ← S. Now set

$$(\mathtt{B(S)}, \mathtt{B(R)}) \leftarrow \begin{cases} (-a, 0), & \text{if } \mathtt{B(P)} = a; \\ (0, 0), & \text{if } \mathtt{B(P)} = 0; \\ (0, a), & \text{if } \mathtt{B(P)} = -a; \end{cases} \tag{3}$$

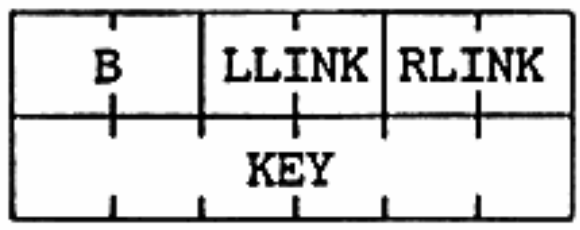
and then set B(P) ← 0.

A10. [Finishing touch.] (We have completed the rebalancing transformation, taking (1) to (2), with P pointing to the new root and T pointing to the father of the old root.) If S = RLINK(T) then set RLINK(T) ← P, otherwise set LLINK(T) ← P. ∎

This algorithm is rather long, but it divides into three simple parts: Steps A1–A4 do the search, steps A5–A7 insert a new node, and steps A8–A10 rebalance the tree if necessary.

We know that the algorithm takes about $C \log N$ units of time, for some C, but it is important to know the approximate value of C so that we can tell how large N should be in order to make balanced trees worth all the trouble. The following MIX implementation gives some insight into this question.

Program A (*Balanced tree search and insertion*). This program for Algorithm A uses tree nodes having the form



; (4)

rA ≡ K, rI1 ≡ P, rI2 ≡ Q, rI3 ≡ R, rI4 ≡ S, rI5 ≡ T. The code for steps A7–A9 is duplicated so that the value of a appears implicitly (not explicitly) in the program.

Analysis of balanced tree insertion. [Nonmathematical readers, please skip to (10).] In order to figure out the running time of Algorithm A, we would like to know the answers to the following questions:

- How many comparisons are made during the search?
- How far apart will nodes `S` and `Q` be? (In other words, how much adjustment is needed in step A6?)
- How often do we need to do a single or double rotation?

It is not difficult to derive upper bounds on the worst case running time, using Theorem A, but of course in practice we want to know the average behavior. No theoretical determination of the average behavior has been successfully completed as yet, since the algorithm appears to be rather complicated, but some interesting empirical results have been obtained.

In the first place we can ask about the number B_{nh} of balanced binary trees with n internal nodes and height h. It is not difficult to compute the generating function $B_h(z) = \sum_{n\geq 0} B_{nh} z^n$ for small h, from the relations

$$B_0(z) = 1, \qquad B_1(z) = z, \qquad B_{h+1}(z) = zB_h(z)\big(B_h(z) + 2B_{h-1}(z)\big). \tag{5}$$

(See exercise 6.) Thus

$$\begin{aligned} B_2(z) &= 2z^2 + z^3, \\ B_3(z) &= 4z^4 + 6z^5 + 4z^6 + z^7, \\ B_4(z) &= 16z^7 + 32z^8 + 44z^9 + \cdots + 8z^{14} + z^{15}, \end{aligned}$$

and in general $B_h(z)$ has the form

$$2^{F_{h+1}-1} z^{F_{h+2}-1} + 2^{F_{h+1}-2} L_{h-1} z^{F_{h+2}} + \text{complicated terms} + 2^{h-1} z^{2^h-2} + z^{2^h-1} \tag{6}$$

for $h \geq 3$, where $L_k = F_{k+1} + F_{k-1}$. (This formula generalizes Theorem A.) The total number of balanced trees with height h is $B_h = B_h(1)$, which satisfies the recurrence

$$B_0 = B_1 = 1, \qquad B_{h+1} = B_h^2 + 2B_hB_{h-1}, \tag{7}$$

so that $B_2 = 3$, $B_3 = 3 \cdot 5$, $B_4 = 3^2 \cdot 5 \cdot 7$, $B_5 = 3^3 \cdot 5^2 \cdot 7 \cdot 23$; and, in general,

$$B_h = A_0^{F_h} \cdot A_1^{F_{h-1}} \cdot \ldots \cdot A_{h-1}^{F_1} \cdot A_h^{F_0}, \tag{8}$$

where $A_0 = 1$, $A_1 = 3$, $A_2 = 5$, $A_3 = 7$, $A_4 = 23$, $A_5 = 347$, $\ldots$, $A_h = A_{h-1}B_{h-2} + 2$. The sequences B_h and A_h grow very rapidly, in fact, they are "doubly exponential": Exercise 7 shows that there is a real number $\theta \approx 1.43684$ such that

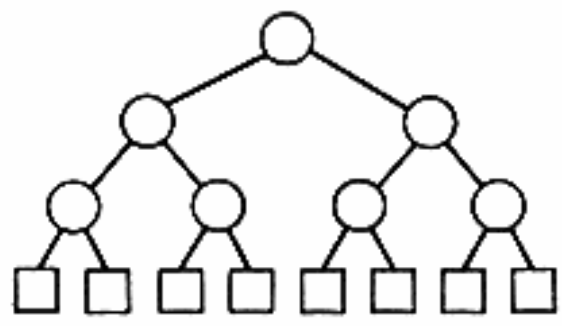
$$B_h = \lfloor \theta^{2^h} \rfloor - \lfloor \theta^{2^{h-1}} \rfloor + \lfloor \theta^{2^{h-2}} \rfloor - \cdots + (-1)^h \lfloor \theta^{2^0} \rfloor. \tag{9}$$

If we consider each of the B_h trees to be equally likely, exercise 8 shows that the average number of nodes in a tree of height h is

$$B_h'(1)/B_h(1) \approx (0.70118)2^h. \tag{10}$$

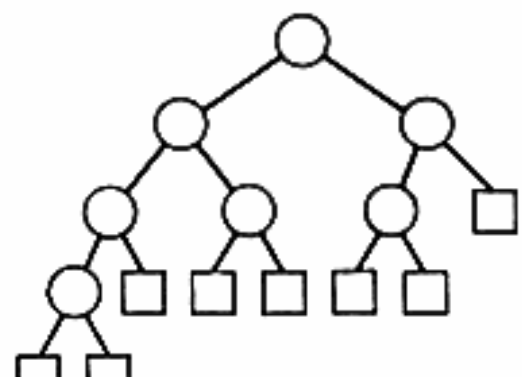
This indicates that the height of a balanced tree with n nodes usually is much closer to $\log_2 n$ than to $\log_\phi n$.

Unfortunately, none of these results have much to do with Algorithm A, since the mechanism of that algorithm makes some trees much more probable than others. For example, consider the case $N = 7$, where 17 balanced trees are possible. There are $7! = 5040$ possible orderings in which seven keys can be inserted, and the perfectly balanced "complete" tree,



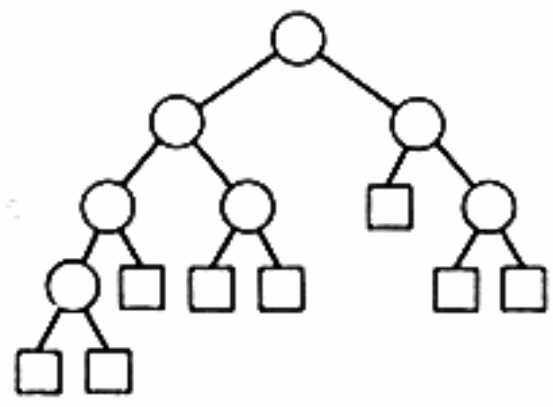
(11)

is obtained 2160 times. By contrast, the Fibonacci tree,



(12)

occurs only 144 times, and the similar tree,



(13)

occurs 216 times. [Replacing the left subtrees of (12) and (13) by arbitrary four-node balanced trees, and then reflecting left and right, yields 16 different trees; the eight generated from (12) each occur 144 times, and those generated from (13) each occur 216 times. It is somewhat surprising that (13) is more common than (12).]

The fact that the perfectly balanced tree is obtained with such high probability—together with (10), which corresponds to the case of equal probabilities—makes it extremely plausible that the average search time for a balanced tree is about $\log_2 N + c$ comparisons for some small constant c. Empirical tests support this conjecture: The average number of comparisons needed to insert the Nth item seems to be approximately $\log_2 N + 0.25$ for large N.

In order to study the behavior of the insertion and rebalancing phases of Algorithm A, we can classify the external nodes of balanced trees as shown in

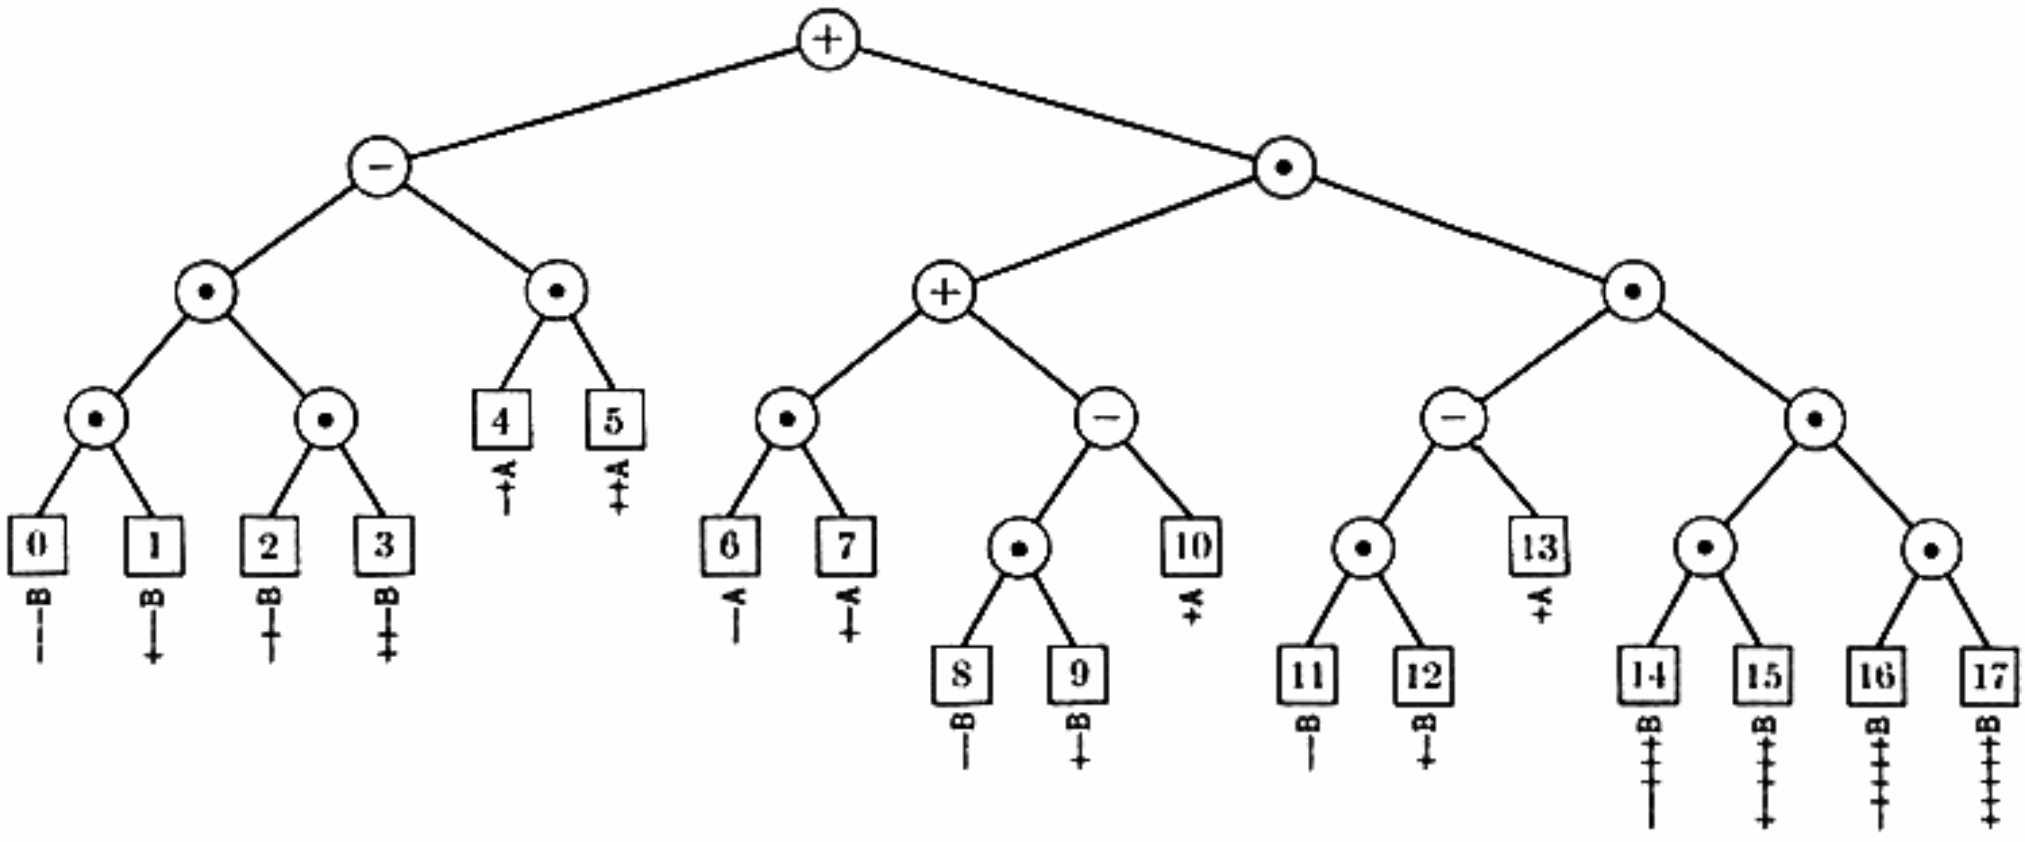


Fig. 23. Classification codes which specify the behavior of Algorithm A after insertion.

Fig. 23. The path leading up from an external node can be specified by a sequence of +'s and −'s (+ for a right link, − for a left link); we write down the link specifications until reaching the first node with a nonzero balance factor, or until reaching the root, if there is no such node. Then we write A or B according as the new tree will be balanced or unbalanced when an internal node is inserted in the given place. Thus the path up from [3] is ++−B, meaning "right link, right link, left link, unbalance." A specification ending in A requires no rebalancing after insertion of a new node; a specification ending in ++B or −−B requires a single rotation; and a specification ending in +−B or −+B requires a double rotation. When k links appear in the specification, step A6 has to adjust exactly $k - 1$ balance factors. Thus the specifications give the essential facts governing the running time of steps A6 to A10.

Empirical tests on random numbers for $100 \leq N \leq 2000$ gave the approximate probabilities shown in Table 1 for paths of various types; apparently these probabilities rapidly approach limiting values as $N \to \infty$. Table 2 gives the exact probabilities corresponding to Table 1 when $N = 10$, considering the 10! permutations of the input as equally probable.

Table 1

APPROXIMATE PROBABILITIES FOR INSERTING THE NTH ITEM

Path length k	No rebalancing	Single rotation	Double rotation
1	.144	.000	.000
2	.153	.144	.144
3	.093	.048	.048
4	.058	.023	.023
5	.036	.010	.010
> 5	.051	.008	.007
ave 2.8	.535	.233	.232

Table 2

EXACT PROBABILITIES FOR INSERTING THE 10TH ITEM

Path length k	No rebalancing	Single rotation	Double rotation
1	1/7	0	0
2	6/35	1/7	1/7
3	4/21	2/35	2/35
4	0	1/21	1/21
ave	247/105	53/105	26/105	26/105

From Table 1 we can see that k is ≤ 2 with probability $.144 + .153 + .144 + .144 = .585$; thus, step A6 is quite simple almost 60 percent of the time. The average number of balance factors changed from 0 to ± 1 in that step is about 1.8. The average number of balance factors changed from ± 1 to 0 in steps A7 through A10 is $.535 + 2(.233 + .232) = 1.5$; thus, inserting one new node adds about .3 unbalanced nodes, on the average. This agrees with the fact that about 68 percent of all nodes were found to be balanced in random trees built by Algorithm A.

An approximate model of the behavior of Algorithm A has been proposed by C. C. Foster [*Proc. ACM Nat. Conf.* **20** (1965), 192–205]. This model is not rigorously accurate, but it is close enough to the truth to give some insight. Let us assume that p is the probability that the balance factor of a given node in a large tree built by Algorithm A is 0; then the balance factor is $+1$ with probability $\frac{1}{2}(1 - p)$, and it is -1 with the same probability $\frac{1}{2}(1 - p)$. Let us assume further (without justification) that the balance factors of all nodes are independent. Then the probability that step A6 sets exactly $k - 1$ balance factors nonzero is $p^{k-1}(1 - p)$, so the average value of $k - 1$ is $p/(1 - p)$. The probability that we need to rotate part of the tree is $\frac{1}{2}$. Inserting a new node should increase the number of balanced nodes by p, on the average; this number is actually increased by 1 in step A5, by $-p/(1 - p)$ in step A6, by $\frac{1}{2}$ in step A7, and by $\frac{1}{2} \cdot 2$ in step A8 or A9, so we should have

$$p = 1 - p/(1 - p) + \tfrac{1}{2} + 1.$$

Solving for p yields fair agreement with Table 1:

$$p = \frac{9 - \sqrt{41}}{4} \approx 0.649; \qquad p/(1 - p) \approx 1.851. \tag{14}$$

The running time of the search phase of Program A (lines 01–19) is

$$10C + C1 + 2D + 2 - 3S, \tag{15}$$

where C, $C1$, S are the same as in previous algorithms of this chapter and D is the number of unbalanced nodes encountered on the search path. Empirical

tests show that we may take $D \approx \frac{1}{3}C, C1 \approx \frac{1}{2}(C+S), C+S \approx \log_2 N + 0.25$, so the average search time is approximately $11.17 \log_2 N + 4.8 - 13.7S$ units. (If searching is done much more often than insertion, we could of course use a separate, faster program for searching, since it would be unnecessary to look at the balance factors; the average running time for a successful search would then be only about $(6.5 \log_2 N + 4.1)u$, and the worst case running time would in fact be better than the average running time obtained with Algorithm 6.2.2T.)

The running time of the insertion phase of Program A (lines 20–45) is $8F + 26 +$ (0, 1, or 2) units, when the search is unsuccessful. The data of Table 1 indicate that $F \approx 1.8$ on the average. The rebalancing phase (lines 46–101) takes either 16.5, 8, 27.5, or 45.5 (± 0.5) units, depending on whether we increase the total height, or simply exit without rebalancing, or do a single or double rotation. The first case almost never occurs, and the others occur with the approximate probabilities .535, .233, .232, so the average running time of the combined insertion-rebalancing portion of Program A is about $63u$.

These figures indicate that maintenance of a balanced tree in memory is reasonably fast, even though the program is rather lengthy. If the input data are random, the simple tree insertion algorithm of Section 6.2.2 is roughly $50u$ faster per insertion; but the balanced tree algorithm is guaranteed to be reliable even with nonrandom input data.

One way to compare Program A with Program 6.2.2T is to consider the worst case of the latter. If we study the amount of time necessary to insert N keys in increasing order into an initially empty tree, it turns out that Program A is slower for $N \leq 26$ and faster for $N \geq 27$.

Linear list representation. Now let us return to the claim made at the beginning of this section, that balanced trees can be used to represent linear lists in such a way that we can insert items rapidly (overcoming the difficulty of sequential allocation), yet we can also perform random accesses to list items (overcoming the difficulty of linked allocation).

The idea is to introduce a new field in each node, called the RANK field. This field indicates the relative position of that node in its subtree, i.e., one plus the

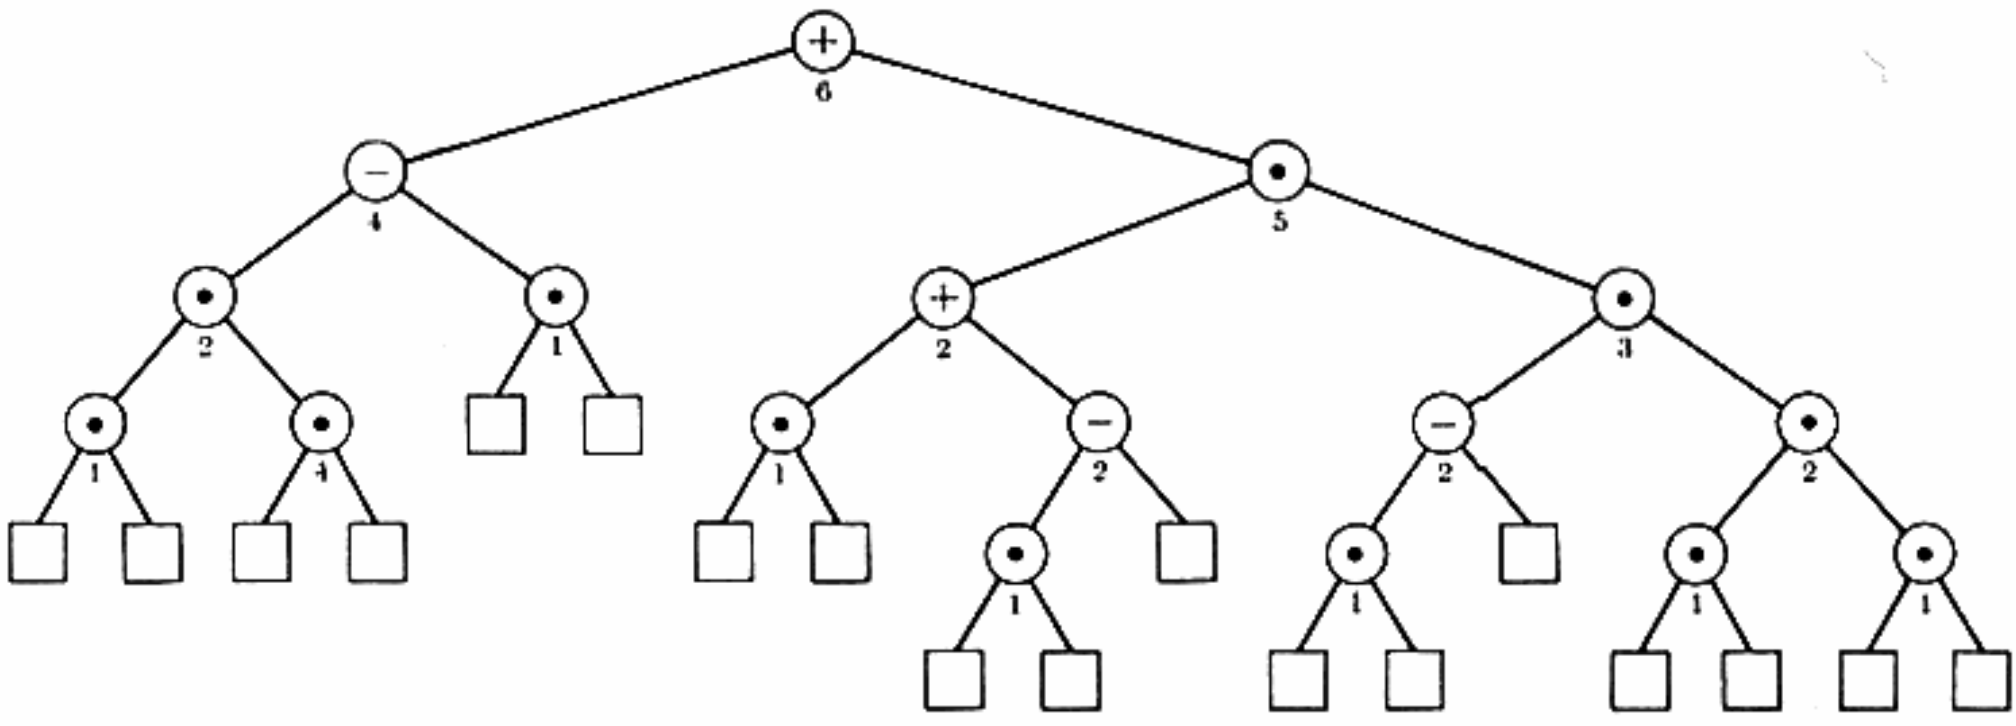

Fig. 24. RANK fields, used for searching by position.

number of nodes in its left subtree. Figure 24 shows the RANK values for the binary tree of Fig. 23. We can eliminate the KEY field entirely; or, if desired, we can have both KEY and RANK fields, so that it is possible to retrieve items either by their key value or by their relative position in the list.

Using such a RANK field, retrieval by position is a straightforward modification of the search algorithms we have been studying.

Algorithm B (*Tree search by position*). Given a linear list represented as a binary tree, this algorithm finds the kth element of the list (the kth node of the tree in symmetric order), given k. The binary tree is assumed to have LLINK and RLINK fields and a header as in Algorithm A, plus a RANK field as described above.

B1. [Initialize.] Set $\texttt{M} \leftarrow k$, $\texttt{P} \leftarrow \texttt{RLINK(HEAD)}$.

B2. [Compare.] If $\texttt{P} = \Lambda$, the algorithm terminates unsuccessfully. (This can happen only if k was greater than the number of nodes in the tree, or $k \leq 0$.) Otherwise if $\texttt{M} < \texttt{RANK(P)}$, go to B3; if $\texttt{M} > \texttt{RANK(P)}$, go to B4; and if $\texttt{M} = \texttt{RANK(P)}$, the algorithm terminates successfully (P points to the kth node).

B3. [Move left.] Set $\texttt{P} \leftarrow \texttt{LLINK(P)}$ and return to B2.

B4. [Move right.] Set $\texttt{M} \leftarrow \texttt{M} - \texttt{RANK(P)}$ and $\texttt{P} \leftarrow \texttt{RLINK(P)}$ and return to B2. ∎

The only new point of interest in this algorithm is the manipulation of M in step B4. We can modify the insertion procedure in a similar way, although the details are somewhat trickier:

Algorithm C (*Balanced tree insertion by position*). Given a linear list represented as a balanced binary tree, this algorithm inserts a new node just before the kth element of the list, given k and a pointer Q to the new node. If $k = N + 1$, the new node is inserted just after the last element of the list.

The binary tree is assumed to be nonempty and to have LLINK, RLINK, and B fields and a header, as in Algorithm A, plus a RANK field as described above. This algorithm is merely a transcription of Algorithm A; the difference is that it uses and updates the RANK fields instead of the KEY fields.

C1. [Initialize.] Set $\texttt{T} \leftarrow \texttt{HEAD}$, $\texttt{S} \leftarrow \texttt{P} \leftarrow \texttt{RLINK(HEAD)}$, $\texttt{U} \leftarrow \texttt{M} \leftarrow k$.

C2. [Compare.] If $\texttt{M} \leq \texttt{R(P)}$, go to C3, otherwise go to C4.

C3. [Move left.] Set $\texttt{RANK(P)} \leftarrow \texttt{RANK(P)} + 1$ (we will be inserting a new node to the left of P). Set $\texttt{R} \leftarrow \texttt{LLINK(P)}$. If $\texttt{R} = \Lambda$, set $\texttt{LLINK(P)} \leftarrow \texttt{Q}$ and go to C5. Otherwise if $\texttt{B(R)} \neq 0$ set $\texttt{T} \leftarrow \texttt{P}$, $\texttt{S} \leftarrow \texttt{R}$, and $\texttt{U} \leftarrow \texttt{M}$. Finally set $\texttt{P} \leftarrow \texttt{R}$ and return to C2.

C4. [Move right.] Set $\texttt{M} \leftarrow \texttt{M} - \texttt{RANK(P)}$, and $\texttt{R} \leftarrow \texttt{RLINK(P)}$. If $\texttt{R} = \Lambda$, set $\texttt{RLINK(P)} \leftarrow \texttt{Q}$ and go to C5. Otherwise if $\texttt{B(R)} \neq 0$ set $\texttt{T} \leftarrow \texttt{P}$, $\texttt{S} \leftarrow \texttt{R}$, and $\texttt{U} \leftarrow \texttt{M}$. Finally set $\texttt{P} \leftarrow \texttt{R}$ and return to C2.

C5. [Insert.] Set $\texttt{RANK(Q)} \leftarrow 1$, $\texttt{LLINK(Q)} \leftarrow \texttt{RLINK(Q)} \leftarrow \Lambda$, $\texttt{B(Q)} \leftarrow 0$.

C6. [Adjust balance factors.] Set M ← U. (This restores the former value of M when P was S; all RANK fields are now properly set.) If M < RANK(S), set R ← P ← LLINK(S), otherwise set R ← P ← RLINK(S) and M ← M − RANK(S). Then repeatedly do the following operation until P = Q: If M < RANK(P), set B(P) ← −1 and P ← LLINK(P); if M > RANK(P), set B(P) ← +1 and M ← M − RANK(P) and P ← RLINK(P). (If M = RANK(P), then P = Q and we may go on to the next step.)

C7. [Balancing act.] If U < RANK(S), set $a \leftarrow -1$, otherwise set $a \leftarrow +1$. Several cases now arise:

i) If B(S) = 0, set B(S) ← a, LLINK(HEAD) ← LLINK(HEAD) + 1, and terminate the algorithm.

ii) If B(S) = $-a$, set B(S) ← 0 and terminate the algorithm.

iii) If B(S) = a, go to step C8 if B(R) = a, to C9 if B(R) = $-a$.

C8. [Single rotation.] Set P ← R, LINK(a, S) ← LINK($-a$, R), LINK($-a$, R) ← S, B(S) ← B(R) ← 0. If $a = +1$, set RANK(R) ← RANK(R) + RANK(S); if $a = -1$, set RANK(S) ← RANK(S) − RANK(R).

C9. [Double rotation.] Do all the operations of step A9 (Algorithm A). Then if $a = +1$, set RANK(R) ← RANK(R) − RANK(P), RANK(P) ← RANK(P) + RANK(S); if $a = -1$, set RANK(P) ← RANK(P) + RANK(R), then RANK(S) ← RANK(S) − RANK(P).

C10. [Finishing touch.] If S = RLINK(T) then set RLINK(T) ← P, otherwise set LLINK(T) ← P. ∎

***Deletion, concatenation, etc.** It is possible to do many other things to balanced trees and maintain the balance, but the algorithms are sufficiently lengthy that the details are beyond the scope of this book. We shall discuss the general ideas here, and an interested reader will be able to fill in the details without much difficulty.

The problem of deletion can be solved in $O(\log N)$ steps if we approach it correctly [C. C. Foster, "A Study of AVL Trees," Goodyear Aerospace Corp. report *GER*-12158 (April, 1965)]. In the first place we can reduce deletion of an arbitrary node to the simple deletion of a node P for which LLINK(P) or RLINK(P) is Λ, as in Algorithm 6.2.2D. The algorithm should also be modified so that it constructs a list of pointers which specifies the path to node P, namely

$$(P_0, a_0), \quad (P_1, a_1), \quad \ldots, \quad (P_l, a_l), \tag{16}$$

where P_0 = HEAD, $a_0 = +1$; LINK(a_i, P_i) = P_{i+1}, for $0 \le i < l$; P_l = P; and LINK(a_l, P_l) = Λ. This list can be placed on an auxiliary stack as we search down the tree. The process of deleting node P sets LINK(a_{l-1}, P_{l-1}) ← LINK($-a_l$, P_l), and we must adjust the balance factor at node P_{l-1}. Suppose that we need to adjust the balance factor at node P_k, because the a_k subtree of this node has just decreased in height; the following adjustment procedure should be used: If $k = 0$, set LLINK(HEAD) ← LLINK(HEAD) − 1 and terminate the algorithm, since the whole tree has decreased in height. Otherwise look at

the balance factor $B(P_k)$; there are three cases:

i) $\texttt{B}(P_k) = a_k$. Set $\texttt{B}(P_k) \leftarrow 0$, decrease k by 1, and repeat the adjustment procedure for this new value of k.

ii) $\texttt{B}(P_k) = 0$. Set $\texttt{B}(P_k)$ to $-a_k$ and terminate the deletion algorithm.

iii) $\texttt{B}(P_k) = -a_k$. Rebalancing is required!

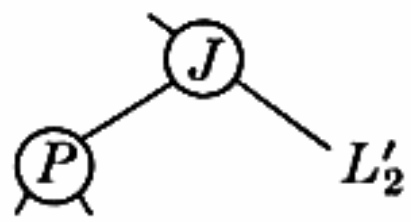
The situations requiring rebalancing are almost the same as we met in the insertion algorithm; referring again to (1), A is node P_k, and B is node $\texttt{LINK}(-a_k, P_k)$, the *opposite* branch from where the deletion has occurred. The only new feature is that node B might be balanced; this leads to a new Case 3 which is like Case 1 except that β has height $h + 1$. In Cases 1 and 2, rebalancing as in (2) means that we decrease the height, so we set $\texttt{LINK}(a_{k-1}, P_{k-1})$ to the root of (2), decrease k by 1, and restart the adjustment procedure for this new value of k. In Case 3 we do a single rotation, and this leaves the balance factors of both A and B nonzero without changing the overall height; after making $\texttt{LINK}(a_{k-1}, P_{k-1})$ point to node B, we therefore terminate the algorithm.

The important difference between deletion and insertion is that deletion might require up to $\log N$ rotations, while insertion never needs more than one. The reason for this becomes clear if we try to delete the rightmost node of a Fibonacci tree (see Fig. 8 in Section 6.2.1).

The use of balanced trees for linear list representation suggests also the need for a *concatenation* algorithm, where we want to insert an entire tree L_2 to the right of tree L_1, without destroying the balance. An elegant algorithm for concatenation has been devised by Clark A. Crane: Assume that $\text{height}(L_1) \geq \text{height}(L_2)$; the other case is similar. Delete the first node of L_2, calling it the "juncture node" J, and let L_2' be the new tree for $L_2 \backslash \{J\}$. Now go down the right links of L_1 until reaching a node P such that

$$\text{height}(P) - \text{height}(L_2') = 0 \text{ or } 1;$$

this is always possible, since the height changes by 1 or 2 each time we go down one level. Then replace (P) by



and proceed to adjust L_1 as if the new node J had just been inserted by Algorithm A.

Crane has also solved the more difficult inverse problem, to *split* a list into two parts whose concatenation would be the original list. Consider, for example, the problem of splitting the list in Fig. 20 to obtain two lists, one containing $\{\texttt{A}, \ldots, \texttt{I}\}$ and the other containing $\{\texttt{J}, \ldots, \texttt{Q}\}$; a major reassembly of the subtrees is required. In general, when we want to split a tree at some given node P, the path to P will be something like that in Fig. 25. We wish to con-

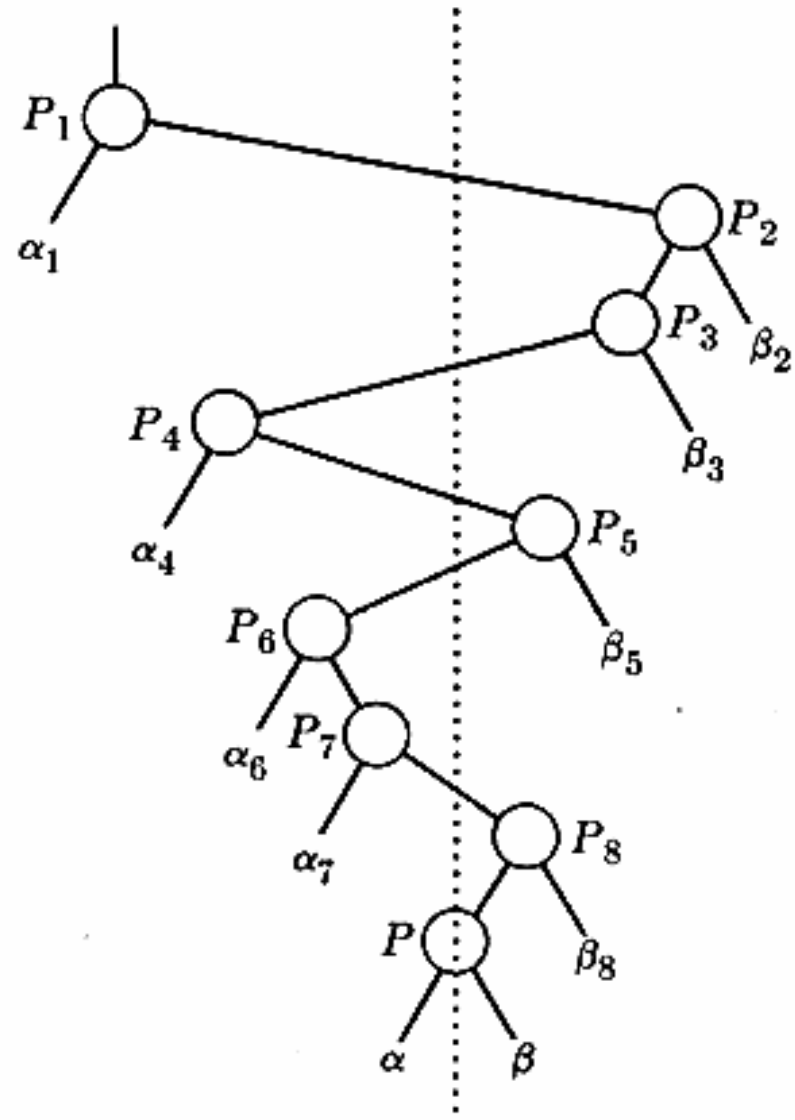


Fig. 25. The problem of splitting a list.

struct a left tree which contains the nodes of $\alpha_1, P_1, \alpha_4, P_4, \alpha_6, P_6, \alpha_7, P_7, \alpha, P$ in symmetric order, and a right tree containing $\beta, P_8, \beta_8, P_5, \beta_5, P_3, \beta_3, P_2, \beta_2$. This can be done by a sequence of concatenations: First insert P at the right of α, then concatenate β with β_8 using P_8 as juncture node, concatenate α_7 with αP using P_7 as juncture node, α_6 with $\alpha_7 P_7 \alpha P$ using P_6, $\beta P_8 \beta_8$ with β_5 using P_5, etc.; the nodes $P_8, P_7, \ldots, P_1$ on the path to P are used as juncture nodes. Crane has proved that this splitting algorithm takes only $O(\log N)$ units of time, when the original tree contains N nodes; the essential reason is that concatenation using a given juncture node takes $O(k)$ steps, where k is the difference in heights between the trees being concatenated, and the values of k that must be summed essentially form a telescoping series for both the left and right trees being constructed.

All of these algorithms can be used with either KEY or RANK fields or both (although in the case of concatenation the keys of L_2 must all be greater than the keys of L_1). For general purposes it is often preferable to use a *triply-linked tree*, with UP links as well as LLINKs and RLINKs, together with a new one-bit field which specifies whether a node is the left or right son of its father. The triply-linked tree representation simplifies the algorithms slightly, and makes it possible to specify nodes in the tree without explicitly tracing the path to that node; we can write a subroutine to delete NODE(P), given P, or to delete the NODE(P$) which follows P in symmetric order, or to find the list containing NODE(P), etc. In the deletion algorithm for triply-linked trees it is unnecessary to construct the list (16), since the UP links provide the information we need. Of course a triply-linked tree requires that a few more links be changed when insertions, deletions, and rotations are being performed. The use of a triply-

linked tree instead of a doubly-linked tree is analogous to the use of two-way linking instead of one-way: we can start at any point and go either forward or backward. A complete description of list algorithms based on triply-linked balanced trees appears in Clark A. Crane's Ph.D. thesis (Stanford University, 1972).

Alternatives to balanced trees. Some other ways of organizing trees, so as to guarantee logarithmic accessing time, have recently been proposed. At the present time they have not yet been studied very thoroughly; it is possible that they may prove to be superior to balanced trees on some computers.

The interesting concept of *weight-balanced tree* has been studied by J. Nievergelt, E. Reingold, and C. K. Wong. Instead of considering the height of trees, we stipulate that the subtrees of all nodes must satisfy

$$\sqrt{2} - 1 < \frac{\text{left weight}}{\text{right weight}} < \sqrt{2} + 1, \tag{17}$$

where the left and right weights count the number of *external* nodes in the left and right subtrees, respectively. It is possible to show that weight-balance can be maintained under insertion, using only single and double rotations for rebalancing as in Algorithm A (see exercise 25). However, it may be necessary to do many rebalancings during a single insertion. It is possible to relax the conditions of (17), decreasing the amount of rebalancing at the expense of increased search time.

Weight-balanced trees may seem at first glance to require more memory than plain balanced trees, but in fact they sometimes require slightly less! If we already have a RANK field in each node, for the linear list representation, this is precisely the left weight, and it is possible to keep track of the corresponding right weights as we move down the tree. However, it appears that the bookkeeping required for maintaining weight balance takes more time than Algorithm A, and this small savings of two bits per node is probably not worth the trouble.

Another interesting alternative to balanced trees, called "3-2 trees," was introduced by John Hopcroft in 1970 (unpublished). The idea is to have either 2-way or 3-way branching at each node, and to stipulate that all external nodes appear on the same level. Every internal node contains either one or two keys, as shown in Fig. 26.

Insertion into a 3-2 tree is somewhat easier to explain than insertion into a balanced tree: If we want to put a new key into a node that contains just one

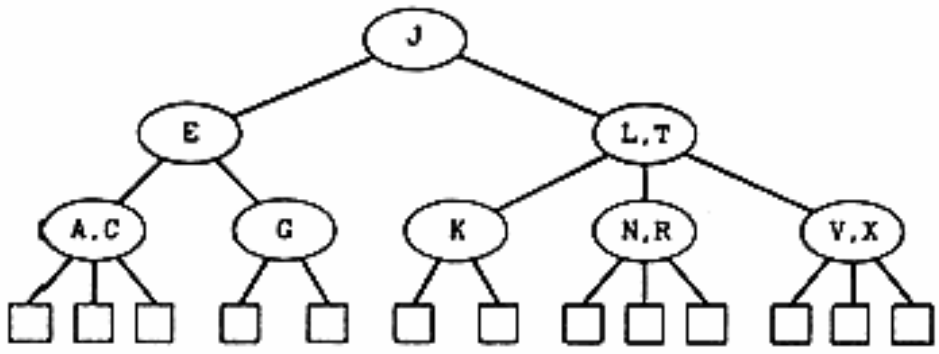

Fig. 26. A 3-2 tree.

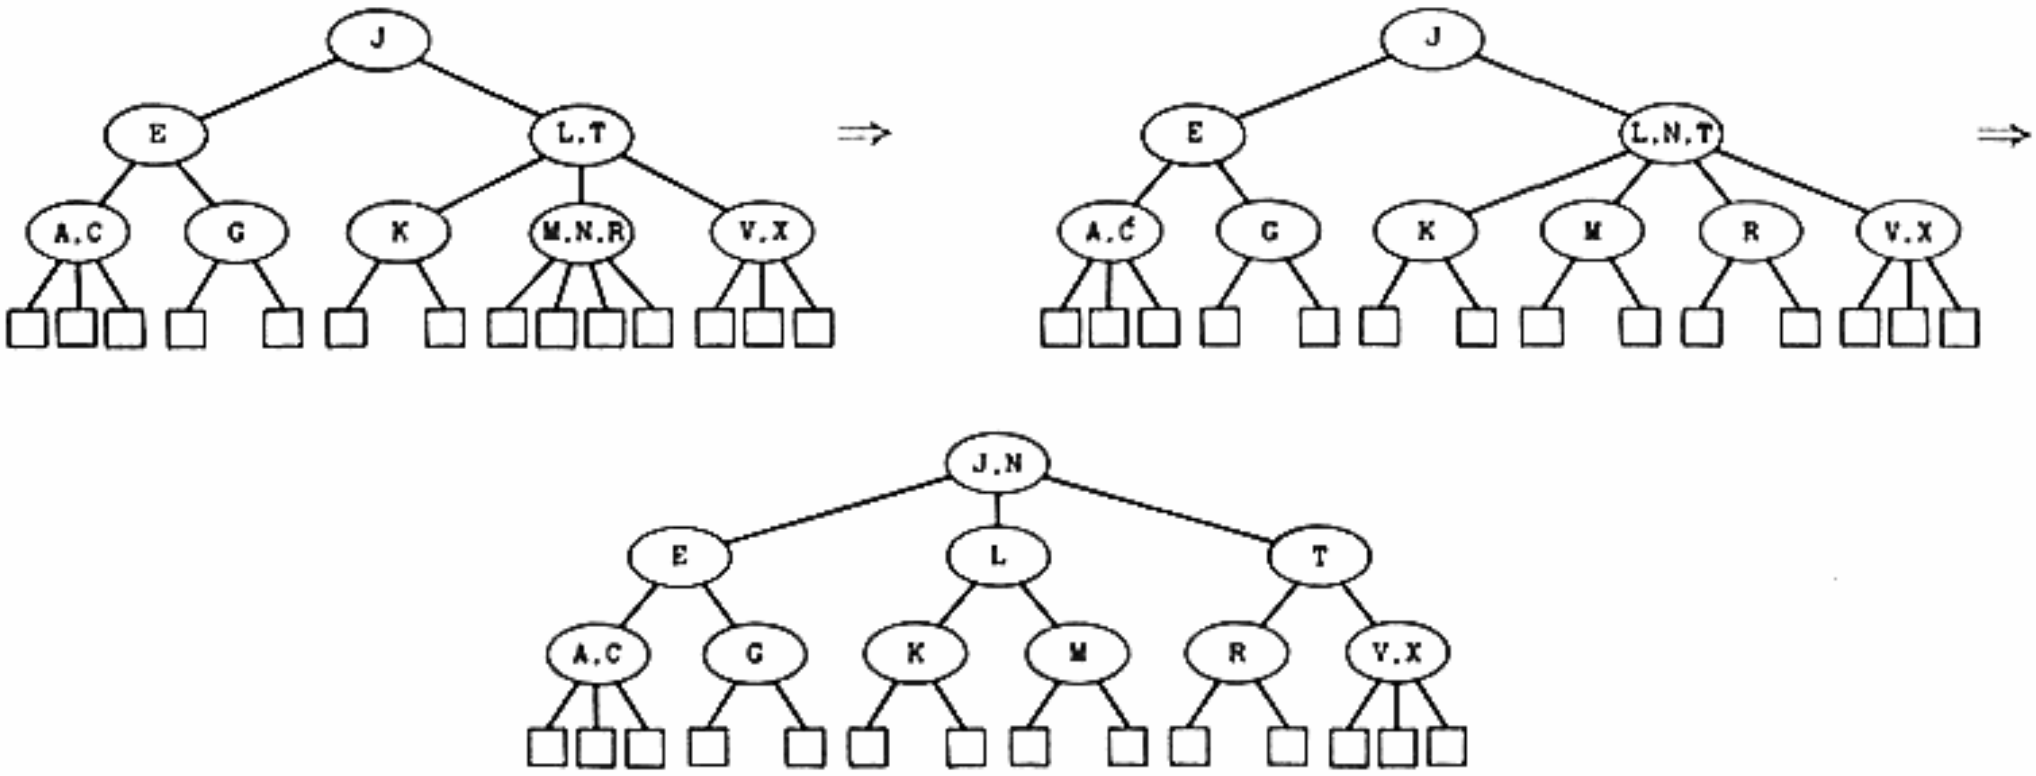

Fig. 27. Inserting the new key "M" into the 3-2 tree of Fig. 26.

key, we simply insert it as the second key. On the other hand, if the node already contains two keys, we divide it into two one-key nodes, and insert the middle key into the parent node. This may cause the parent node to be divided in a similar way, if it already contains two keys. Figure 27 shows the process of inserting a new key into the 3-2 tree of Fig. 26.

Hopcroft has observed that deletion, concatenation, and splitting can all be done with 3-2 trees, in a reasonably straightforward manner analogous to the corresponding operations with balanced trees.

R. Bayer [*Proc. ACM-SIGFIDET Workshop* (1971), 219–235] has suggested an interesting binary tree representation for 3-2 trees. See Fig. 28, which shows the binary tree representation of Fig. 26; one bit in each node is used to distinguish "horizontal" RLINKs from "vertical" ones. Note that the keys of the tree appear from left to right in symmetric order, just as in any binary search tree. It turns out that the transformations we need to perform on such a binary tree, while inserting a new key as in Fig. 27, are precisely the single and double rotations used while inserting a new key into a balanced tree, although we need just one version of each rotation (not the left-right reflections as in Algorithms A and C).

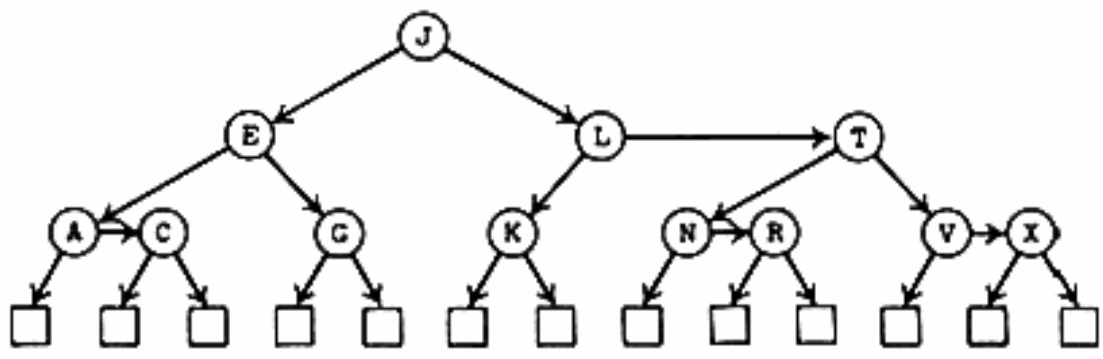

Fig. 28. The 3-2 tree of Fig. 26 represented as a binary search tree.

EXERCISES

1. [*01*] In Case 2 of (1), why isn't it a good idea to restore the balance by simply interchanging the left subtrees of A and B?

2. [*16*] Explain why the tree has gotten one level higher if we reach step A7 with B(S) = 0.

▸ **3.** [*M25*] Prove that a balanced tree with N internal nodes never contains more than $(\phi - 1)N = 0.61803\,N$ nodes whose balance factor is nonzero.

4. [*M22*] Prove or disprove: Among all balanced trees with $F_{n+1} - 1$ internal nodes, the Fibonacci tree of order n has the greatest internal path length.

▸ **5.** [*M25*] Prove or disprove: If Algorithm A is used to insert N keys into an initially empty tree, and if these keys arrive in increasing order, the tree produced is always *optimum* (i.e., it has minimum internal path length over all N-node binary trees).

6. [*M21*] Prove that Eq. (5) defines the generating function for balanced trees of height h.

7. [*M27*] (N. J. A. Sloane and A. V. Aho.) Prove the remarkable formula (9) for the number of balanced trees of height h. [*Hint:* Let $C_n = B_n + B_{n-1}$, and use the fact that $\log (C_{n+1}/C_n^2)$ is exceedingly small for large n.]

8. [*M24*] (L. A. Khizder.) Show that there is a constant β such that $B_h'(1)/B_h(1) - 2^h\beta \to 1$ as $h \to \infty$.

9. [*M47*] What is the asymptotic number of balanced binary trees with n internal nodes, $\sum_{h\geq 0} B_{nh}$? What is the asymptotic average height, $\sum_{h\geq 0} hB_{nh}/\sum_{h\geq 0} B_{nh}$?

10. [*M48*] Does Algorithm A make an average of $\sim\log_2 N + c$ comparisons to insert the Nth item, for some constant c?

▸ **11.** [*22*] The value .144 appears three times in Table 1, once for $k = 1$ and twice for $k = 2$. The value $\frac{1}{7}$ appears in the same three places in Table 2. Is it a coincidence that the same value should appear in all three places, or is there some good reason for this?

▸ **12.** [*24*] What is the maximum possible running time of Program A when the eighth node is inserted into a balanced tree? What is the minimum possible running time for this insertion?

13. [*10*] Why is it better to use RANK fields as defined in the text, instead of simply to store the index of each node as its key (calling the first node "1", the second node "2", and so on)?

14. [*11*] Could Algorithms 6.2.2T and 6.2.2D be adapted to work with linear lists, using a RANK field, just as the balanced tree algorithms of this section have been so adapted?

15. [*18*] (C. A. Crane.) Suppose that an ordered linear list is being represented as a binary tree, with both KEY and RANK fields in each node. Design an algorithm which searches the tree for a given key, K, and determines the position of K in the list; i.e., it finds the number M such that K is the Mth smallest key.

▸ **16.** [*20*] Draw the balanced tree that would be obtained if the root node F were deleted from Fig. 20, using the deletion algorithm suggested in the text.

▸ **17.** [*21*] Draw the balanced trees that would be obtained if the Fibonacci tree (12) were concatenated (a) to the right, (b) to the left, of the tree in Fig. 20, using the concatenation algorithm suggested in the text.

18. [*21*] Draw the balanced trees that would be obtained if Fig. 20 were split into two parts {A, . . . , I} and {J, . . . , Q}, using the splitting algorithm suggested in the text.

▸**19.** [*26*] Find a way to transform a given balanced tree so that the balance factor at the root is not -1. Your transformation should preserve the symmetric order of the nodes; and it should produce another balanced tree in $O(1)$ units of time, regardless of the size of the original tree.

20. [*40*] Explore the idea of using the restricted class of balanced trees whose nodes all have balance factors of 0 or $+1$. (Then the length of the B field can be reduced to one bit.) Is there a reasonably efficient insertion procedure for such trees?

▸**21.** [*30*] Design an algorithm which constructs optimum N-node binary trees (in the sense of exercise 5), in $O(N)$ steps. Your algorithm should be "on line," in the sense that it inputs the nodes one by one in increasing order and builds partial trees as it goes, without knowing the final value of N in advance. (It would be appropriate to use such an algorithm when restructuring a badly balanced tree, or when merging the keys of two trees into a single tree.)

22. [*M20*] What is the analog of Theorem A, for weight-balanced trees?

23. [*M20*] (E. Reingold.) (a) Prove that there exist balanced trees whose weight balance (left weight)/(right weight) is arbitrarily small. (b) Prove that there exist weight-balanced trees having arbitrarily large differences between left and right subtree heights.

24. [*M22*] (E. Reingold.) Prove that if we strengthen condition (17) to

$$\frac{1}{2} < \frac{\text{left weight}}{\text{right weight}} < 2,$$

the only binary trees which satisfy this condition are perfectly balanced trees with $2^n - 1$ internal nodes. (In such trees, the left and right weights are exactly equal at all nodes.)

25. [*27*] (J. Nievergelt, E. Reingold, C. Wong.) Show that it is possible to design an insertion algorithm for weight-balanced trees so that condition (17) is preserved, making at most $O(\log N)$ rotations per insertion.

26. [*40*] Explore the properties of balanced t-ary trees, for $t > 2$.

▸**27.** [*M23*] Estimate the maximum number of comparisons needed to search in a 3-2 tree with N internal nodes.

28. [*41*] Prepare efficient implementations of 3-2 tree algorithms.

29. [*M47*] Analyze the average behavior of 3-2 trees under random insertions.

30. [*26*] (E. McCreight.) Section 2.5 discusses several strategies for dynamic storage allocation, including "best-fit" (choosing an available area as small as possible from among all those which fulfill the request) and "first-fit" (choosing the available area with lowest address among all those that fulfill the request). Show that if the available space is linked together as a balanced tree in an appropriate way, it is possible to do (a) best-fit (b) first-fit allocation in only $O(\log n)$ units of time, where n is the number of available areas. (The algorithms given in Section 2.5 take order n steps.)

6.2.4. Multiway Trees

The tree search methods we have been discussing were developed primarily for internal searching, when we want to look at a table that is contained entirely within a computer's high-speed internal memory. Let's now consider the prob-

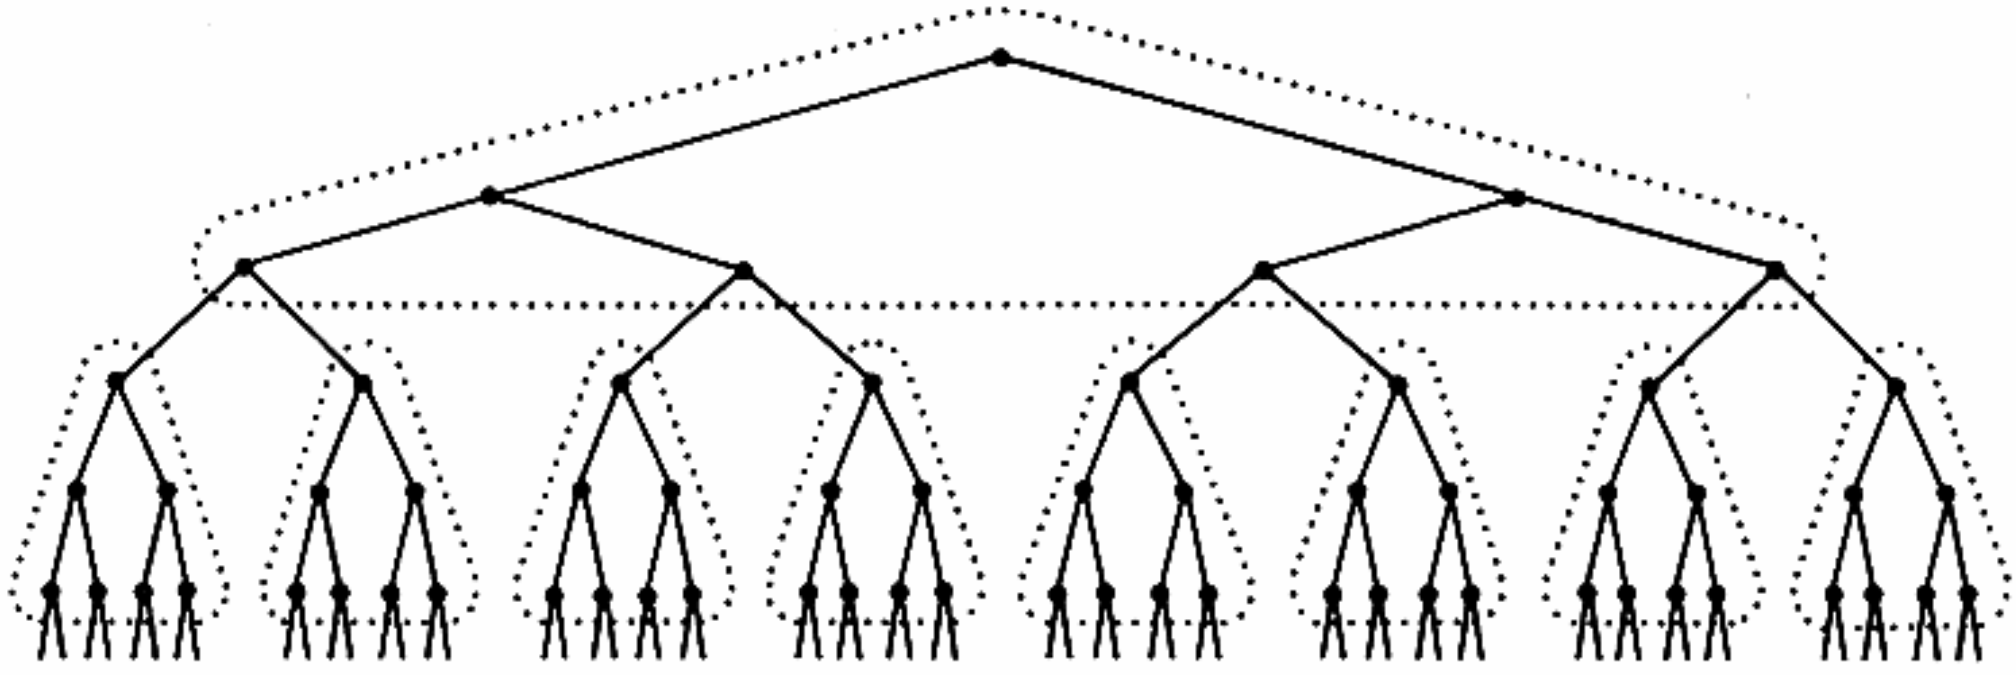

Fig. 29. A large binary search tree can be divided into "pages."

lem of *external* searching, when we want to retrieve information from a very large file that appears on direct access storage units such as disks or drums. (An introduction to disks and drums appears in Section 5.4.9.)

Tree structures lend themselves nicely to external searching, if we choose an appropriate way to represent the tree. Consider the large binary search tree shown in Fig. 29, and imagine that it has been stored in a disk file. (The LLINKs and RLINKs of the tree are now disk addresses instead of internal memory addresses.) If we search this tree in a naïve manner, simply applying the algorithms we have learned for internal tree searching, we will have to make about $\log_2 N$ disk accesses before our search is complete. When N is a million, this means we will need 20 or so seeks. But suppose we divide the table into 7-node "pages," as shown by the dotted lines in Fig. 29; if we access one page at a time, we need only about one third as many seeks, so the search goes about three times as fast!

Grouping the nodes into pages in this way essentially changes the tree from a binary tree to an octonary tree, with 8-way branching at each page-node. If we let the pages be still larger, with 128-way branching after each disk access, we can find any desired key in a million-entry table after looking at only three pages. We can keep the root page in the internal memory at all times, so that only two references to the disk are required even though we never have more than 254 keys in the internal memory at any time.

Of course we don't want to make the pages arbitrarily large, since the internal memory size is limited and also since it takes a longer time to read in a larger page. For example, suppose that it takes $72.5 + 0.05m$ milliseconds to read a page that allows m-way branching. The internal processing time per page will be about $a + b \log m$, where a is small compared to 72.5 ms, so the total amount of time needed for searching a large table is approximately proportional to $\log N$ times

$$(72.5 + 0.05m)/\log m + b.$$

This quantity achieves a minimum when $m \approx 350$; actually the minimum is very "broad," a nearly optimum value is achieved for all m between 200 and 500. In practice there will be a similar range of good values for m, based on

the characteristics of particular external memory devices and on the length of the records in the table.

W. I. Landauer [*IEEE Trans.* **EC-12** (1963), 863–871] suggested building an m-ary tree by requiring level l to become nearly full before anything is allowed to appear on level $l + 1$. This scheme requires a rather complicated rotation method, since we may have to make major changes throughout the tree just to insert a single new item; Landauer was assuming that we need to search for items in the tree much more often than we need to insert or delete them.

When a file is stored on disk, and is subject to comparatively few insertions and deletions, a three-level tree is appropriate, where the first level of branching determines what cylinder is to be used, the second level of branching determines the appropriate track on that cylinder, and the third level contains the records themselves. This method is called *indexed-sequential* file organization [cf. *JACM* **16** (1969), 569–571].

R. Muntz and R. Uzgalis [*Proc. Princeton Conf. on Inf. Sciences and Systems* **4** (1970), 345–349] have suggested modifying the tree search and insertion method, Algorithm 6.2.2T, so that all insertions go onto nodes belonging to the same page as their father node, whenever possible; if that page is full, a new page is started, whenever possible. If the number of pages is unlimited, and if the data arrives in random order, it can be shown that the average number of page accesses is approximately $H_N/(H_m - 1)$, only slightly more than we would obtain in the best possible m-ary tree. (See exercise 10.)

B-trees. A new approach to external searching by means of multiway tree branching was discovered in 1970 by R. Bayer and E. McCreight [*Acta Informatica* (1972), 173–189], and independently at about the same time by M. Kaufman [unpublished]. Their idea, based on a versatile new kind of data structure called a *B-tree*, makes it possible both to search and to update a large file with "guaranteed" efficiency, in the worst case, using comparatively simple algorithms.

A *B-tree of order m* is a tree which satisfies the following properties:

i) Every node has $\leq m$ sons.

ii) Every node, except for the root and the leaves, has $\geq m/2$ sons.

iii) The root has at least 2 sons (unless it is a leaf).

iv) All leaves appear on the same level, and carry no information.

v) A nonleaf node with k sons contains $k - 1$ keys.

(As usual, a "leaf" is a terminal node, one with no sons. Since the leaves carry no information, we may regard them as external nodes which aren't really in the tree, so that Λ is a pointer to a leaf.)

Figure 30 shows a B-tree of order 7. Each node (except for the root and the leaves) has between $\lceil 7/2 \rceil$ and 7 sons, so it contains 3, 4, 5, or 6 keys. The root node is allowed to contain from 1 to 6 keys; in this case it has 2. All of the leaves are at level 3. Note that (a) the keys appear in increasing order from

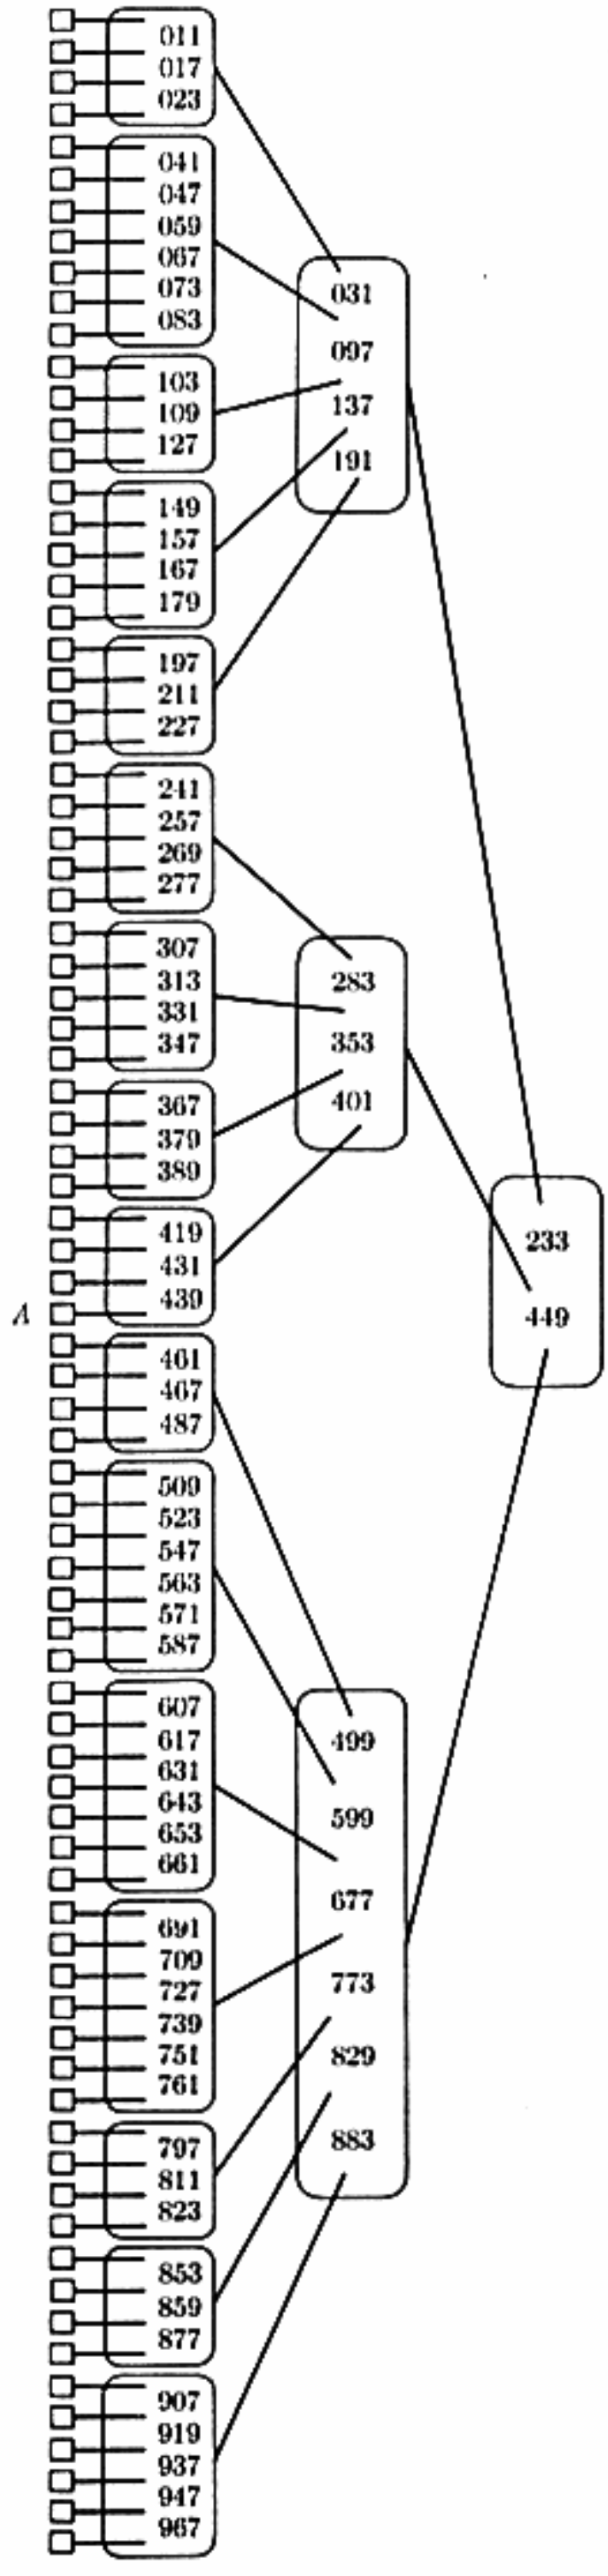

Fig. 30. A B-tree of order 7, with all leaves on level 3.

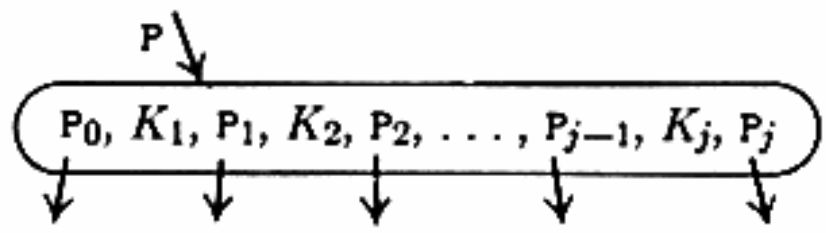
left to right, using a natural extension of the concept of symmetric order; and (b) the number of leaves is exactly one greater than the number of keys.

B-trees of order 1 or 2 are obviously uninteresting, so we will consider only the case $m \geq 3$. Note that "3-2 trees," defined at the close of Section 6.2.3, are *B*-trees of order 3; and conversely, a *B*-tree of order 3 is a 3-2 tree.

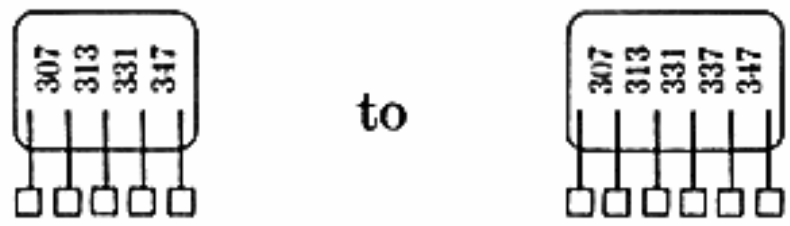
A node which contains j keys and $j + 1$ pointers can be represented as



(1)

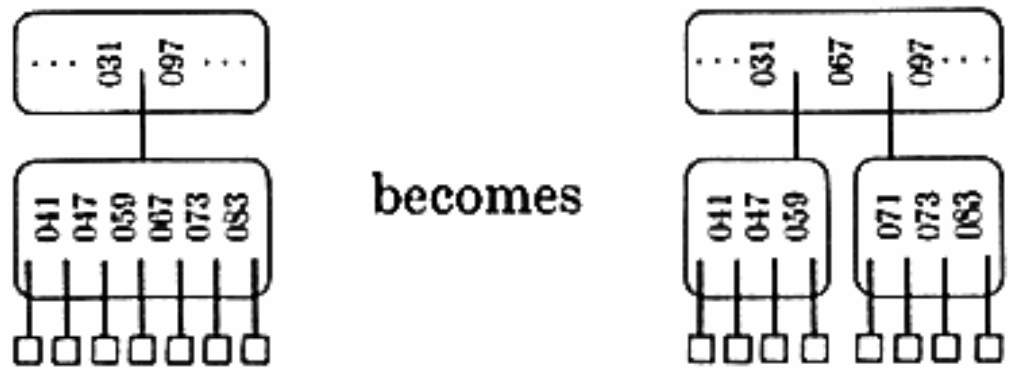
where $K_1 < K_2 < \cdots < K_j$ and $\mathtt{P}_i$ points to the subtree for keys between K_i and K_{i+1}. Therefore searching in a *B*-tree is quite straightforward: After node (1) has been fetched into the internal memory, we search for the given argument among the keys $K_1, K_2, \ldots, K_j$. (When j is large, we probably do a binary search; but when j is smallish, a sequential search is best.) If the search is successful, we have found the desired key; but if the search is unsuccessful because the argument lies between K_i and K_{i+1}, we fetch the node indicated by $\mathtt{P}_i$ and continue the process. The pointer $\mathtt{P}_0$ is used if the argument is less than K_1, and $\mathtt{P}_j$ is used if the argument is greater than K_j. If $\mathtt{P}_i = \Lambda$, the search is unsuccessful.

The nice thing about *B*-trees is that insertion is also quite simple. Consider Fig. 30, for example; every leaf corresponds to a place where a new insertion might happen. If we want to insert the new key 337, we simply change the appropriate node from



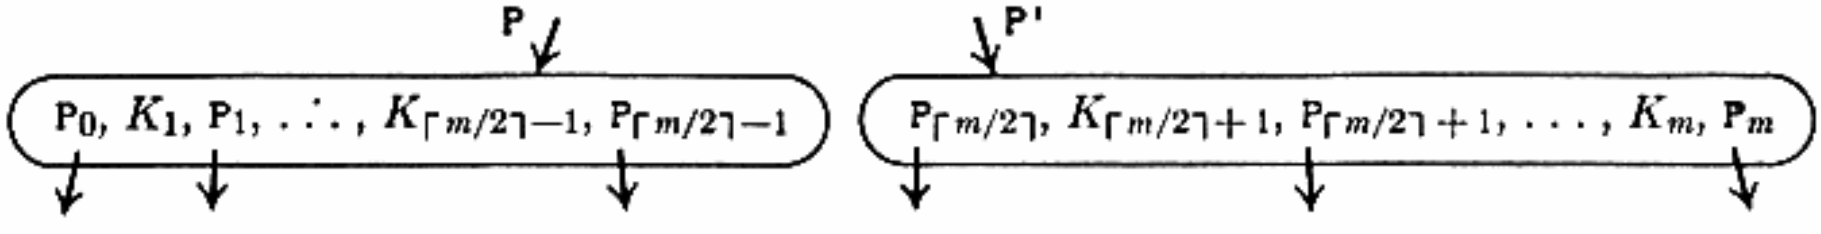
(2)

On the other hand, if we want to insert the new key 071, there is no room since the corresponding node on level 2 is already "full." This case can be handled by splitting the node into two parts, with three keys in each part, and passing the middle key up to level 1:



(3)

In general, if we want to insert a new item into a *B*-tree of order m, when all the leaves are at level l, we insert the new key into the appropriate node on level $l - 1$. If that node now contains m keys, so that it has the form (1) with $j = m$, we split it into two nodes



(4)

and insert the key $K_{\lceil m/2 \rceil}$ into the father of the original node. (Thus the pointer P in the father node is replaced by the sequence P, $K_{\lceil m/2 \rceil}$, P′.) This insertion may cause the father node to contain m keys, and if so, it should be split in the same way. (Cf. Fig. 27, which shows the case $m = 3$.) If we need to split the root node, which has no father, we simply create a new root node containing the single key $K_{\lceil m/2 \rceil}$; the tree gets one level taller in this case.

This insertion procedure neatly preserves all of the B-tree properties; in order to appreciate the full beauty of the idea, the reader should work exercise 1. Note that the tree more or less grows up from the top, instead of down from the bottom, since it gains in height only when the root splits.

Deletion from B-trees is only slightly more complicated than insertion (see exercise 7).

Upper bounds on the performance. Let us now see how many nodes have to be accessed in the worst case, while searching in a B-tree of order m. Suppose that there are N keys, and that the $N + 1$ leaves appear on level l. Then the number of nodes on levels 1, 2, 3, . . . is at least 2, $2\lceil m/2 \rceil$, $2\lceil m/2 \rceil^2$, . . .; hence

$$N + 1 \geq 2 \lceil m/2 \rceil^{l-1}. \tag{5}$$

In other words,

$$l \leq 1 + \log_{\lceil m/2 \rceil} \left(\frac{N+1}{2} \right); \tag{6}$$

this means, for example, that if $N = 1{,}999{,}998$ and $m = 199$, then l is at most 3. Since we need to access at most l nodes during a search, this formula guarantees that the running time is quite small.

When a new node is being inserted, we may have to split as many as l nodes. However, the average number of nodes that need to be split is much less, since the total number of splittings that occur while the entire tree is being constructed is just one less than the total number of nodes in the tree. If there are p nodes, there are at least $1 + (\lceil m/2 \rceil - 1)(p - 1)$ keys; hence

$$p \leq 1 + \frac{N-1}{\lceil m/2 \rceil - 1}. \tag{7}$$

It follows that the average number of times we need to split a node is less than $1/(\lceil m/2 \rceil - 1)$ split per insertion!

Refinements and variations. There are several ways to improve upon the basic B-tree structure defined above, by breaking the rules a little.

In the first place, we note that all of the pointers in the level $l - 1$ nodes are Λ, and none of the pointers in the other levels are Λ. This often represents a significant amount of wasted space, so we can save both time and space by eliminating all the Λ's and using a different value of m for all of the "bottom"

nodes. This use of two different m's does not foul up the insertion algorithm, since both halves of a node that is being split remain on the same level as the original node. We could in fact define a generalized B-tree of orders m_1, m_2, m_3, . . . by requiring all nonroot nodes on level $l - i$ to have between $m_i/2$ and m_i sons; such a B-tree has different m's on each level, yet the insertion algorithm still works essentially as before.

To carry the idea in the preceding paragraph even further, we might use a completely different node format in each level of the tree, and we might also store information in the leaves. Sometimes the keys form only a small part of the records in a file, and in such cases it is a mistake to store the entire records in the branch nodes near the root of the tree; this would make m too small for efficient multiway branching.

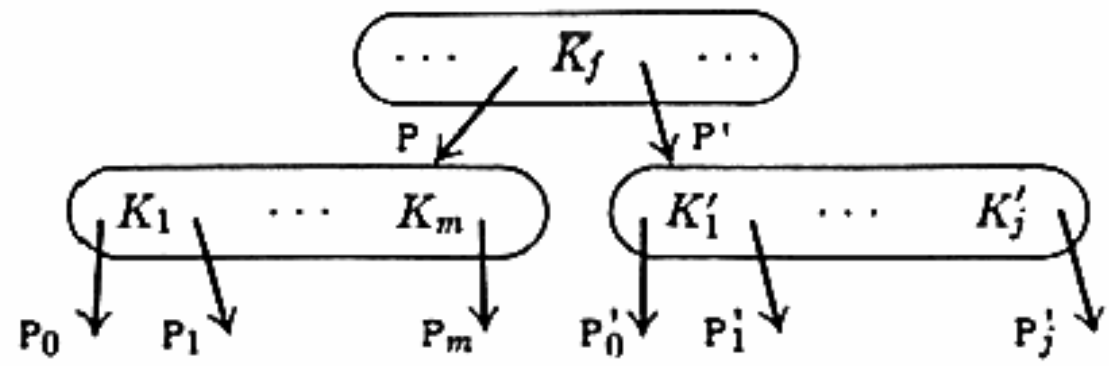
We can therefore reconsider Fig. 30, imagining that all the records of the file are now stored in the leaves, and that only a few of the keys have been duplicated in the branch nodes. Under this interpretation, the leftmost leaf contains all records whose key is ≤ 011; the leaf marked A contains all records whose key satisfies $439 < K \leq 449$; and so on. Under this interpretation the leaf nodes grow and split just as the branch nodes do, except that a record is never passed up from a leaf to the next level. Thus the leaves are always at least half filled to capacity. A new key enters the nonleaf part of the tree whenever a leaf splits. If each leaf is linked to its successor in symmetric order, we gain the ability to traverse the file both sequentially and randomly in an efficient and convenient manner.

Some calculations by S. P. Ghosh and M. E. Senko [*JACM* **16** (1969), 569–579] suggest that it might be a good idea to make the leaves fairly large, say up to about 10 consecutive pages long. By linear interpolation in the known range of keys for each leaf, we can guess which of the 10 pages probably contains a given search argument. If our guess is wrong, we lose time, but experiments indicate that this loss might be less than the time we save by decreasing the size of the tree.

T. H. Martin [unpublished] has pointed out that the idea underlying B-trees can be used also for *variable-length* keys. We need not put bounds $[m/2, m]$ on the number of sons of each node, instead we can say merely that each node should be at least about half full of data. The insertion and splitting mechanism still works fine, even though the exact number of keys per node depends on whether the keys are long or short. However, the keys shouldn't be allowed to get extremely long, or they can mess things up. (See exercise 5.)

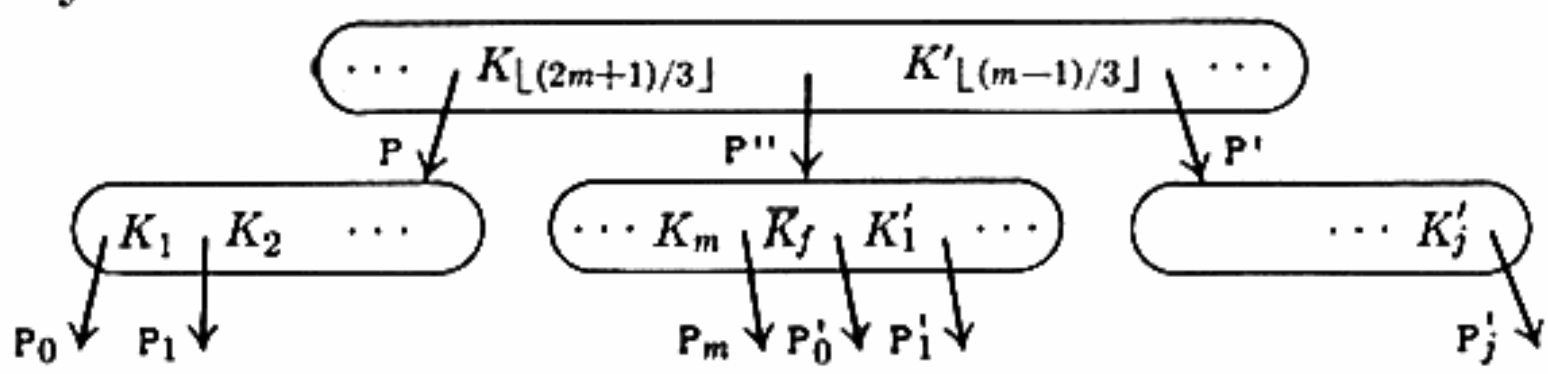
Another important modification to the basic B-tree scheme is the idea of "overflow" introduced by Bayer and McCreight. The idea is to improve the insertion algorithm by resisting its temptation to split nodes so often; a local rotation is used instead. Suppose we have a node that is over-full because it contains m keys and $m + 1$ pointers; instead of splitting it, we can look first at its brother node on the right, which has say j keys and $j + 1$ pointers. In

the father node there is a key $\overline{K}_f$ which separates the keys of the two brothers; schematically,



(8)

If $j < m - 1$, a simple rearrangement makes splitting unnecessary: we leave $\lfloor (m+j)/2 \rfloor$ keys in the left node, we replace $\overline{K}_f$ by $K_{\lfloor (m+j)/2 \rfloor + 1}$ in the father node, and we put the $\lceil (m+j)/2 \rceil$ remaining keys (including $\overline{K}_f$) and the corresponding pointers into the right node. Thus the full node "flows over" into its brother node. On the other hand, if the brother node is already full ($j = m - 1$), we can split *both* of the nodes, making three nodes each about two-thirds full, containing, respectively, $\lfloor (2m-2)/3 \rfloor$, $\lfloor (2m-1)/3 \rfloor$, and $\lfloor 2m/3 \rfloor$ keys:



(9)

If the original node has no right brother, we can look at its left brother in essentially the same way. (If the original node has both a right and a left brother, we could even refrain from splitting off a new node unless *both* left and right brothers are full.) Finally if the original node to be split has no brothers at all, it must be the root; we can change the definition of B-tree, allowing the root to contain as many as $2\lfloor (2m-2)/3 \rfloor$ keys, so that when the root splits it produces two nodes of $\lfloor (2m-2)/3 \rfloor$ keys each.

The effect of all the technicalities in the preceding paragraph is to produce a superior breed of tree, say a B^*-tree of order m, which can be defined as follows:

i) Every node except the root has at most m sons.

ii) Every node, except for the root and the leaves, has $\geq (2m-1)/3$ sons.

iii) The root has at least 2 and at most $2\lfloor (2m-2)/3 \rfloor + 1$ sons.

iv) All leaves appear on the same level.

v) A nonleaf node with k sons contains $k - 1$ keys.

The important change is condition (ii), which asserts that we utilize at least two-thirds of the available space in every node. This change not only uses space more efficiently, it also makes the search process faster, since we may replace "$\lceil m/2 \rceil$" by "$\lceil (2m-1)/3 \rceil$" in (6) and (7).

Perhaps the reader has been skeptical of B-trees because the degree of the root can be as low as 2. Why should we waste a whole disk access on merely a 2-way decision?! A simple buffering scheme, called "least-recently-used page

replacement," overcomes this objection; we can keep several bufferloads of information in the internal memory, so that input commands can be avoided when the corresponding page is already present. Under this scheme, the algorithms for searching or insertion issue "virtual read" commands that are translated into actual input instructions only when the necessary page is not in memory; a subsequent "release" command is issued when the buffer has been read and possibly modified by the algorithm. When an actual read is required, the buffer which has least recently been released is chosen; we write out that buffer, if its contents have changed since they were read in, then we read the desired page into the chosen buffer.

Since the number of levels in the tree is generally small compared to the number of buffers, this paging scheme will ensure that the root page is always present in memory; and if the root has only 2 or 3 sons, the first level pages will probably stay there too. Some special mechanism could be incorporated to ensure that a certain minimum number of pages near the root are always present. Note that the least-recently-used scheme implies that the pages that might need to be split during an insertion are automatically in memory when they are needed.

Some experiments by E. McCreight have shown that this idea is quite successful. For example, he found that with 10 page-buffers and $m = 121$, the process of inserting 100,000 keys in ascending order required only 22 actual read commands, and only 857 actual write commands; thus most of the activity took place in the internal memory. Furthermore the tree contained only 835 nodes, just one higher than the minimum possible value $\lceil 100000/(m-1) \rceil = 834$; thus the storage utilization was nearly 100 percent. For this experiment he used the overflow technique, but with only 2-way node splitting as in (4), not 3-way splitting as in (9). (See exercise 3.)

In another experiment, again with 10 buffers and $m = 121$ and the overflow technique, he inserted 5000 keys into an initially empty tree, in *random* order; this produced a 2-level tree with 48 nodes (87 percent storage utilization), after making 2762 actual reads and 2739 actual writes. Then 1000 random searches required 786 actual reads. The same experiment *without* the overflow feature produced a 2-level tree with 62 nodes (67 percent storage utilization), after making 2743 actual reads and 2800 actual writes; 1000 subsequent random searches required 836 actual reads. This shows not only that the paging scheme is effective but also that it is wise to handle overflows locally before deciding to split a node.

EXERCISES

1. [*10*] What B-tree of order 7 is obtained after the key 613 is inserted into Fig. 30? (Do not use the "overflow" technique.)

2. [*15*] Work exercise 1, but use the overflow technique, with 3-way splitting as in (9).

▸ **3.** [*23*] Suppose we insert the keys 1, 2, 3, . . . in ascending order into an initially empty B-tree of order 101. Which key causes the leaves to be on level 4 for the first time, (a) when we use no overflow; (b) when we use overflow and only 2-way splitting as in (4); (c) when we use a B^*-tree of order 101, with overflow and 3-way splitting as in (9)?

4. [*21*] (Bayer and McCreight.) Explain how to handle insertions into a generalized B-tree so that all nodes except the root and leaves will be guaranteed to have at least $\frac{3}{4}m - \frac{1}{2}$ sons.

▸ **5.** [*21*] Suppose that a node represents 1000 character positions of external memory. If each pointer takes up 5 characters, and if the keys are variable in length, between 5 and 50 characters long, what is the minimum number of character positions occupied in a node after it splits during an insertion? (Consider only a simple splitting procedure analogous to that described in the text for fixed-length-key B-trees, without "overflowing.")

6. [*22*] Can the B-tree idea be used to retrieve items of a linear list by position instead of by key value? (Cf. Algorithm 6.2.3B)

7. [*23*] Design a deletion algorithm for B-trees.

8. [*28*] Design a concatenation algorithm for B-trees (cf. Section 6.2.3).

9. [*30*] Discuss how a large file, organized as a B-tree, can be used for multiple accessing and updating by a large number of simultaneous users, in such a way that users of different pages rarely interfere with each other.

10. [*HM37*] Consider the generalization of tree insertion suggested by Muntz and Uzgalis, where each page can hold M keys. After N random items have been inserted into such a tree, so that there are $N+1$ external nodes, let $b_{Nk}^{(\mathcal{O})}$ be the probability that an unsuccessful search requires k page accesses and that it ends at an external node whose father node belongs to a page containing j keys. If $B_N^{(\mathcal{O})}(z) = \sum b_{Nk}^{(\mathcal{O})} z^k$ is the corresponding generating function, prove that $B_1^{(\mathcal{O})}(z) = \delta_{j1} z$;

$$B_N^{(\mathcal{O})}(z) = \frac{N-j-1}{N+1} B_{N-1}^{(\mathcal{O})}(z) + \frac{j+1}{N+1} B_{N-1}^{(\mathcal{O}-1)}(z), \quad \text{for} \quad 1 < j < M;$$

$$B_N^{(1)}(z) = \frac{N-2}{N+1} B_{N-1}^{(1)}(z) + \frac{2z}{N+1} B_{N-1}^{(M)}(z);$$

$$B_N^{(M)}(z) = \frac{N-1}{N+1} B_{N-1}^{(M)}(z) + \frac{M+1}{N+1} B_{N-1}^{(M-1)}(z).$$

Find the asymptotic behavior of $C'_N = \sum_{1 \le j \le M} B_N^{(\mathcal{O})\prime}(1)$, the average number of page accesses per unsuccessful search. [*Hint:* Express the recurrence in terms of the matrix

$$\mathbf{W}(z) = \begin{pmatrix} -3 & 0 & \dots & 0 & 2z \\ 3 & -4 & \dots & 0 & 0 \\ 0 & 4 & \dots & 0 & 0 \\ \vdots & \vdots & & \vdots & \vdots \\ 0 & 0 & \dots & -M-1 & 0 \\ 0 & 0 & \dots & M+1 & -2 \end{pmatrix},$$

and relate C'_N to an Nth degree polynomial in $\mathbf{W}(1)$.]

Instead of basing a search method on comparisons between keys, we can make use of their representation as a sequence of digits or alphabetic characters. Consider, for example, the "thumb-index" on a large dictionary; from the first letter of a given word, we can immediately locate the pages which contain all words beginning with that letter.

If we pursue the thumb-index idea to one of its logical conclusions, we come up with a searching scheme based on repeated "subscripting" as illustrated in Table 1. Suppose that we want to test a given search argument to see whether it is one of the 31 most common words of English (cf. Figs. 12 and 13 in Section 6.2.2). The data is represented in Table 1 as a so-called "trie" structure; this name was suggested by E. Fredkin [*CACM* **3** (1960), 490–500] because it is a part of information re*trie*val. A trie is essentially an M-ary tree, whose nodes are M-place vectors with components corresponding to digits or characters. Each node on level l represents the set of all keys that begin with a certain sequence of l characters; the node specifies an M-way branch, depending on the $(l + 1)$st character.

For example, the trie of Table 1 has 12 nodes; node (1) is the root, and we look up the first letter here. If the first letter is, say, N, the table tells us that our word must be NOT (or else it isn't in the table). On the other hand, if the first letter is W, node (1) tells us to go on to node (9), looking up the second letter in the same way; node (9) says that the second letter should be A, H, or I.

The node vectors in Table 1 are arranged according to MIX character code. This means that a trie search will be quite fast, since we are merely fetching words of an array by using the characters of our keys as subscripts. Techniques for making quick multiway decisions by subscripting have been called "Table Look-At" as opposed to "Table Look-Up" [see P. M. Sherman, *CACM* **4** (1961), 172–173, 175].

Algorithm T (*Trie search*). Given a table of records which form an M-ary trie, this algorithm searches for a given argument K. The nodes of the trie are vectors whose subscripts run from 0 to $M - 1$; each component of these vectors is either a key or a link (possibly null).

T1. [Initialize.] Set the link variable P so that it points to the root of the tree.

T2. [Branch.] Set k to the next character of the input argument, K, from left to right. (If the argument has been completely scanned, we set k to a "blank" or end-of-word symbol. The character should be represented as a number in the range $0 \le k < M$.) Let X be table entry number k in NODE(P). If X is a link, go to T3; but if X is a key, go to T4.

T3. [Advance.] If $X \neq \Lambda$, set P $\leftarrow X$ and return to step T2; otherwise the algorithm terminates unsuccessfully.

T4. [Compare.] If $K = X$, the algorithm terminates successfully; otherwise it terminates unsuccessfully. ∎

Note that if the search is unsuccessful, the *longest match* has been found. This property is occasionally useful in applications.

In order to compare the speed of this algorithm to the others in this chapter, we can write a short MIX program assuming that the characters are bytes and that the keys are at most five bytes long.

Program T (*Trie search*). This program assumes that all keys are represented in one MIX word, with blank spaces at the right whenever the key has less than

five characters. Since we use the MIX character code, each byte of the search argument is assumed to contain a number less than 30. Links are represented as negative numbers in the 0:2 field of a node word. rI1 ≡ P, rX ≡ unscanned part of K.

```
01    START   LDX    K            1    T1. Initialize.
02            ENT1   ROOT         1    P ← pointer to root of trie.
03    2H      SLAX   1            C    T2. Branch.
04            STA    *+1(2:2)     C    Extract next character, k.
05            ENT2   0,1          C    Q ← P + k.
06            LD1N   0,2(0:2)     C    P ← LINK(Q).
07            J1P    2B           C    T3. Advance. To T2 if P is a link ≠ Λ.
08            LDA    0,2          1    T4. Compare. rA ← KEY(Q).
09            CMPA   K            1
10            JE     SUCCESS      1    Exit successfully if rA = K.
11    FAILURE EQU    *                 Exit if not in the trie. ∎
```

The running time of this program is $8C + 8$ units, where C is the number of characters examined. Since $C \leq 5$, the search will never take more than 48 units of time.

If we now compare the efficiency of this program (using the trie of Table 1) to Program 6.2.2T (using the *optimum* binary search tree of Fig. 13), we can make the following observations:

1. The trie takes much more memory space; we are using 360 words just to represent 31 keys, while the binary search tree uses only 62 words of memory. (However, exercise 4 shows that, with some fiddling around, we can actually fit the trie of Table 1 into only 55 words.)

2. A successful search takes about 26 units of time for both programs. But an unsuccessful search will go faster in the trie, slower in the binary search tree. For this data the search will be unsuccessful more often than it is successful, so the trie is preferable from the standpoint of speed.

3. If we consider the KWIC indexing application of Fig. 15 instead of the 31 commonest English words, the trie loses its advantage because of the nature of the data. For example, a trie requires 12 iterations to distinguish between COMPUTATION and COMPUTATIONS. (In this case it would be better to build the trie so that words are scanned from right to left instead of from left to right.)

The idea of trie memory was first published by Rene de la Briandais [*Proc. Western Joint Computer Conf.* **15** (1959), 295–298]. He pointed out that we can save memory space at the expense of running time if we use a linked list for each node vector, since most of the entries in the vectors tend to be empty. In effect, this idea amounts to replacing the trie of Table 1 by the forest of trees shown in Fig. 31. Searching in such a forest proceeds by finding the root which matches the first character, then finding the son node of that root which matches the second character, etc.

In his article, de la Briandais did not actually stop the tree branching exactly as shown in Table 1 or Fig. 31; instead, he continued to represent each key, character by character, until reaching the end-of-word delimiter. Thus he

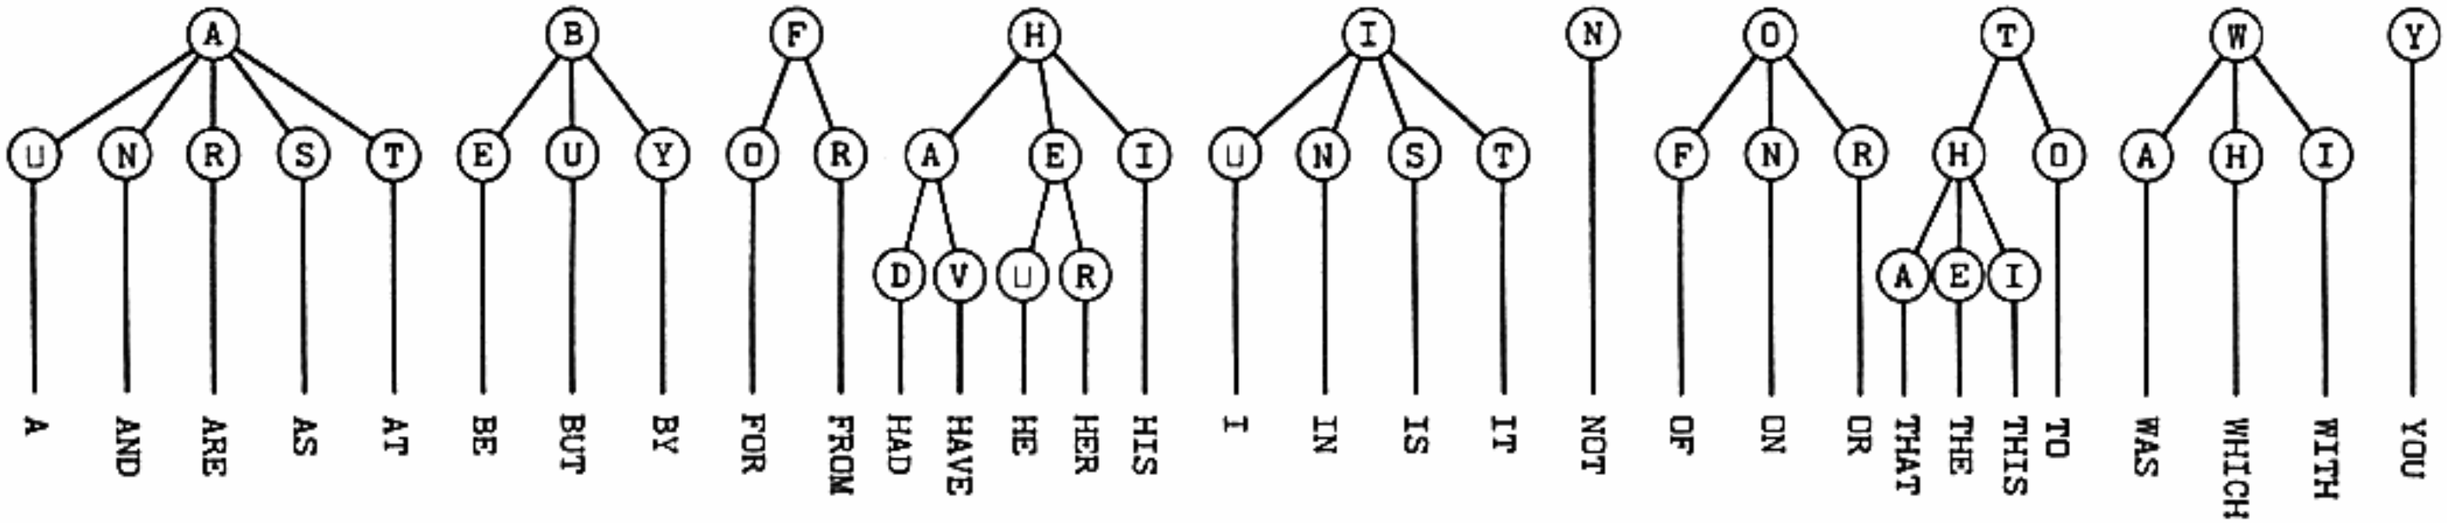

Fig. 31. The trie of Table 1, converted into a "forest."

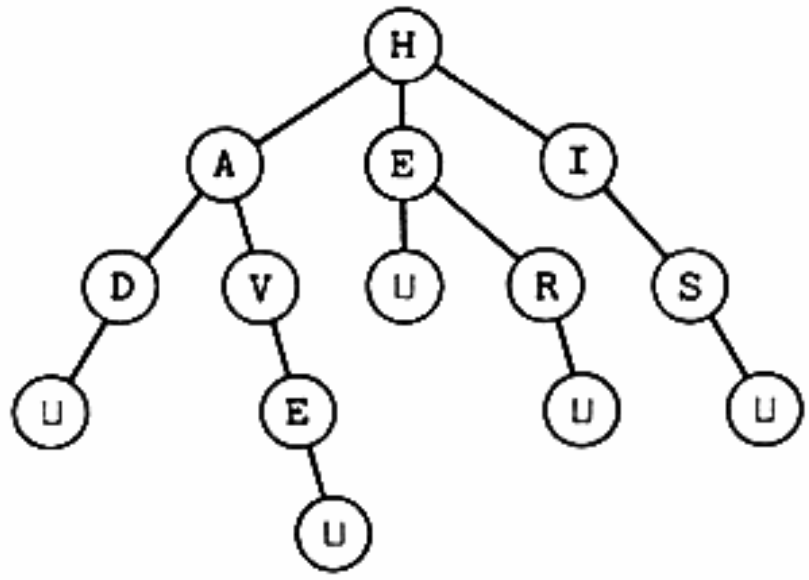
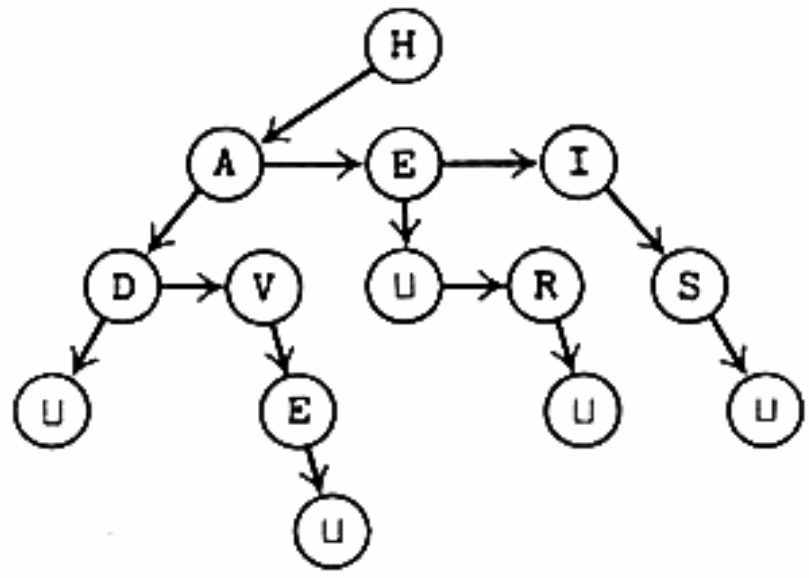
would actually have used



(1)

in place of the "H" tree in Fig. 31. This representation requires more storage, but it makes the processing of variable-length data especially easy. If we use two link fields per character, dynamic insertions and deletions can be handled in a simple manner. Furthermore there are many applications in which the search argument appears in "unpacked form," one character per word, and such a tree makes it unnecessary to pack the data before conducting the search.

If we use the normal way of representing trees as binary trees, (1) becomes the binary tree



(2)

(In the representation of the full forest, Fig. 31, we would also have a pointer leading to the right from H to its neighboring root I.) The search in this binary tree proceeds by comparing a character of the argument to the character in the tree, and following RLINKs until finding a match; then the LLINK is taken and we treat the next character of the argument in the same way.

With such a binary tree, we are more or less doing a search by comparison, with equal-unequal branching instead of less-greater branching. The elementary theory of Section 6.2.1 tells that we must make at least $\log_2 N$ comparisons, on the average, to distinguish between N keys; the average number of tests made when searching a tree like that of Fig. 31 must be at least as many as we make when doing a binary search using the techniques of Section 6.2.

On the other hand, the trie in Table 1 is capable of making an M-way branch all at once; we shall see that the average search time for large N involves only about $\log_M N = \log_2 N/\log_2 M$ iterations, if the input data is random. We shall also see that a "pure" trie scheme like that in Algorithm T requires a total of approximately $N/\ln M$ nodes to distinguish between N random inputs; hence the total amount of space is proportional to $MN/\ln M$.

From these considerations it is clear that the trie idea pays off only in the first few levels of the tree. We can get better performance by mixing two strategies, using a trie for the first few characters and then switching to some other technique. For example, E. H. Sussenguth, Jr. [*CACM* **6** (1963), 272–279] has suggested using a character-by-character scheme until we reach part of the tree where only, say, six or less keys of the file are possible, and then we can sequentially run through the short list of remaining keys. We shall see that this mixed strategy decreases the number of trie nodes by roughly a factor of six, without substantially changing the running time.

An application to English. Many variations on the basic trie and character search strategies suggest themselves. In order to get a feeling for some of these possibilities, let us consider a hypothetical large-scale application: Suppose that we want to store a fairly complete dictionary of the English language in the memory of our computer. For this purpose we will, of course, need a reasonably large internal memory, say 50,000 words. Our goal is to find a compact way to represent the dictionary, yet to keep the searching reasonably fast.

Such a project is obviously no small task; it may be expected to require a good knowledge of the contents of the dictionary as well as considerable programming ingenuity. For the moment, let us try to put ourselves in the position of someone embarking on such a major project.

A typical college dictionary contains over 100,000 words; this is somewhat larger than contemplated here, but a glance through such a dictionary will give us some idea of what to expect. If we try to apply the trie memory approach, we soon notice that important simplifications can be made. For example, suppose that we discount proper names and abbreviations. Then if the first letter of a word is b, the second letter will never be any of the characters b, c, d, f, g, j, k, m, n, p, q, s, t, v, w, x, or z (*except* for the word "bdellium," which we might choose to leave out of our dictionary!). In fact, the same 17 possibilities are excluded as second letters in words starting with c, d, f, g, h, j, k, l, m, n, p, q, r, t, v, w, x, z, except for a few words starting with ct, cz, dw, fj, gn, mn, nt, pf, pn, pt, tc, tm, ts, tz, zw and a fair number of words which begin with kn, ps, tw. One way to make use of this fact is to encode the letters (e.g., to have a 26-word table and to perform the equivalent of "`LDI TABLE,1`"), so that the consonants b, c, d, . . . , z listed above are converted into a special representation greater than the numeric code for the remaining letters a, e, h, i, l, o, r, u, y. In this way, many nodes of a trie can be shortened to a 9-way branch, with another "escape" cell to be used for the rarely occurring exceptional letters. This will save memory space in many parts of a trie for English, not just in the second letter position.

Of the $26^2 = 676$ possible combinations of two letters, only 309 actually occur at the beginning of words in a typical college dictionary; and of these 309 pairs, 88 are the initial letters of 15 or less words. (Typical examples of these 88 rare pairs are aa, ah, aj, ak, ao, aq, ay, az, bd, bh, . . . , xr, yc, yi, yp,

yt, yu, yw, za, zu, zw; most people can't name more than one word from most of these categories.) When one of the rare categories occurs, we can shift from trie memory to some other scheme like a sequential search.

Another way to cut down the storage requirement for a dictionary is to make use of prefixes. For example, if we are looking up a word that begins with re-, pre-, anti-, trans-, dis-, un-, etc., we might wish to detach the prefix and look up the remainder of the word. In this way we can remove many words like reapply, recompute, redecorate, redesign, redeposit, etc.; but we still need to retain words like remainder, requirement, retain, remove, readily, etc., since their meaning is not readily deducible when the prefix "re-" is suppressed. Thus we should first look up the word and then try deleting the prefix only if the first search fails.

The use of suffixes is even more important than the use of prefixes. It would certainly be wasteful to incorporate each noun and verb twice, in both singular and plural form; and there are many other types of suffixes. For example, the following endings may be added to many verb stems, to make a family of related words:

-e	-es	-ing
-ed	-s	-ings
-edly	-able	-ingly
-er	-ible	-ion
-or	-ably	-ions
-ers	-ibly	-ional
-ors	-ability	-ionally
	-abilities	

(Many of these suffixes are themselves composed of suffixes.) If we try to apply these suffixes to the stems

comput-
calculat-
search-
suffix-
translat-
interpret-
confus-

we see that a great many words are formed; this greatly multiplies the capacity of our dictionary. Of course a lot of nonwords are formed also, e.g. "compution"; the stem computat- seems to be necessary as well as comput-. But this causes no harm since such combinations will never appear in the input anyway; and if some author chooses to coin the word "computedly," we will have a ready-made translation of it for him. Note that most people would understand the word "confusability," although it appears in few dictionaries; our dictionary

will give a suitable interpretation. If prefixes and suffixes are correctly handled, our dictionary may even be able to deduce the meaning of "antidisestablishmentarianism," given only the verb stem "establish."

Of course we must be careful that the meaning of each word is properly determined by its stem and suffix; if not, the exceptions should be entered into the dictionary so that they will be found before we attempt to look for a suffix. For example, the analogy between the words "socialism" and "socialist" is not at all the same as between "organism" and "organist"!

These are some of the tricks that can be used to reduce the amount of memory needed. But how shall we represent this hodge-podge of methods compactly in a single system? The answer is to think of the dictionary as a *program* written in a special machine language for a special *interpretive system* (cf. Section 1.4.3); the entries within each node of a trie can be thought of as *instructions*. For example, in Table 1 we have two kinds of "instructions," and Program T uses the sign bit as the "op-code"; a minus sign means branch to another node and advance to the next character for the next instruction, while a plus sign means that the argument is supposed to be compared to a specified key.

We might have the following types of op-codes in the interpretive language for our dictionary application:

- Test n, α, β. "If the next character of the argument has an encoded value $k \le n$, go to location $\alpha + k$ for the next instruction; otherwise go to location β."
- Compare n, α, β. "Compare the remaining characters of the argument to the n words stored in locations α, $\alpha + 1$, . . . , $\alpha + n - 1$. If a match is found in location $\alpha + k$, the search terminates successfully with 'meaning' $\beta + k$, but if no match is found, it terminates unsuccessfully."
- Split α, β. "The word scanned up to this point is a possible prefix or stem. Continue searching by going to location α for the next instruction. If that search is unsuccessful, continue searching by looking up the remaining characters of the argument as if they were a new argument. If this second search is successful, combine the 'meaning' found with the 'meaning' β."

The test operation is essentially the trie search concept, and the compare operation denotes a changeover to sequential searching. The split operation handles both prefixes and suffixes. Several other operations can be envisioned based on further idiosyncrasies of English. It would be possible to save further memory space by eliminating the parameter β from each instruction, since the memory can be arranged so that β is implied by α, n, or the location of the instruction, in each case.

For additional information about dictionary organization, see the interesting articles by Sydney M. Lamb and William H. Jacobsen, Jr., *Mechanical*

Translation **6** (1961), 76–107; Eugene S. Schwartz, *JACM* **10** (1963), 413–439; E. J. Galli and H. Yamada, *IBM Systems J.* **6** (1967), 192–207.

The binary case. Let us now consider the special case $M = 2$, in which we scan the search argument one bit at a time. Two interesting methods have been developed which are especially appropriate for this case.

The first method, which we shall call *digital tree search*, is due to E. G. Coffman and J. Eve [*CACM* **13** (1970), 427–432, 436]. The idea is to store full keys in the nodes just as we did in the tree search algorithm of Section 6.2.2, but to use bits of the argument (instead of results of the comparisons) to govern whether to take the left or right branch at each step. Figure 32 shows the tree constructed by this method when we insert the 31 most common English words in order of decreasing frequency. In order to provide binary data for this illustration, the words have been expressed in MIX character code which was then converted into binary numbers with 5 bits per byte. Thus, the word WHICH is represented as "11010 01000 01001 00011 01000".

To search for this word WHICH in Fig. 32, we compare it first with the word THE at the root of the tree. Since there is no match and since the first bit of WHICH is 1, we move to the right and compare with OF. Since there is no match and since the second bit of WHICH is 1, we move to the right and compare with WITH; and so on.

It is interesting to note the contrast between Fig. 32 and Fig. 12 in Section 6.2.2, since the latter tree was formed in the same way but using comparisons instead of key bits for the branching. If we consider the given frequencies, the digital search tree of Fig. 32 requires an average of 3.42 comparisons per successful search; this is somewhat better than the 4.04 comparisons needed by Fig. 12, although of course the computing time per comparison will probably be different.

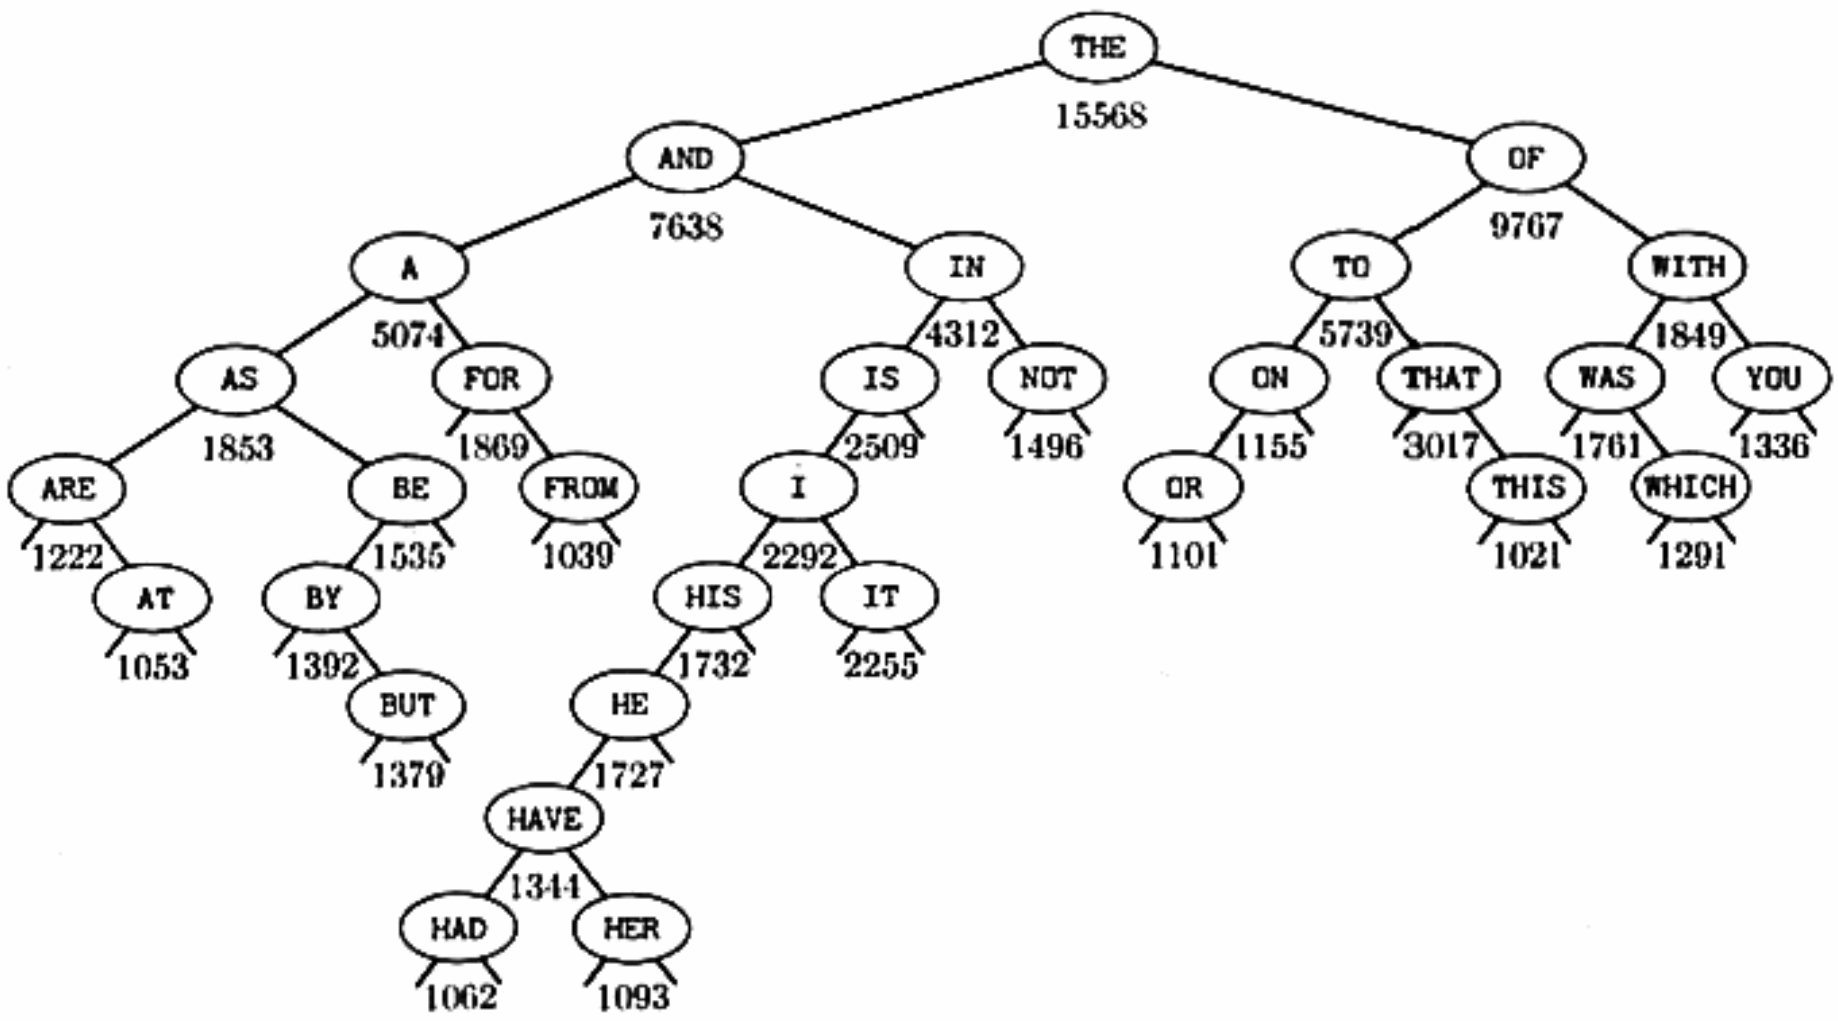


Fig. 32. A digital search tree for the 31 most common English words, inserted in decreasing order of frequency.

Algorithm D (*Digital tree search*). Given a table of records which form a binary tree as described above, this algorithm searches for a given argument K. If K is not in the table, a new node containing K is inserted into the tree in the appropriate place.

This algorithm assumes that the nodes of the tree have KEY, LLINK, and RLINK fields just as in Algorithm 6.2.2T. In fact, the two algorithms are almost identical, as the reader may verify.

D1. [Initialize.] Set P $\leftarrow$ ROOT, and $K1 \leftarrow K$.

D2. [Compare.] If $K =$ KEY(P), the search terminates successfully. Otherwise set b to the leading bit of $K1$, and shift $K1$ left one place (thereby removing that bit and introducing a 0 at the right). If $b = 0$, go to D3, otherwise go to D4.

D3. [Move left.] If LLINK(P) $\neq \Lambda$, set P $\leftarrow$ LLINK(P) and go back to D2. Otherwise go to D5.

D4. [Move right.] If RLINK(P) $\neq \Lambda$, set P $\leftarrow$ RLINK(P) and go back to D2.

D5. [Insert into tree.] Set Q $\Leftarrow$ AVAIL, KEY(Q) $\leftarrow K$, LLINK(Q) $\leftarrow$ RLINK(Q) $\leftarrow \Lambda$. If $b = 0$ set LLINK(P) $\leftarrow$ Q, otherwise set RLINK(P) $\leftarrow$ Q. ∎

Although the tree search of Algorithm 6.2.2T is inherently binary, it is not difficult to see that the present algorithm could be extended to an M-ary digital search for any $M \geq 2$ (see exercise 13).

Donald R. Morrison [*JACM* **15** (1968), 514–534] has discovered a very pretty way to form N-node search trees based on the binary representation of keys, *without* storing keys in the nodes. His method, called "Patricia" (Practical Algorithm To Retrieve Information Coded In Alphanumeric), is especially suitable for dealing with extremely long, variable-length keys such as titles or phrases stored within a large bulk file.

Patricia's basic idea is to build a binary trie, but to avoid one-way branching by including in each node the number of bits to skip over before making the next test. There are several ways to exploit this idea; perhaps the simplest to explain is illustrated in Fig. 33. We have a TEXT array of bits, which is usually quite long; it may be stored as an external direct-access file, since each search accesses TEXT only once. Each key to be stored in our table is specified by a starting place in the text, and it can be imagined to go from this starting place all the way to the end of the text. (Patricia does not search for strict equality between key and argument, rather it will determine whether or not there exists a key *beginning* with the argument.)

The situation depicted in Fig. 33 involves seven keys, one starting at each word, namely "THIS IS THE HOUSE THAT JACK BUILT." and "IS THE HOUSE THAT JACK BUILT." and . . . and "BUILT.". There is one important restriction, namely that *no one key may be a prefix of another*; this restriction can be met if we end the text with a unique end-of-text code (in this case ".") that appears

```
          1 2 3 4 5 6 7 8 9 10 11 12 13 14 15 16 17 18 19 20 21 22 23 24 25 26 27 28 29 30 31 32 33 34
TEXT:     T H I S   I S   T H E   H O U S E   T H A T   J A C K   B U I L T .
```

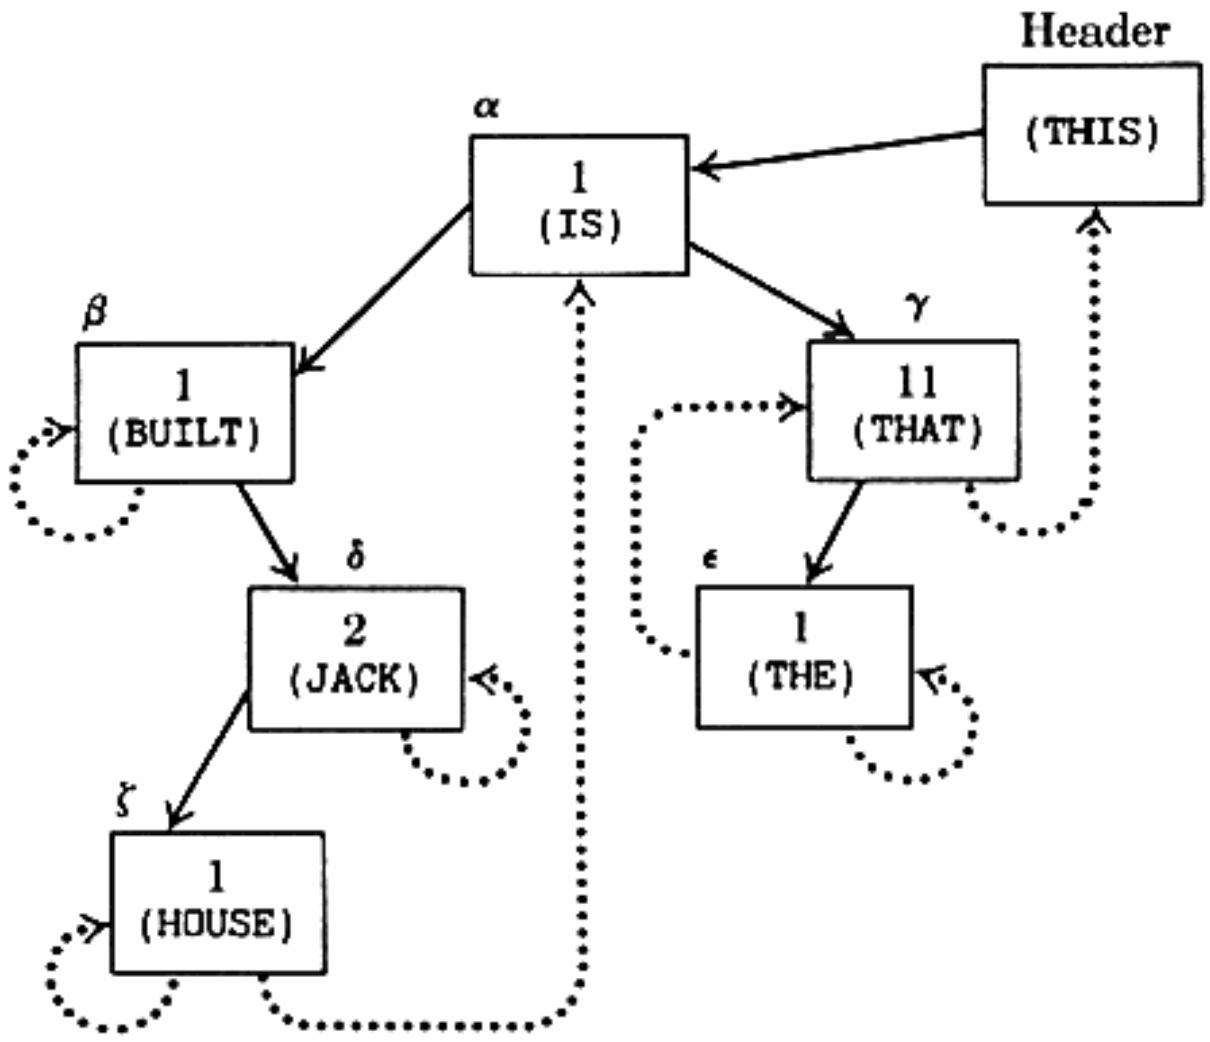

Fig. 33. An example of Patricia's tree and TEXT.

nowhere else. The same restriction was implicit in the trie scheme of Algorithm T, where "␣" was the termination code.

The tree which Patricia uses for searching should be contained in random-access memory, or it should be arranged on pages as suggested in Section 6.2.4. It consists of a header and $N - 1$ nodes, where the nodes contain several fields:

KEY, a pointer to the text. This field must be at least $\log_2 C$ bits long, if the text contains C characters. In Fig. 33 the words shown within each node would really be represented by pointers to the text, e.g. instead of "(JACK)" the node contains the number 24 (the starting place of "JACK BUILT.").

LLINK and RLINK, pointers within the tree. These fields must be at least $\log_2 N$ bits long.

LTAG and RTAG, one-bit fields which tell whether or not LLINK and RLINK, respectively, are pointers to sons or to ancestors of the node. The dotted lines in Fig. 33 correspond to pointers whose TAG bit is 1.

SKIP, a number which tells how many bits to skip when searching, as explained below. This field should be large enough to hold the largest number k such that identical k-bit substrings occur in two different keys; in practice, we may usually assume that k isn't too large, and an error indication can be given if the size of the SKIP field is exceeded. The SKIP fields are shown as numbers within each node of Fig. 33.

The header contains only KEY, LLINK, and LTAG fields.

A search in Patricia's tree is carried out as follows: Suppose we are looking up the word THAT (bit pattern 10111 01000 00001 10111). We start by looking at the SKIP field of the root node, which tells us to examine the first bit of the argument. It is 1, so we move to the right. The SKIP field in the next node tells us to look at the $1 + 11 = 12$th bit of the argument. It is 0, so we move to the left. The SKIP field of the next node tells us to look at the $(12 + 1)$st bit, which is 0; now we find LTAG = 1, so we go to node γ which refers us to the TEXT. The search path we have taken would occur for any argument whose bit pattern is 1xxxx xxxxx x00 . . . , and we must check to see if it matches the unique key which begins with that pattern.

Suppose, on the other hand, that we are looking for any or all keys starting with TH. The search process begins as above, but it eventually tries to look at the (nonexistent) 12th bit of the 10-bit argument. At this point we compare the argument to the TEXT at the point specified in the current node (in this case node γ); if it does not match, the argument is not the beginning of any key, but if it does match, the argument is the beginning of every key represented by dotted links in node γ and its descendants.

This process can be spelled out more precisely as follows.

Algorithm P (*Patricia*). Given a TEXT array and a tree with KEY, LLINK, RLINK, LTAG, RTAG, and SKIP fields as described above, this algorithm determines whether or not there is a key in the TEXT which begins with a specified argument K. (If r such keys exist, for $r \geq 1$, it is subsequently possible to locate them all in $O(r)$ steps; see exercise 14.) We assume that at least one key is present.

P1. [Initialize.] Set P ← HEAD and $j \leftarrow 0$. (Variable P is a pointer which will move down the tree, and j is a counter which will designate bit positions of the argument.) Set $n \leftarrow$ number of bits in K.

P2. [Move left.] Set Q ← P and P ← LLINK(Q). If LTAG(Q) = 1, go to P6.

P3. [Skip bits.] (At this point we know that if the first j bits of K match any key whatsoever, they match the key which starts at KEY(P).) Set $j \leftarrow j +$ SKIP(P). If $j > n$, go to P6.

P4. [Test bit.] (At this point we know that if the first $j - 1$ bits of K match any key, they match the key starting at KEY(P).) If the jth bit of K is 0, go to P2, otherwise go to P5.

P5. [Move right.] Set Q ← P and P ← RLINK(Q). If RTAG(Q) = 0, go to P3.

P6. [Compare.] (At this point we know that if K matches any key, it matches the key starting at KEY(P).) Compare K to the key starting at position KEY(P) in the TEXT array. If they are equal (up to n bits, the length of K), the algorithm terminates successfully; if unequal, it terminates unsuccessfully. ∎

Exercise 15 shows how Patricia's tree can be built in the first place. We can also add to the text and insert new keys, provided that the new text material always ends with a unique delimiter (e.g., an end-of-text symbol followed by a serial number).

Patricia is a little tricky, and she requires careful scrutiny before all of her beauties are revealed.

Analyses of the algorithms. We shall conclude this section by making a mathematical study of tries, digital search trees, and Patricia. A summary of the main consequences of these analyses appears at the very end.

Let us consider first the case of binary tries, i.e., tries with $M = 2$. Figure 34 shows the binary trie that is formed when the sixteen keys from the sorting examples of Chapter 5 are treated as 10-bit binary numbers. (The keys are shown in octal notation, so that for example *1144* represents the 10-bit number $(1001100100)_2$.) As in Algorithm T, we use the trie to store information about the leading bits of the keys until we get to the first point where the key is uniquely identified; then the key is recorded in full.

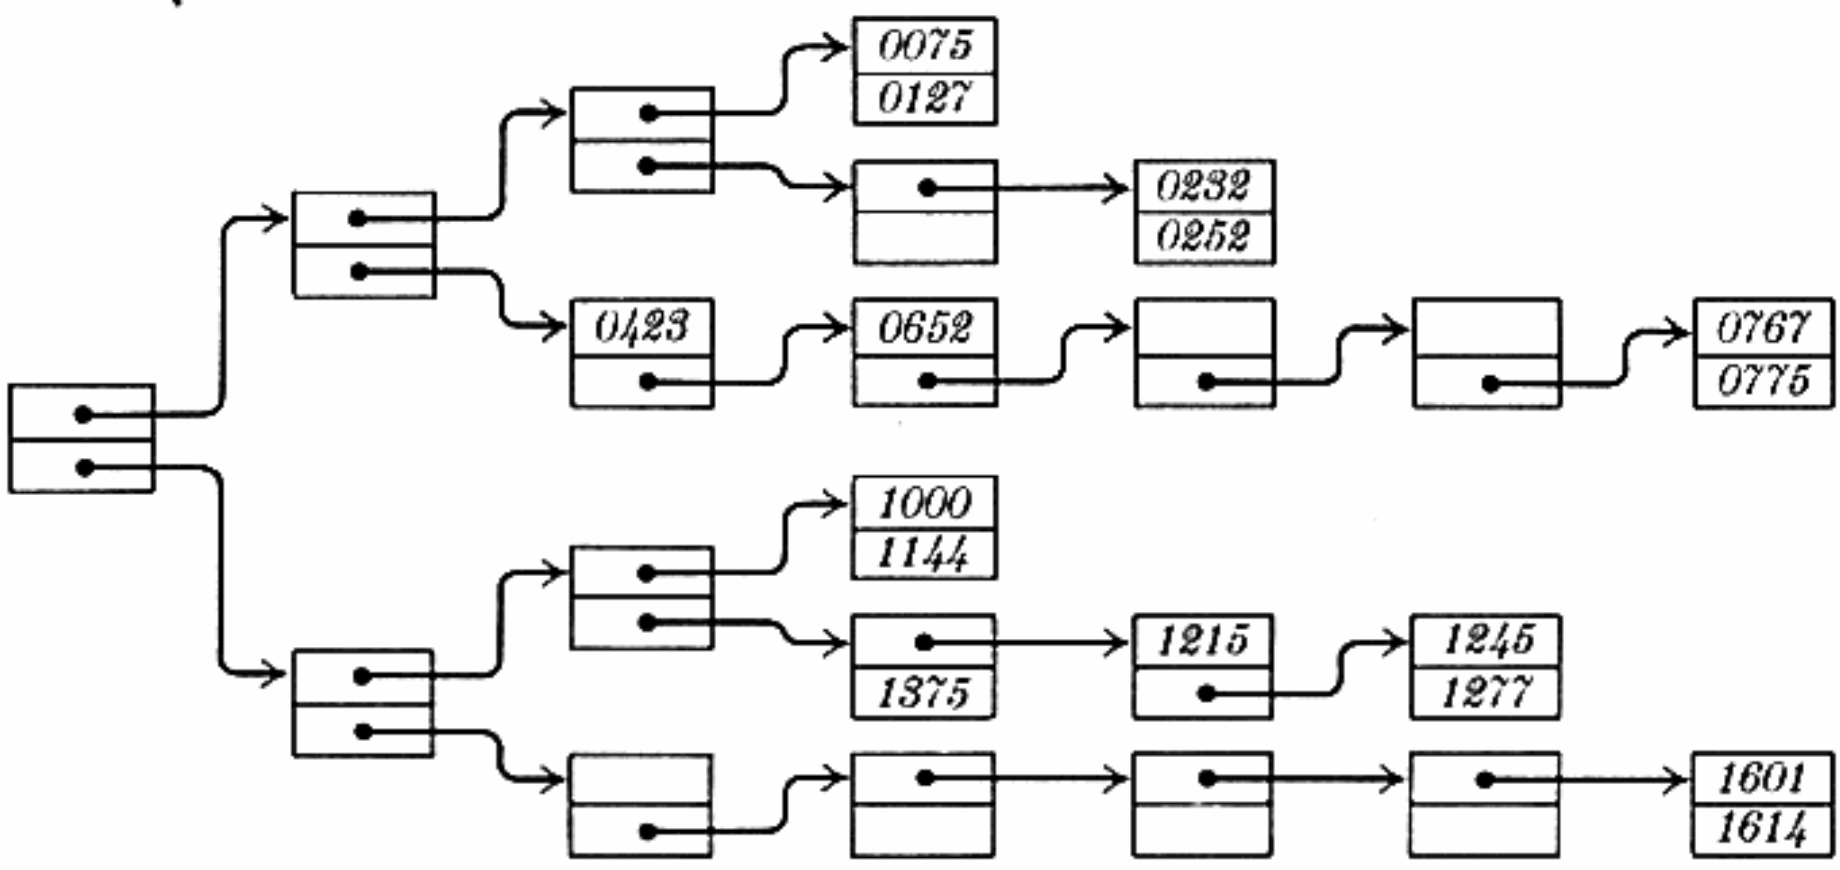

Fig. 34. Example of a random binary trie.

If Fig. 34 is compared to Table 5.2.2–3, an amazing relationship between trie memory and radix-exchange sorting is revealed. (Then again, perhaps this relationship is obvious.) The 22 nodes of Fig. 34 correspond precisely to the 22 partitioning stages in Table 5.2.2–3, with the pth node in preorder corresponding to Stage p. The number of bit inspections in a partitioning stage is equal to the number of keys within the corresponding node and its subtries; consequently we may state the following result.

Theorem T. *If N distinct binary numbers are put into a binary trie as described above, then* (i) *the number of nodes of the trie is equal to the number of partitioning stages required if these numbers are sorted by radix-exchange; and* (ii) *the average number of bit inspections required to retrieve a key by means of Algorithm T is $1/N$ times the number of bit inspections required by the radix-exchange sort.* ▮

Because of this theorem, we can make use of all the mathematical machinery that was developed for radix exchange in Section 5.2.2. For example, if we assume that our keys are infinite-precision random uniformly distributed real numbers between 0 and 1, the number of bit inspections needed for retrieval will be $\log_2 N + \gamma/(\ln 2) + 1/2 + f(N) + O(N^{-1})$, and the number of trie nodes will be $N/(\ln 2) + Ng(N) + O(1)$. Here $f(N)$ and $g(N)$ are complicated functions which may be neglected since their value is always less than 10^{-6} (see exercises 5.2.2–38, 48).

Of course there is still more work to be done, since we need to generalize from binary tries to M-ary tries. We shall describe only the starting point of the investigations here, leaving the instructive details as exercises.

Let A_N be the average number of nodes in a random M-ary search trie that contains N keys. Then $A_0 = A_1 = 0$, and for $N \geq 2$ we have

$$A_N = 1 + \sum_{k_1+\cdots+k_M=N} \left(\frac{N!}{k_1! \ldots k_M!} M^{-N}\right) (A_{k_1} + \cdots + A_{k_M}), \qquad (3)$$

since $N!M^{-N}/k_1! \ldots k_M!$ is the probability that k_1 of the keys are in the first subtrie, . . . , k_M in the Mth. This equation can be rewritten

$$A_N = 1 + M^{1-N} \sum_{k_1+\cdots+k_M=N} \left(\frac{N!}{k_1! \ldots k_M!}\right) A_{k_1}$$

$$= 1 + M^{1-N} \sum_k \binom{N}{k} (M-1)^{N-k} A_k, \qquad \text{for} \qquad N \geq 2, \qquad (4)$$

by using symmetry and then summing over $k_2, \ldots, k_M$. Similarly, if C_N denotes the average total number of bit inspections needed to look up all N keys in the trie, we find $C_0 = C_1 = 0$ and

$$C_N = N + M^{1-N} \sum_k \binom{N}{k} (M-1)^{N-k} C_k \qquad \text{for} \qquad N \geq 2. \qquad (5)$$

Exercise 17 shows how to deal with general recurrences of this type, and exercises 18–25 work out the corresponding theory of random tries. [The analysis of A_N was first approached from another point of view by L. R. Johnson and M. H. McAndrew, *IBM J. Res. and Devel.* **8** (1964), 189–193, in connection with an equivalent hardware-oriented sorting algorithm.]

If we now turn to a study of digital search trees, we find that the formulas are similar, yet different enough that it is not easy to see how to deduce the asymptotic behavior. For example, if $\overline{C}_N$ denotes the average total number of bit inspections made when looking up all N keys in a binary digital search tree, it is not difficult to deduce as above that $\overline{C}_0 = \overline{C}_1 = 0$, and

$$\overline{C}_{N+1} = N + M^{1-N} \sum_k \binom{N}{k} (M-1)^{N-k} \overline{C}_k \qquad \text{for} \qquad N \geq 0. \qquad (6)$$

This is almost identical to Eq. (5); but the appearance of $N + 1$ instead of N on the left-hand side of this equation is enough to change the entire character of the recurrence, and so the methods we have used to study (5) are wiped out.

Let's consider the binary case first. Figure 35 shows the digital search tree corresponding to the sixteen example keys of Fig. 34, when they have been inserted in the order used in the examples of Chapter 5. If we want to determine the average number of bit inspections made in a random successful search, this is just the internal path length of the tree divided by N, since we need l bit inspections to find a node on level l. Note, however, that the average number of bit inspections made in a random *unsuccessful* search is *not* simply related to the external path length of the tree, since unsuccessful searches are more likely to occur at external nodes near the root; thus, the probability of reaching the left sub-branch of node *0075* in Fig. 35 is $\frac{1}{8}$ (assuming infinitely precise keys), and the left sub-branch of node *0232* will be encountered with probability only $\frac{1}{32}$. (For this reason, digital search trees tend to stay better balanced than the binary search trees of Algorithm 6.2.2T, when the keys are uniformly distributed.)

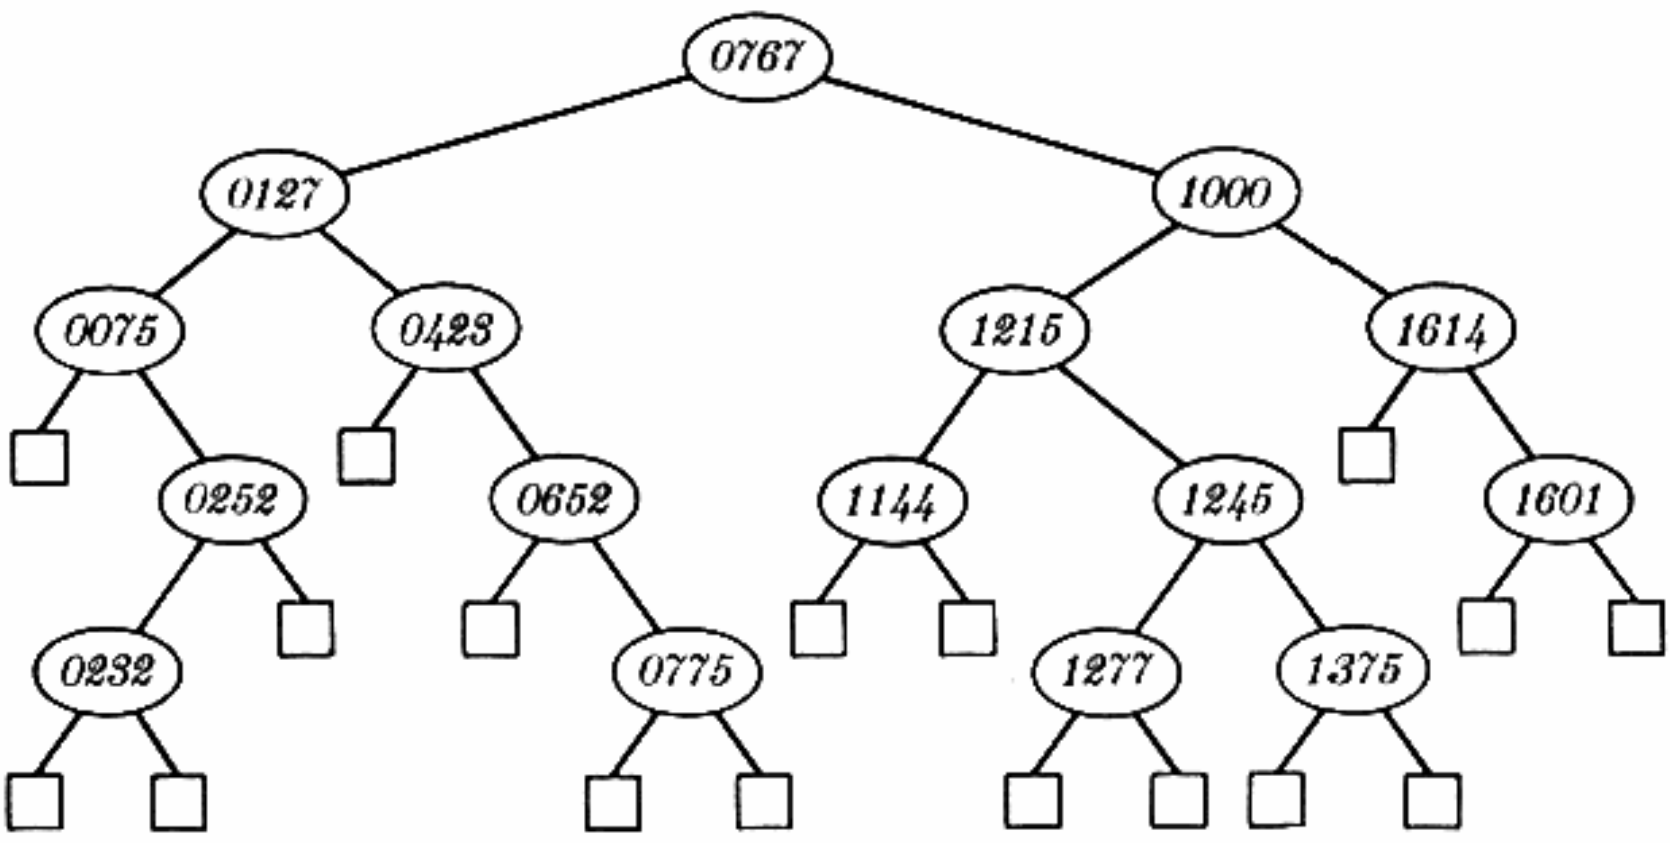

Fig. 35. A random digital search tree constructed by Algorithm D.

We can use a generating function to describe the pertinent characteristics of a digital search tree. If there are a_l internal nodes on level l, consider the generating function $a(z) = \sum a_l z^l$; for example, the generating function corresponding to Fig. 35 is $a(z) = 1 + 2z + 4z^2 + 5z^3 + 4z^4$. If there are b_l external nodes on level l, and if $b(z) = \sum b_l z^l$, we have

$$b(z) = 1 + (2z - 1)a(z) \tag{7}$$

by exercise 6.2.1–25. For example, $1 + (2z - 1)(1 + 2z + 4z^2 + 5z^3 + 4z^4) = 3z^3 + 6z^4 + 8z^5$. The average number of bit inspections made in a random successful search is $a'(1)/a(1)$, since $a'(1)$ is the internal path length of the tree and $a(1)$ is the number of internal nodes. The average number of bit inspections

made in a random *unsuccessful* search is $\sum l b_l 2^{-l} = \frac{1}{2}b'(\frac{1}{2}) = a(\frac{1}{2})$, since we end up at a given external node on level l with probability 2^{-l}. The number of comparisons is the same as the number of bit inspections, plus one in a successful search. For example, in Fig. 35, a successful search will take $2\frac{9}{16}$ bit inspections and $3\frac{9}{16}$ comparisons, on the average; an unsuccessful search will take $3\frac{7}{8}$ of each.

Now let $g_N(z)$ be the "average" $a(z)$ for trees with N nodes; in other words, $g_N(z)$ is the sum $\sum p_T a_T(z)$ over all binary digital search trees T with N internal nodes, where $a_T(z)$ is the generating function for the internal nodes of T and p_T is the probability that T occurs when N random numbers are inserted using Algorithm D. Then the average number of bit inspections will be $g'_N(1)/N$ in a successful search, $g_N(\frac{1}{2})$ in an unsuccessful search.

We can compute $g_N(z)$ by mimicking the tree construction process, as follows. If $a(z)$ is the generating function for a tree of N nodes, we can form $N+1$ trees from it by making the next insertion into any one of the external node positions. The insertion goes into a given external node on level l with probability 2^{-l}; hence the sum of the generating functions for the $N+1$ new trees, multiplied by the probability of occurrence, is $a(z) + b(\frac{1}{2}z) = a(z) + 1 + (z-1)a(\frac{1}{2}z)$. Averaging over all trees for N nodes, it follows that

$$g_{N+1}(z) = g_N(z) + 1 + (z-1)g_N(\tfrac{1}{2}z); \qquad g_0(z) = 0. \tag{8}$$

The corresponding generating function for external nodes, $h_N(z) = 1 + (2z-1)g_N(z)$, is somewhat easier to work with, because (8) is equivalent to the formula

$$h_{N+1}(z) = h_N(z) + (2z-1)h_N(\tfrac{1}{2}z); \qquad h_0(z) = 1. \tag{9}$$

Applying this rule repeatedly, we find that

$$\begin{aligned} h_{N+1}(z) &= h_{N-1}(z) + 2(2z-1)h_{N-1}(\tfrac{1}{2}z) + (2z-1)(z-1)h_{N-1}(\tfrac{1}{4}z) \\ &= h_{N-2}(z) + 3(2z-1)h_{N-2}(\tfrac{1}{2}z) + 3(2z-1)(z-1)h_{N-2}(\tfrac{1}{4}z) \\ &\quad + (2z-1)(z-1)(\tfrac{1}{2}z-1)h_{N-2}(\tfrac{1}{8}z) \end{aligned}$$

and so on, so that eventually we have

$$h_N(z) = \sum_k \binom{N}{k} \prod_{0\le j<k} (2^{1-j}z - 1); \tag{10}$$

$$g_N(z) = \sum_{k\ge 0} \binom{N}{k+1} \prod_{0\le j<k} (2^{-j}z - 1). \tag{11}$$

For example, $g_4(z) = 4 + 6(z-1) + 4(z-1)(\frac{1}{2}z-1) + (z-1)(\frac{1}{2}z-1)(\frac{1}{4}z-1)$. These formulas make it possible to express the quantities we are looking for as

sums of products:

$$\overline{C}_N = g'_N(1) = \sum_{k\ge 0} \binom{N}{k+2} \prod_{1\le j\le k} (2^{-j} - 1); \tag{12}$$

$$g_N(\tfrac{1}{2}) = \sum_{k\ge 0} \binom{N}{k+1} \prod_{1\le j\le k} (2^{-j} - 1) = \overline{C}_{N+1} - \overline{C}_N. \tag{13}$$

It is not at all obvious that this formula for $\overline{C}_N$ satisfies (6)!

Unfortunately, these expressions are not suitable for calculation or for finding an asymptotic expansion, since $2^{-j} - 1$ is negative; we get large terms and a lot of cancellation. A more useful formula for $\overline{C}_N$ can be obtained by applying the partition identities of exercise 5.1.1–16. We have

$$\begin{aligned}
\overline{C}_N &= \Big(\prod_{j\ge 1} (1 - 2^{-j})\Big) \sum_{k\ge 0} \binom{N}{k+2} (-1)^k \prod_{l\ge 0} (1 - 2^{-l-k-1})^{-1} \\
&= \Big(\prod_{j\ge 1} (1 - 2^{-j})\Big) \sum_{k\ge 0} \binom{N}{k+2} (-1)^k \sum_{m\ge 0} (2^{-k-1})^m \prod_{1\le r\le m} (1 - 2^{-r})^{-1} \\
&= \sum_{m\ge 0} 2^m \Big(\sum_k \binom{N}{k} (-2^{-m})^k - 1 + 2^{-m}N\Big) \prod_{j\ge 0} (1 - 2^{-j-m-1}) \\
&= \sum_{m\ge 0} 2^m ((1 - 2^{-m})^N - 1 + 2^{-m}N) \sum_{n\ge 0} (-2^{-m-1})^n 2^{-n(n-1)/2} \\
&\qquad\qquad \times \prod_{1\le r\le n} (1 - 2^{-r})^{-1}.
\end{aligned} \tag{14}$$

This may not seem at first glance to be an improvement over Eq. (12), but it has the great advantage that it converges rapidly for each fixed n. A precisely analogous situation occurred for the trie case in Eq. 5.2.2–38, 39; in fact, if we consider only the $n = 0$ terms of (14), we have exactly $N - 1$ plus the number of bit inspections in a binary trie. We can now proceed to get the asymptotic value in essentially the same way as before; see exercise 27. [The above derivation is largely based on an approach suggested by A. J. Konheim and D. J. Newman, *Discrete Mathematics* (to appear).]

Finally let us take a mathematical look at Patricia. In her case the binary tree is like the corresponding binary trie on the same keys, but squashed together (because the SKIP fields eliminate 1-way branching), so that there are $N - 1$ internal nodes and N external nodes. Figure 36 shows the Patrician tree corresponding to the sixteen keys in the trie of Fig. 34. The number shown in each branch node is the amount of SKIP; the keys are indicated with the external nodes, although the external node is not explicitly present (there is actually a tagged link to an internal node which references the TEXT, in place

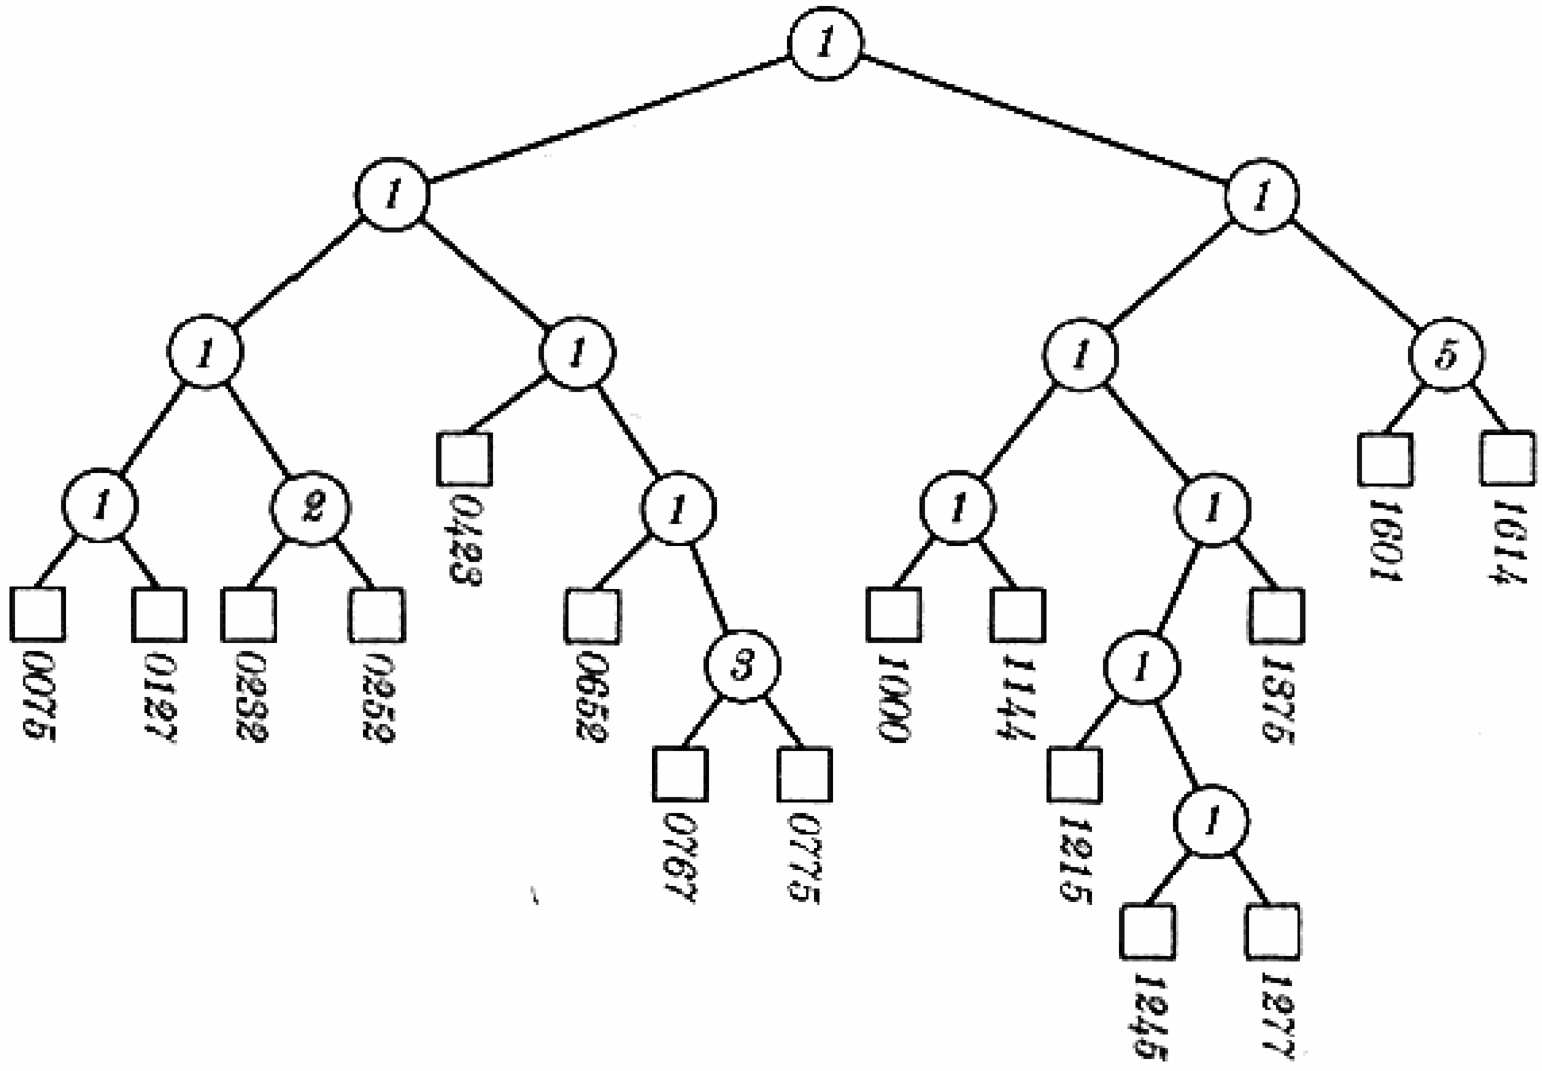

Fig. 36. Patricia constructs this tree instead of Fig. 34.

of each external node.) For the purposes of analysis, we may assume that external nodes exist as shown.

Since successful searches with Patricia end at external nodes, the average number of bit inspections made in a random successful search will be the external path length, divided by N. If we form the generating function $b(z)$ for external nodes as above, this will be $b'(1)/b(1)$. An *unsuccessful* search with Patricia also ends at an external node, but weighted with probability 2^{-l} for external nodes on level l, so the average number of bit inspections is $\frac{1}{2}b'(\frac{1}{2})$. For example, in Fig. 36 we have $b(z) = 3z^3 + 8z^4 + 3z^5 + 2z^6$; there are $4\frac{1}{4}$ bit inspections per successful search and $3\frac{25}{32}$ per unsuccessful search, on the average.

Let $h_N(z)$ be the "average" $b(z)$ for a Patrician tree constructed with N external nodes, using uniformly distributed keys. The recurrence relation

$$h_n(z) = 2^{1-n} \sum_k \binom{n}{k} h_k(z)\bigl(z + \delta_{kn}(1 - z)\bigr), \quad h_0(z) = 0, \quad h_1(z) = 1 \tag{15}$$

appears to have no simple solution. But fortunately, there is a simple recurrence for the average external path length $h_n'(1)$, since

$$\begin{aligned} h_n'(1) &= 2^{1-n} \sum_k \binom{n}{k} h_k'(1) + 2^{1-n} \sum_k \binom{n}{k} k(1 - \delta_{kn}) \\ &= n - 2^{n-1}n + 2^{1-n} \sum_k \binom{n}{k} h_k'(1). \end{aligned} \tag{16}$$

Since this has the form of (6), we can use the methods already developed to solve for $h_n'(1)$, which turns out to be exactly n less than the corresponding number of bit inspections in a random binary trie. Thus, the SKIP fields save us

about one bit inspection per successful search, on random data. (See exercise 31.) The redundancy of typical real data will lead to greater savings.

When we try to find the average number of bit inspections for a random *un*successful search by Patricia, we obtain the recurrence

$$a_n = 1 + \frac{1}{2^n - 2} \sum_{k<n} \binom{n}{k} a_k, \qquad \text{for} \qquad n \geq 2; \qquad a_0 = a_1 = 0. \tag{17}$$

Here $a_n = \frac{1}{2}h_n'(\frac{1}{2})$. This does *not* have the form of any recurrences we have studied, nor is it easily transformed into such a recurrence. In fact, it turns out that the solution involves the Bernoulli numbers:

$$\frac{na_{n-1}}{2} - n + 2 = \sum_{2\leq k<n} \binom{n}{k} \frac{B_k}{2^{k-1} - 1}. \tag{18}$$

This formula is probably the hardest asymptotic nut we have yet had to crack; the solution in exercise 34 is an instructive review of many things we have done before, with some slightly different twists.

Summary of the analyses. As a result of all the complicated mathematics in this section, the following facts are perhaps the most noteworthy:

(a) The number of nodes needed to store N random keys in an M-ary trie, with the trie branching terminated for subfiles of $\leq s$ keys, is approximately $N/(s \ln M)$. (This approximation is valid for large N, small s, and small M.) Since a trie node involves M link fields, we will need only about $N/\ln M$ link fields if we choose $s = M$.

(b) The number of digits or characters examined during a random search is approximately $\log_M N$ for all methods considered. When $M = 2$, the various analyses give us the following more accurate approximations to the number of bit inspections:

	Successful	Unsuccessful
Trie search	$\log_2 N + 1.33275$	$\log_2 N - 0.10995$
Digital tree search	$\log_2 N - 1.71665$	$\log_2 N - 0.27395$
Patricia	$\log_2 N + 0.33275$	$\log_2 N - 0.31875$

(These approximations can all be expressed in terms of fundamental mathematical constants, e.g. 0.31875 stands for $(\ln \pi - \gamma)/(\ln 2) - 1/2$.)

(c) "Random" data here means that the M-ary digits are uniformly distributed, as if the keys were real numbers between 0 and 1 expressed in M-ary notation. Digital search methods are insensitive to the order in which keys are entered into the file (except for Algorithm D, which is only slightly sensitive to the order); but they are very sensitive to the distribution of digits. For example, if 0 bits are much more common than 1 bits, the trees will become much more skewed than they would be for random data as considered in the analyses cited above. (Exercise 5.2.2–53 works out one example of what happens when the data is biased in this way.)

EXERCISES

1. [*00*] If a tree has leaves, what does a trie have?

2. [*20*] Design an algorithm for the insertion of a new key into an M-ary trie, using the conventions of Algorithm T.

3. [*21*] Design an algorithm for the deletion of a key from an M-ary trie, using the conventions of Algorithm T.

▶ 4. [*21*] Most of the 360 entries in Table 1 are blank (null links). But we can compress the table into only 55 entries, by overlapping nonblank entries with blank ones, as follows:

Position	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20	21	22	23	24	25	26	27	28
Entry	A	---	THAT	(26)	---	WAS	THE	(15)	(2)	I	THIS	HIS	WHICH	WITH	HE	AND	TO	OF	BE	ARE	(1)	(14)	AS	AT	IN	(21)	ON	(3)

Position	29	30	31	32	33	34	35	36	37	38	39	40	41	42	43	44	45	46	47	48	49	50	51	52	53	54	55
Entry	(10)	HAD	OR	IS	IT	HER	NOT	(12)	FOR	BUT	---	FROM	---	BY	(1)	---	---	(5)	---	YOU	---	---	HAVE	---	---	---	---

(Nodes (1), (2), . . . , (12) of Table 1 begin, respectively, at positions 20, 1, 14, 21, 3, 10, 12, 1, 5, 26, 15, 2 within this compressed table.)

Show that if the compressed table is substituted for Table 1, Program T will still work, but not quite as fast.

▶ 5. [*M26*] (Y. N. Patt.) The trees of Fig. 31 have their letters arranged in alphabetic order within each family. This order is not necessary, and if we rearrange the order of nodes within the families before constructing binary tree representations such as (2) we may get a faster search. What rearrangement of Fig. 31 is optimum from this standpoint? (Use the frequency assumptions of Fig. 32, and find the forest which minimizes the successful search time when it has been represented as a binary tree.)

6. [*15*] What digital search tree is obtained if the fifteen 4-bit binary keys 0001, 0010, 0011, . . . , 1111 are inserted in increasing order by Algorithm D? (Start with 0001 at the root and then do fourteen insertions.)

▶ 7. [*M26*] If the fifteen keys of exercise 6 are inserted in a different order, we may get a different tree. Of all the 15! possible permutations of these keys, which is the *worst*, in the sense that it produces a tree with the greatest internal path length?

8. [*20*] Consider the following changes to Algorithm D, which have the effect of eliminating variable $K1$: Change "$K1$" to "K" in both places in step D2, and delete the operation "$K1 \leftarrow K$" from step D1. Will the resulting algorithm still be valid for searching and insertion?

9. [*21*] Write a MIX program for Algorithm D, and compare it to Program 6.2.2T. You may use binary operations such as SLB (shift left AX binary), JAE (jump if A even), etc.; and you may also use the idea of exercise 8 if it helps.

10. [*23*] Given a file in which all the keys are n-bit binary numbers, and given a search argument $K = b_1 b_2 \ldots b_n$, suppose we want to find the maximum value of k such that there is a key in the file beginning with the bit pattern $b_1 b_2 \ldots b_k$. How can we

do this efficiently if the file is represented as (a) a binary search tree (cf. Algorithm 6.2.2T); (b) a binary trie (cf. Algorithm T); (c) a binary digital search tree (cf. Algorithm D)?

11. [*21*] Can Algorithm 6.2.2D be used without change to delete a node from a digital search tree?

12. [*25*] After a random element is deleted from a random digital search tree constructed by Algorithm D, is the resulting tree still random? (Cf. exercise 11 and Theorem 6.2.2H.)

13. [*20*] (*M-ary digital searching.*) Explain how Algorithms T and D can be combined into a generalized algorithm that is essentially the same as Algorithm D when $M = 2$. What changes would be made to Table 1, if your algorithm is used for $M = 30$?

▶**14.** [*25*] Design an efficient algorithm that can be performed just after Algorithm P has terminated successfully, to locate *all* places where K appears in the TEXT.

15. [*28*] Design an efficient algorithm that can be used to construct the tree used by Patricia, or to insert new TEXT references into an existing tree. Your insertion algorithm should refer to the TEXT array at most twice.

16. [*22*] Why is it desirable for Patricia to make the restriction that no key is a prefix of another?

17. [*M25*] Find a way to express the solution of the recurrence

$$x_0 = x_1 = 0; \qquad x_n = a_n + m^{1-n} \sum_k \binom{n}{k} (m-1)^{n-k} x_k, \qquad n \geq 2,$$

in terms of binomial transforms, by generalizing the technique of exercise 5.2.2–36.

18. [*M21*] Use the result of exercise 17 to express the solutions to (4) and (5) in terms of functions U_n and V_n analogous to those defined in exercise 5.2.2–38.

19. [*HM23*] Find the asymptotic value of the function

$$K(n, s, m) = \sum_{k \geq 2} \binom{n}{k} \binom{k}{s} \frac{(-1)^k}{m^{k-1} - 1}$$

to $O(1)$ as $n \to \infty$, for fixed $s \geq 0$ and $m > 1$. [The case $s = 0$ has already been solved in exercise 5.2.2–50, and the case $s = 1$, $m = 2$ has been solved in exercise 5.2.2–48.]

▶**20.** [*M30*] Consider M-ary trie memory in which we use a sequential search whenever reaching a subfile of s or less keys. (Algorithm T is the special case $s = 1$.) Apply the results of the preceding exercises to analyze (a) the average number of trie nodes; (b) the average number of digit or character inspections in a successful search; and (c) the average number of comparisons made in a successful search. State your answers as asymptotic formulas as $N \to \infty$, for fixed M and s; the answer for (a) should be correct to within $O(1)$, and the answers for (b) and (c) should be correct to within $O(N^{-1})$. [When $M = 2$, this analysis applies also to the modified radix-exchange sort, in which subfiles of size $\leq s$ are sorted by insertion.]

21. [*M25*] How many of the nodes, in a random M-ary trie containing N keys, have a null pointer in table entry 0? (For example, 9 of the 12 nodes in Table 1 have a null

pointer in the "␣" position. "Random" in this exercise means as usual that the characters of the keys are uniformly distributed between 0 and $M - 1$.)

22. [*M25*] How many trie nodes are on level l of a random M-ary trie containing N keys, for $l = 0, 1, 2, \ldots$?

23. [*M26*] How many digit inspections are made on the average during an *un*successful search in an M-ary trie containing N random keys?

24. [*M30*] Consider an M-ary trie which has been represented as a forest (cf. Fig. 31). Find exact and asymptotic expressions for (a) the average number of nodes in the forest, and (b) the average number of times "P ← RLINK(P)" is performed during a random successful search.

▸**25.** [*M24*] The mathematical derivations of asymptotic values in this section have been quite difficult, involving complex variable theory, because it is desirable to get more than just the leading term of the asymptotic behavior (and the second term is intrinsically complicated). The purpose of this exercise is to show that elementary methods are good enough to deduce some of the results in weaker form. (a) Prove by induction that the solution to (4) satisfies $A_N \leq M(N-1)/(M-1)$ for $N \geq 1$. (b) Let $D_N = C_N - NH_{N-1}/(\ln M)$, where C_N is defined by (5). Prove that $D_N = O(N)$; hence $C_N = N \log_M N + O(N)$. [*Hint:* Use (a) and Theorem 1.2.7A.]

26. [*23*] Determine the value of the infinite product

$$(1 - \tfrac{1}{2})(1 - \tfrac{1}{4})(1 - \tfrac{1}{8})(1 - \tfrac{1}{16}) \ldots$$

correct to five decimal places, by hand calculation. [*Hint:* Cf. exercise 5.1.1–16.]

27. [*HM31*] What is the asymptotic value of $\overline{C}_N$, as given by (14), to within $O(1)$?

28. [*HM26*] Find the asymptotic average number of digit inspections when searching in a random M-ary digital search tree, for general $M \geq 2$. Consider both successful and unsuccessful search, and give your answer to within $O(N^{-1})$.

29. [*M46*] What is the asymptotic average number of nodes, in an M-ary digital search tree, for which all M links are null? (We might save memory space by eliminating such nodes, cf. exercise 13.)

30. [*M24*] Show that the Patrician generating function $h_n(z)$ defined in (15) can be expressed in the rather horrible form

$$n \sum_{m \geq 1} z^m \left(\sum_{\substack{a_1 + \cdots + a_m = n-1 \\ a_1, \ldots, a_m \geq 1}} \binom{n-1}{a_1, \ldots, a_m} \frac{1}{(2^{a_1} - 1)(2^{a_1 + a_2} - 1) \ldots (2^{a_1 + \cdots + a_m} - 1)} \right).$$

[Thus, if there is a simple formula for $h_n(z)$, we will be able to simplify this rather ungainly expression.]

31. [*M21*] Solve the recurrence (16).

32. [*M21*] What is the average value of the sum of all SKIP fields in a random Patrician tree with $N - 1$ internal nodes?

33. [*M30*] Prove that (18) is a solution to the recurrence (17). [*Hint:* Consider the generating function $A(z) = \sum_{n \geq 0} a_n z^n / n!$.]

34. [*HM40*] The purpose of this exercise is to find the asymptotic behavior of (18).

(a) Prove that

$$\frac{1}{n}\sum_{2\le k<n}\binom{n}{k}\frac{B_k}{2^{k-1}-1}=\sum_{j\ge 1}\left(\frac{1^{n-1}+2^{n-1}+\cdots+(2^j-1)^{n-1}}{2^{j(n-1)}}-\frac{2^j}{n}+\frac{1}{2}\right).$$

(b) Show that the summand in (a) can be approximated by $1/(e^x-1)-1/x+1/2$, where $x=n/2^j$; the resulting sum equals the original sum $+\,O(n^{-1})$. (c) Show that

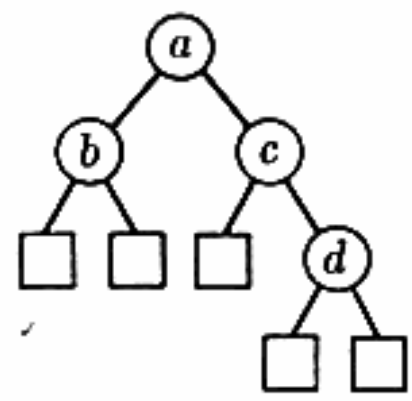
$$\frac{1}{e^x-1}-\frac{1}{x}+\frac{1}{2}=\frac{1}{2\pi i}\int_{-\frac{1}{2}-i\infty}^{-\frac{1}{2}+i\infty}\zeta(z)\Gamma(z)x^{-z}\,dz,\qquad\text{for real } x>0.$$

(d) Therefore the sum equals

$$\frac{1}{2\pi i}\int_{-\frac{1}{2}-i\infty}^{-\frac{1}{2}+i\infty}\frac{\zeta(z)\Gamma(z)n^{-z}}{2^{-z}-1}\,dz+O(n^{-1});$$

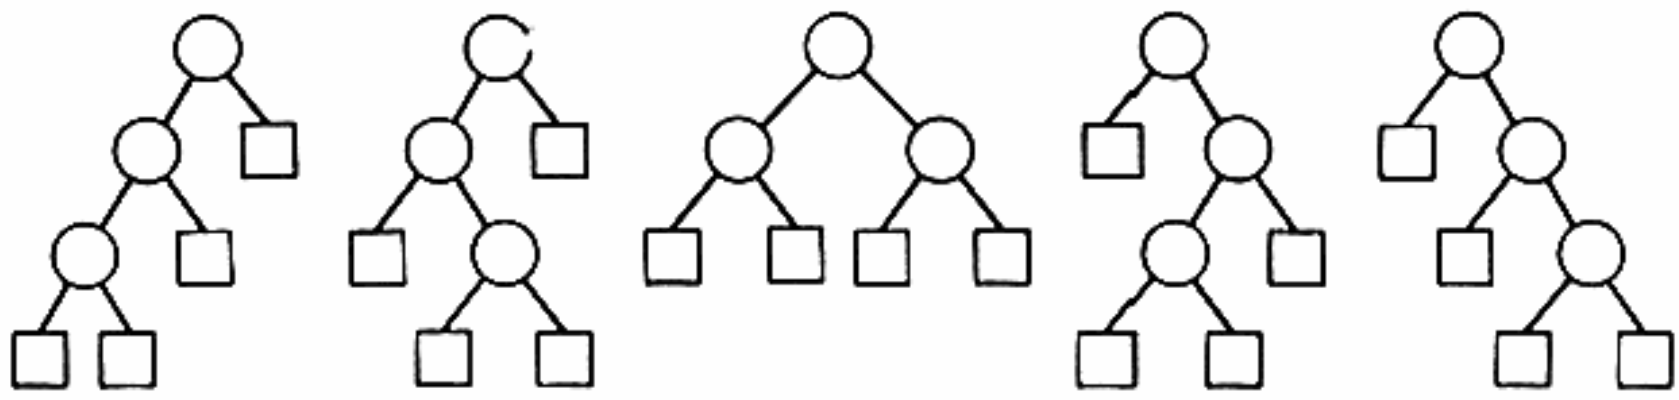
evaluate this integral.

▸**35.** [*M20*] What is the probability that Patricia's tree on five keys will be



with the SKIP fields a, b, c, d as shown? (Assume that the keys have independent random bits, and give your answer as a function of a, b, c and d.)

36. [*M25*] There are five binary trees with three internal nodes. If we consider how frequently each particular one of these occurs as the search tree in various algorithms, for random data, we find the following different probabilities:



Tree search (Algorithm 6.2.2T)	$\frac{1}{6}$	$\frac{1}{6}$	$\frac{1}{3}$	$\frac{1}{6}$	$\frac{1}{6}$
Digital tree search (Algorithm D)	$\frac{1}{8}$	$\frac{1}{8}$	$\frac{1}{2}$	$\frac{1}{8}$	$\frac{1}{8}$
Patricia (Algorithm P)	$\frac{1}{7}$	$\frac{1}{7}$	$\frac{3}{7}$	$\frac{1}{7}$	$\frac{1}{7}$

(Note that the digital search tree tends to be balanced more often than the others.) In exercise 6.2.2–5 we found that the probability of a tree in the tree search algorithm was $\Pi(1/s(x))$, where the product is over all internal nodes x, and $s(x)$ is the number of internal nodes in the subtree rooted at x. Find similar formulas for the probability of a tree in the case of (a) Algorithm D; (b) Algorithm P.

▸**37.** [*M22*] Consider a binary tree with b_l external nodes on level l. The text observes that the running time for unsuccessful searching in digital search trees is not directly related to the external path length $\sum lb_l$, but instead it is essentially proportional to the *modified external path length* $\sum lb_l 2^{-l}$. Prove or disprove: The smallest modified external path length, over all trees with N external nodes, occurs when all of the external nodes appear on at most two adjacent levels. [Cf. exercise 5.3.1–20.]

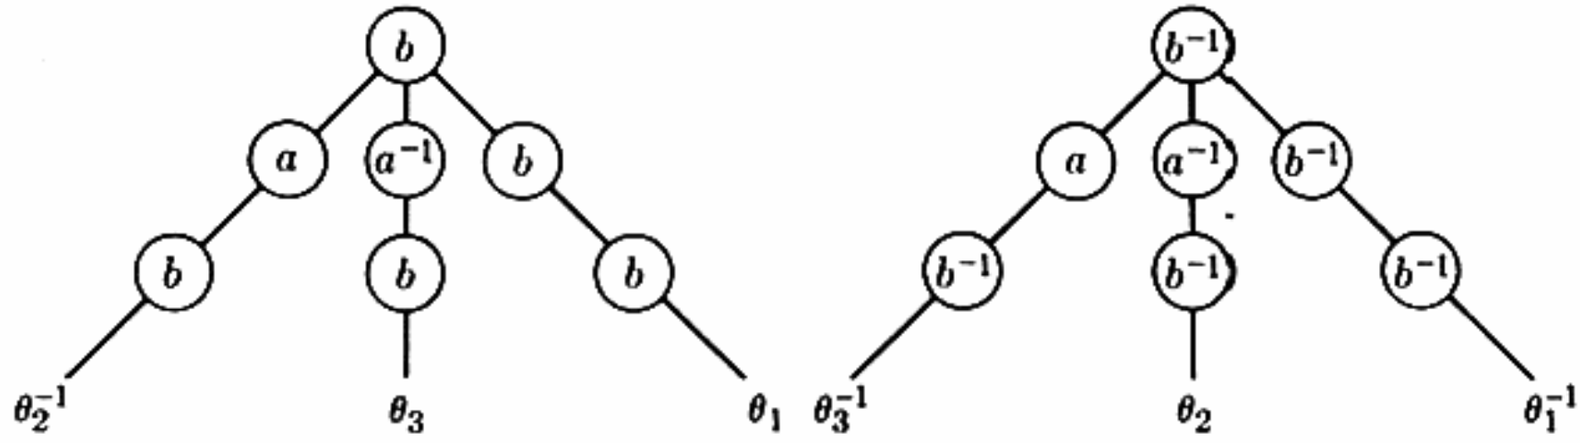
38. [*M40*] Develop an algorithm to find the n-node tree having the minimum value of $\alpha \cdot$ (internal path length) $+ \beta \cdot$ (modified external path length), given α and β. (Cf. exercise 37.)

39. [*M47*] Develop an algorithm to find optimum digital search trees, analogous to the optimum binary search trees considered in Section 6.2.2.

40. [*25*] Let $a_0a_1a_2\ldots$ be a periodic binary sequence with $a_{N+k} = a_k$ for all $k \geq 0$. Show that there is a way to represent any fixed sequence of this type in $O(N)$ memory locations, so that the following operation can be done in only $O(n)$ steps: Given any binary pattern $b_0b_1\ldots b_{n-1}$, determine how often the pattern occurs in the period (i.e., find how many values of p exist with $0 \leq p < N$ and $b_k = a_{p+k}$ for $0 \leq k < n$). (The length n of the pattern is variable as well as the pattern itself. Assume that each memory location is big enough to hold arbitrary integers between 0 and N).

41. [*HM28*] This is an application to group theory. Let G be the free group on the letters $\{a_1, \ldots, a_n\}$, i.e., the set of all strings $\alpha = b_1\ldots b_r$, where each b_i is one of the a_j or a_j^{-1} and no adjacent pair $a_ja_j^{-1}$ or $a_j^{-1}a_j$ occurs. The inverse of α is $b_r^{-1}\ldots b_1^{-1}$, and we multiply two such strings by concatenating them and cancelling adjacent inverse pairs. Let H be the subgroup of G generated by the strings $\{\beta_1, \ldots, \beta_p\}$, i.e., the set of all elements of G which can be written as products of the β's and their inverses. It can be shown (see Marshall Hall, *The Theory of Groups* (New York: Macmillan, 1959), Chapter 7) that we may always find generators $\theta_1, \ldots, \theta_m$ of H, with $m \leq p$, satisfying the "Nielsen property," which states that the middle character of θ_i (or at least one of the two central characters of θ_i if it has even length) is never cancelled in the expressions $\theta_i\theta_j^e$ or $\theta_j^e\theta_i$, $e = \pm 1$, unless $j = i$ and $e = -1$. This property implies that there is a simple algorithm for testing whether an arbitrary element of G is in H: Record the $2m$ keys $\theta_1, \ldots, \theta_m, \theta_1^{-1}, \ldots, \theta_m^{-1}$ in a character-oriented search tree, using the $2n$ letters $a_1, \ldots, a_n, a_1^{-1}, \ldots, a_n^{-1}$. Let $\alpha = b_1\ldots b_r$ be a given element of G; if $r = 0$, α is obviously in H. Otherwise look up α, finding the longest prefix $b_1\ldots b_k$ that matches a key. If there is more than one key beginning with $b_1\ldots b_k$, α is not in H; otherwise let the unique such key be $b_1\ldots b_kc_1\ldots c_l = \theta_i^e$, and replace α by $\theta_i^{-e}\alpha = c_l^{-1}\ldots c_1^{-1}b_{k+1}\ldots b_r$. If this new value of α is longer than the old (i.e., if $l > k$), α is not in H; otherwise repeat the process on the new value of α. The Nielsen property implies that this algorithm will always terminate. If α is eventually reduced to the null string, we can reconstruct the representation of the original α as a product of θ's.

For example, let $\{\theta_1, \theta_2, \theta_3\} = \{bbb, b^{-1}a^{-1}b^{-1}, ba^{-1}b\}$ and $\alpha = bbabaab$. The forest



can be used with the above algorithm to deduce that $\alpha = \theta_1\theta_3^{-1}\theta_1\theta_3^{-1}\theta_2^{-1}$. Implement this algorithm, given the θ's as input to your program.

42. [*23*] (*Front and rear compression.*) When a set of binary keys is being used as an index, to partition a larger file, we need not store the full keys. For example, if the sixteen keys of Fig. 34 are used, they can be truncated at the right, as soon as enough digits have been given to uniquely identify them: 0000, 0001, 00100, 00101, 010, . . . , 1110001. These truncated keys can be used to partition a file into seventeen parts, where for example the fifth part consists of all keys beginning with 0011 or 010, and the last part contains all keys beginning with 111001, 11101, or 1111. The truncated keys can be represented more compactly if we suppress all leading digits common to the previous key: 0000, ***1, **100, ****1, *10, . . . , ******1. The bit following a * is always 1, so it may be suppressed. A large file will have many *'s, and we need store only the number of *'s and the values of the following bits. (This compression technique was shown to the author by A. Heller and R. L. Johnsen.)

Show that the total number of bits in the compressed file, excluding *'s and the following 1 bits, is always equal to the number of nodes in the binary trie for the keys.

(Consequently the average total number of such bits in the entire index is about $N/(\ln 2)$, only 1.44 bits per key. Still further compression is possible, since we need only represent the trie structure; cf. Theorem 2.3.1 A.)

So far we have considered search methods based on comparing the given argument K to the keys in the table, or using its digits to govern a branching process. A third possibility is to avoid all this rummaging around by doing some arithmetical calculation on K, computing a function $f(K)$ which is the location of K and the associated data in the table.

For example, let's consider again the set of 31 English words which we have subjected to various search strategies in Section 6.2.2 and 6.3. Table 1 shows a short MIX program which transforms each of the 31 keys into a unique number $f(K)$ between -10 and 30. If we compare this method to the MIX programs for the other methods we have considered (e.g., binary search, optimal tree search, trie memory, digital tree search), we find that it is superior from the standpoint of both space and speed, except that binary search uses slightly less space. In fact, the average time for a successful search, using the program of Table 1 with the frequency data of Fig. 12, is only about $17.8u$, and only 41 table locations are needed to store the 31 keys.

Unfortunately it isn't very easy to discover such functions $f(K)$. There are $41^{31} \approx 10^{50}$ possible functions from a 31-element set into a 41-element set, and only $41 \cdot 40 \cdot \cdots \cdot 11 = 41!/10! \approx 10^{43}$ of them will give distinct values for each argument; thus only about one of every 10 million functions will be suitable.

Functions which avoid duplicate values are surprisingly rare, even with a fairly large table. For example, the famous "birthday paradox" asserts that if 23 or more people are present in a room, chances are good that two of them

Table 1

will have the same month and day of birth! In other words, if we select a random function which maps 23 keys into a table of size 365, the probability that no two keys map into the same location is only 0.4927 (less than one-half). Skeptics who doubt this result should try to find the birthday mates at the next large parties they attend. [The birthday paradox originated in work of R. von Mises, *İstanbul Üniversitesi Fen Fakültesi Mecmuasi* **4** (1939), 145–163, and W. Feller, *An Introduction to Probability Theory* (New York: Wiley, 1950), Section 2.3.]

On the other hand, the approach used in Table 1 is fairly flexible [cf. M. Greniewski and W. Turski, *CACM* **6** (1963), 322–323], and for a medium-sized table a suitable function can be found after about a day's work. In fact it is rather amusing to solve a puzzle like this.

Of course this method has a serious flaw, since the contents of the table must be known in advance; adding one more key will probably ruin everything, making it necessary to start over almost from scratch. We can obtain a much more versatile method if we give up the idea of uniqueness, permitting different keys to yield the same value $f(K)$, and using a special method to resolve any ambiguity after $f(K)$ has been computed.

These considerations lead to a popular class of search methods commonly known as *hashing* or *scatter storage* techniques. The verb "to hash" means to chop something up or to make a mess out of it; the idea in hashing is to chop off some aspects of the key and to use this partial information as the basis for searching. We compute a *hash function* $h(K)$ and use this value as the address where the search begins.

The birthday paradox tells us that there will probably be distinct keys $K_i \neq K_j$ which hash to the same value $h(K_i) = h(K_j)$. Such an occurrence is

called a *collision*, and several interesting approaches have been devised to handle the collision problem. In order to use a scatter table, a programmer must make two almost independent decisions: He must choose a hash function $h(K)$, and he must select a method for collision resolution. We shall now consider these two aspects of the problem in turn.

Hash functions. To make things more explicit, let us assume throughout this section that our hash function h takes on at most M different values, with

$$0 \le h(K) < M, \tag{1}$$

for all keys K. The keys in actual files that arise in practice usually have a great deal of redundancy; we must be careful to find a hash function that breaks up clusters of almost identical keys, in order to reduce the number of collisions.

It is theoretically impossible to define a hash function that creates random data from the nonrandom data in actual files. But in practice it is not difficult to produce a pretty good imitation of random data, by using simple arithmetic as we have discussed in Chapter 3. And in fact we can often do even better, by exploiting the nonrandom properties of actual data to construct a hash function that leads to fewer collisions than truly random keys would produce.

Consider, for example, the case of 10-digit keys on a decimal computer. One hash function that suggests itself is to let $M = 1000$, say, and to let $h(K)$ be three digits chosen from somewhere near the middle of the 20-digit product $K \times K$. This would seem to yield a fairly good spread of values between 000 and 999, with low probability of collisions. Experiments with actual data show, in fact, that this "middle square" method isn't bad, provided that the keys do not have a lot of leading or trailing zeros; but it turns out that there are safer and saner ways to proceed, just as we found in Chapter 3 that the middle square method is not an especially good random number generator.

Extensive tests on typical files have shown that two major types of hash functions work quite well. One of these is based on division, and the other is based on multiplication.

The division method is particularly easy; we simply use the remainder modulo M:

$$h(K) = K \bmod M. \tag{2}$$

In this case, some values of M are obviously much better than others. For example, if M is an even number, $h(K)$ will be even when K is even and odd when K is odd, and this will lead to a substantial bias in many files. It would be even worse to let M be a power of the radix of the computer, since $K \bmod M$ would then be simply the least significant digits of K (independent of the other digits). Similarly we can argue that M probably shouldn't be a multiple of 3 either; for if the keys are alphabetic, two keys which differ from each other only by permutation of letters would then differ in numeric value by a multiple of 3. (This occurs because $10^n \bmod 3 = 4^n \bmod 3 = 1$.) In general, we want to avoid values of M which divide $r^k \pm a$, where k and a are small numbers and r is the radix of the alphabetic character set (usually $r = 64$, 256, or 100),

since a remainder modulo such a value of M tends to be largely a simple superposition of the key digits. Such considerations suggest that we *choose M to be a prime number* such that $r^k \not\equiv \pm a$ (modulo M) for small k and a. This choice has been found to be quite satisfactory in virtually all cases.

For example, on the MIX computer we could choose $M = 1009$, computing $h(K)$ by the sequence

```
LDX    K          rX ← K.
ENTA   0          rA ← 0.                    (3)
DIV    =1009=     rX ← K mod 1009.
```

The multiplicative hashing scheme is equally easy to do, but it is slightly harder to describe because we must imagine ourselves working with fractions instead of with integers. Let w be the word size of the computer, so that w is usually 10^{10} or 2^{30} for MIX; we can regard an integer A as the fraction A/w if we imagine the radix point to be at the left of the word. The method is to choose some integer constant A relatively prime to w, and to let

$$h(K) = \left\lfloor M \left(\left(\frac{A}{w} K \right) \bmod 1 \right) \right\rfloor. \tag{4}$$

In this case we usually let M be a power of 2 on a binary computer, so that $h(K)$ consists of the leading bits of the least significant half of the product AK.

In MIX code, if we let $M = 2^m$ and assume a binary radix, the multiplicative hash function is

```
LDA    K          rA ← K.
MUL    A          rAX ← AK.
ENTA   0          rAX ← AK mod w.            (5)
SLB    m          Shift rAX m bits to the left.
```

Now $h(K)$ appears in register A. Since MIX has rather slow multiplication and shift instructions, this sequence takes exactly as long to compute as (3); but on many machines multiplication is significantly faster than division.

In a sense this method can be regarded as a generalization of (3), since we could for example take A to be an approximation to $w/1009$; multiplying by the reciprocal of a constant is often faster than dividing by that constant. Note that (5) is almost a "middle square" method, but there is one important difference: We shall see that multiplication by a suitable constant has demonstrably good properties.

One of the nice features of the multiplicative scheme is that no information was lost in (5); we would determine K again, given only the contents of rAX after (5) has finished. The reason is that A is relatively prime to w, so Euclid's algorithm can be used to find a constant A' with $AA' \bmod w = 1$; this implies that $K = (A'(AK \bmod w)) \bmod w$. In other words, if $f(K)$ denotes the contents of register X just before the SLB instruction in (5), then

$$K_1 \neq K_2 \quad \text{implies} \quad f(K_1) \neq f(K_2). \tag{6}$$

Of course $f(K)$ takes on values in the range 0 to $w - 1$, so it isn't any good as a hash function, but it can be very useful as a *scrambling function*, namely a function satisfying (6) and tending to randomize the keys. Such a function can be very useful in connection with the tree search algorithms of Section 6.2.2, if the order of keys is unimportant, since it removes the danger of degeneracy when keys enter the tree in increasing order. A scrambling function is also useful in connection with the digital tree search algorithm of Section 6.3, if the bits of the actual keys are biased.

Another feature of the multiplicative hash method is that it makes good use of the nonrandomness found in many files. Actual sets of keys often have a preponderance of arithmetic progressions, where $\{K, K + d, K + 2d, \ldots, K + td\}$ all appear in the file; for example, consider alphabetic names like {PART1, PART2, PART3} or {TYPEA, TYPEB, TYPEC}. The multiplicative hash method converts an arithmetic progression into an approximate arithmetic progression $h(K)$, $h(K + d)$, $h(K + 2d)$, ... of distinct hash values, reducing the number of collisions from what we would expect in a random situation. The division method has this same property.

Figure 37 illustrates this aspect of multiplicative hashing in a particularly interesting case. Suppose that A/w is approximately the golden ratio $\phi^{-1} = (\sqrt{5} - 1)/2 = 0.6180339887$; then the behavior of successive values $h(K)$, $h(K + 1)$, $h(K + 2)$, ... can be studied by considering the behavior of the successive values $h(0)$, $h(1)$, $h(2)$, ... This suggests the following experiment: Starting with the line segment [0, 1], we successively mark off the points $\{\phi^{-1}\}$, $\{2\phi^{-1}\}$, $\{3\phi^{-1}\}$, ..., where $\{x\}$ denotes the fractional part of x (namely $x - \lfloor x \rfloor = x \bmod 1$). As shown in Fig. 37, these points stay very well separated from each other; in fact, each newly added point falls into one of the largest remaining intervals, and divides it in the golden ratio! [This phenomenon was

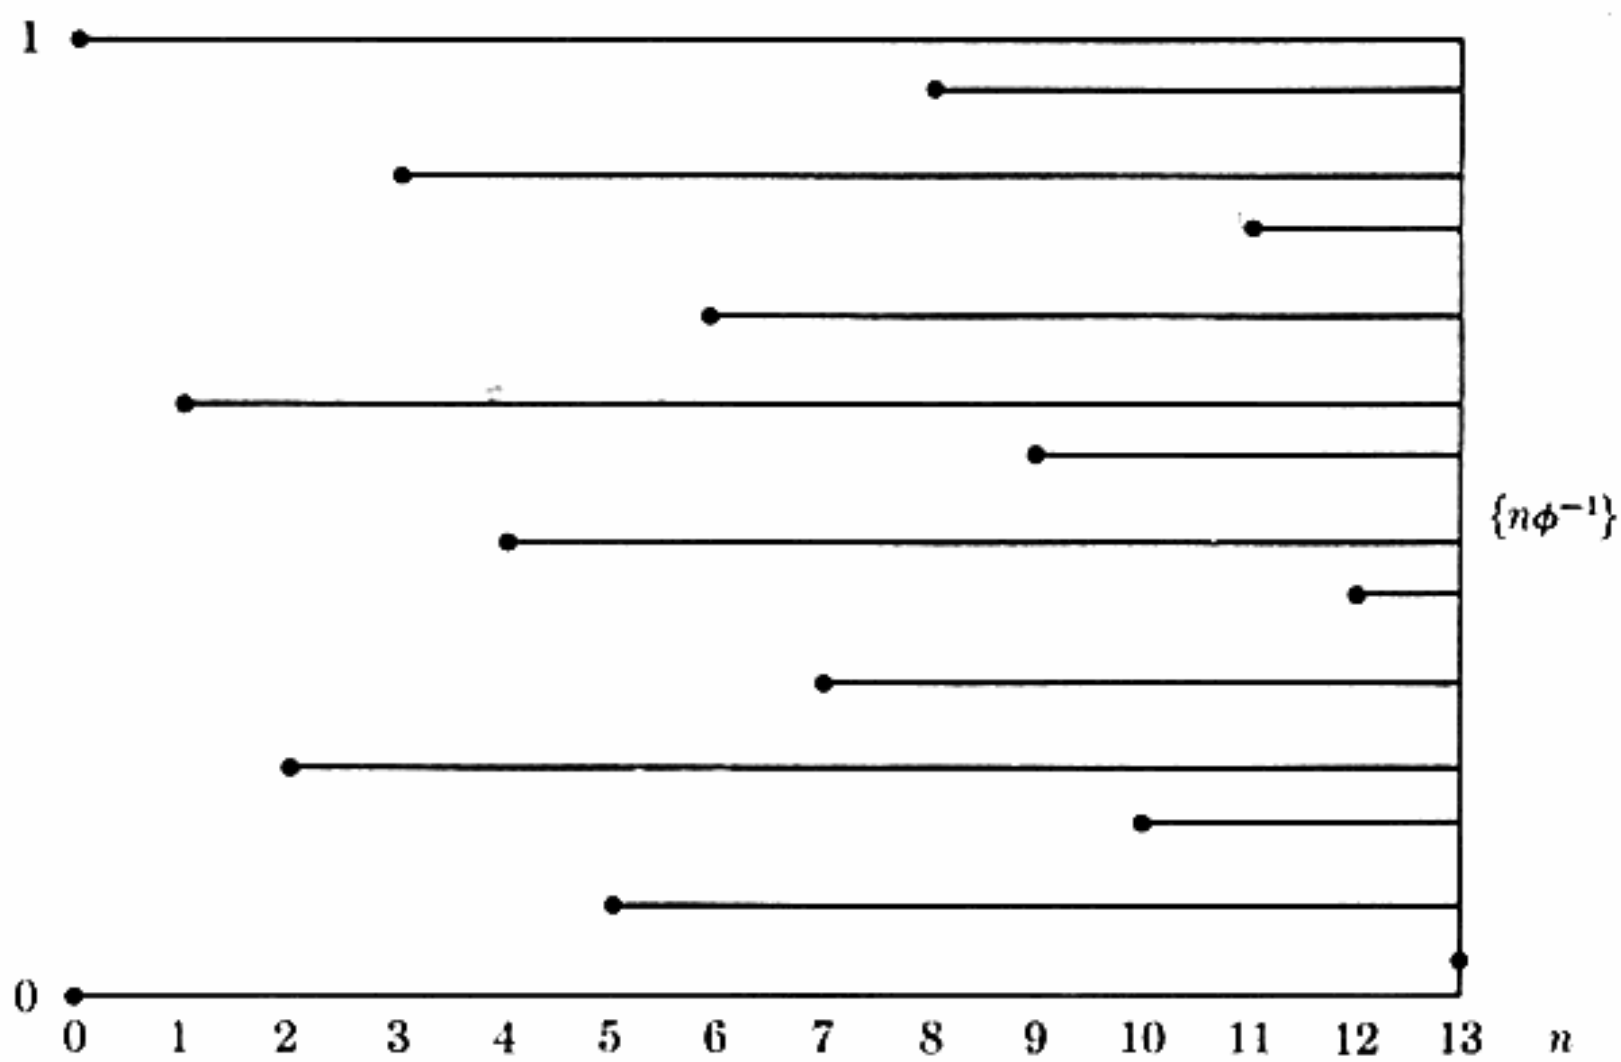

Fig. 37. Fibonacci hashing.

first conjectured by J. Oderfeld and proved by S. Świerczkowski, *Fundamenta Math.* **46** (1958), 187–189. Fibonacci numbers play an important rôle in the proof.]

This remarkable property of the golden ratio is actually just a special case of a very general result, originally conjectured by Hugo Steinhaus and first proved by Vera Turán Sós [*Acta Math. Acad. Sci. Hung.* **8** (1957), 461–471; *Ann. Univ. Sci. Budapest. Eötvös Sect. Math.* **1** (1958), 127–134]:

Theorem S. *Let θ be any irrational number. When the points $\{\theta\}$, $\{2\theta\}$, ..., $\{n\theta\}$ are placed in the line segment* [0, 1], *the $n+1$ line segments formed have at most three different lengths. Moreover, the next point $\{(n+1)\theta\}$ will fall in one of the largest existing segments.* ▮

Thus, the points $\{\theta\}$, $\{2\theta\}$, ..., $\{n\theta\}$ are spread out very evenly between 0 and 1. If θ is rational, the same theorem holds if we give a suitable interpretation to the segments of length 0 that appear when n is greater than or equal to the denominator of θ. A proof of Theorem S, together with a detailed analysis of the underlying structure of the situation, appears in exercise 8; it turns out that the segments of a given length are created and destroyed in a first-in-first-out manner. Of course, some θ's are better than others, since for example a value that is near 0 or 1 will start out with many small segments and one large segment. Exercise 9 shows that the two numbers ϕ^{-1} and $\phi^{-2} = 1 - \phi^{-1}$ lead to the "most uniformly distributed" sequences, among all numbers θ between 0 and 1.

The above theory suggests *Fibonacci hashing*, where we choose the constant A to be the nearest integer to $\phi^{-1}w$ that is relatively prime to w. For example if `MIX` were a decimal computer we would take

$$A = \boxed{+}\boxed{61}\boxed{80}\boxed{33}\boxed{98}\boxed{87}\ . \tag{7}$$

This multiplier will spread out alphabetic keys like `LIST1`, `LIST2`, `LIST3` very nicely. But notice what happens when we have an arithmetic series in the fourth character position, as in the keys `SUM1␣`, `SUM2␣`, `SUM3␣`: The effect is as if Theorem S were being used with $\theta = \{100A/w\} = .80339887$ instead of $\theta = .6180339887 = A/w$. The resulting behavior is still all right, in spite of the fact that this value of θ is not quite as good as ϕ^{-1}. On the other hand, if the progression occurs in the second character position, as in `A1␣␣␣`, `A2␣␣␣`, `A3␣␣␣`, the effective θ is .9887, and this is probably too close to 1.

Therefore we might do better with a multiplier like

$$A = \boxed{+}\boxed{61}\boxed{61}\boxed{61}\boxed{61}\boxed{61} \tag{8}$$

in place of (7); such a multiplier will separate out consecutive sequences of keys differing in *any* character position. Unfortunately this choice suffers from another problem analogous to the difficulty of dividing by $r^k \pm 1$: Keys such as `XY` and `YX` will tend to hash to the same location! One way out of this diffi-

culty is to look more closely at the structure underlying Theorem S; for short progressions of keys, only the first few partial quotients of the continued fraction representation of θ are relevant, and small partial quotients correspond to good distribution properties. Therefore we find that the best values of θ lie in the ranges

$$\tfrac{1}{4} < \theta < \tfrac{3}{10}, \qquad \tfrac{1}{3} < \theta < \tfrac{3}{7}, \qquad \tfrac{4}{7} < \theta < \tfrac{2}{3}, \qquad \tfrac{7}{10} < \theta < \tfrac{3}{4}.$$

A value of A can be found so that each of its bytes lies in a good range and is not too close to the values of the other bytes or their complements, e.g.,

$$A = \boxed{+}\boxed{61}\boxed{25}\boxed{42}\boxed{33}\boxed{71}. \tag{9}$$

Such a multiplier can be recommended. (These ideas about multiplicative hashing are due largely to R. W. Floyd.)

A good hash function should satisfy two requirements:

a) Its computation should be very fast.
b) It should minimize collisions.

Property (a) is somewhat machine-dependent, and property (b) is data-dependent. If the keys were truly random, we could simply extract a few bits from them and use these bits for the hash function; but in practice we nearly always need to have a hash function that depends on all bits of the key in order to satisfy (b).

So far we have considered how to hash one-word keys. Multiword or variable-length keys can be handled by multiple-precision extensions of the above methods, but it is generally adequate to speed things up by combining the individual words together into a single word, then doing a single multiplication or division as above. The combination can be done by addition mod w, or by "exclusive or" on a binary computer; both of these operations have the advantage that they are invertible, i.e., that they depend on all bits of both arguments, and exclusive-or is sometimes preferable because it avoids arithmetic overflow. Note that both of these operations are commutative, so that (X, Y) and (Y, X) will hash to the same address; G. D. Knott has suggested avoiding this problem by doing a cyclic shift just before adding or exclusive-oring.

Many more methods for hashing have been suggested, but none of these has proved to be superior to the simple division and multiplication methods described above. For a survey of some other methods together with detailed statistics on their performance with actual files, see the article by V. Y. Lum, P. S. T. Yuen, and M. Dodd, *CACM* **14** (1971), 228–239.

Of all the other hash methods that have been tried, perhaps the most interesting is a technique based on algebraic coding theory; the idea is analogous to the division method above, but we divide by a polynomial modulo 2 instead of dividing by an integer. (As observed in Section 4.6, this operation is analogous to division, just as addition is analogous to exclusive-or.) For this method, M

should be a power of 2, say $M = 2^m$, and we make use of an mth degree polynomial $P(x) = x^m + p_{m-1}x^{m-1} + \cdots + p_0$. An n-digit binary key $K = (k_{n-1} \ldots k_1 k_0)_2$ can be regarded as the polynomial $K(x) = k_{n-1}x^{n-1} + \cdots + k_1 x + k_0$, and we compute the remainder

$$K(x) \bmod P(x) = h_{m-1}x^{m-1} + \cdots + h_1 x + h_0$$

using polynomial arithmetic modulo 2; then $h(K) = (h_{m-1} \ldots h_1 h_0)_2$. If $P(x)$ is chosen properly, this hash function can be guaranteed to avoid collisions between nearly-equal keys. For example if $n = 15$, $m = 10$, and

$$P(x) = x^{10} + x^8 + x^5 + x^4 + x^2 + x + 1, \tag{10}$$

it can be shown that $h(K_1)$ will be unequal to $h(K_2)$ whenever K_1 and K_2 are distinct keys that differ in fewer than seven bit positions. (See exercise 7 for further information about this scheme; it is, of course, more suitable for hardware or microprogramming implementation than for software.)

It has been found convenient to use the constant hash function $h(K) = 0$ when debugging a program, since all keys will be stored together; an efficient $h(K)$ can be substituted later.

Collision resolution by "chaining." We have observed that some hash addresses will probably be burdened with more than their share of keys. Perhaps the most obvious way to solve this problem is to maintain M linked lists, one for each possible hash code. A `LINK` field should be included in each record, and there will also be M list heads, numbered say from 1 through M. After hashing the key, we simply do a sequential search in list number $h(K) + 1$. (Cf. exercise 6.1–2. The situation is very similar to multiple-list-insertion sorting, Program 5.2.1M.)

Figure 38 illustrates this simple chaining scheme when $M = 9$, for the sequence of seven keys

$$K = \texttt{EN, TO, TRE, FIRE, FEM, SEKS, SYV} \tag{11}$$

(i.e., the numbers 1 through 7 in Norwegian), having the respective hash codes

$$h(K) + 1 = \ 3, \quad 1, \quad 4, \quad 1, \quad 5, \quad 9, \quad 2. \tag{12}$$

The first list has two elements, and three of the lists are empty.

Chaining is quite fast, because the lists are short. If 365 people are gathered together in one room, there will probably be many pairs having the same birthday, but the average number of people with any given birthday will be only 1! In general, if there are N keys and M lists, the average list size is N/M; thus hashing decreases the amount of work needed for sequential searching by roughly a factor of M.

This method is a straightforward combination of techniques we have discussed before, so we do not need to formulate a detailed algorithm for chained scatter tables. It is often a good idea to keep the individual lists in order by key, so that insertions and unsuccessful searches go faster. Thus if we choose

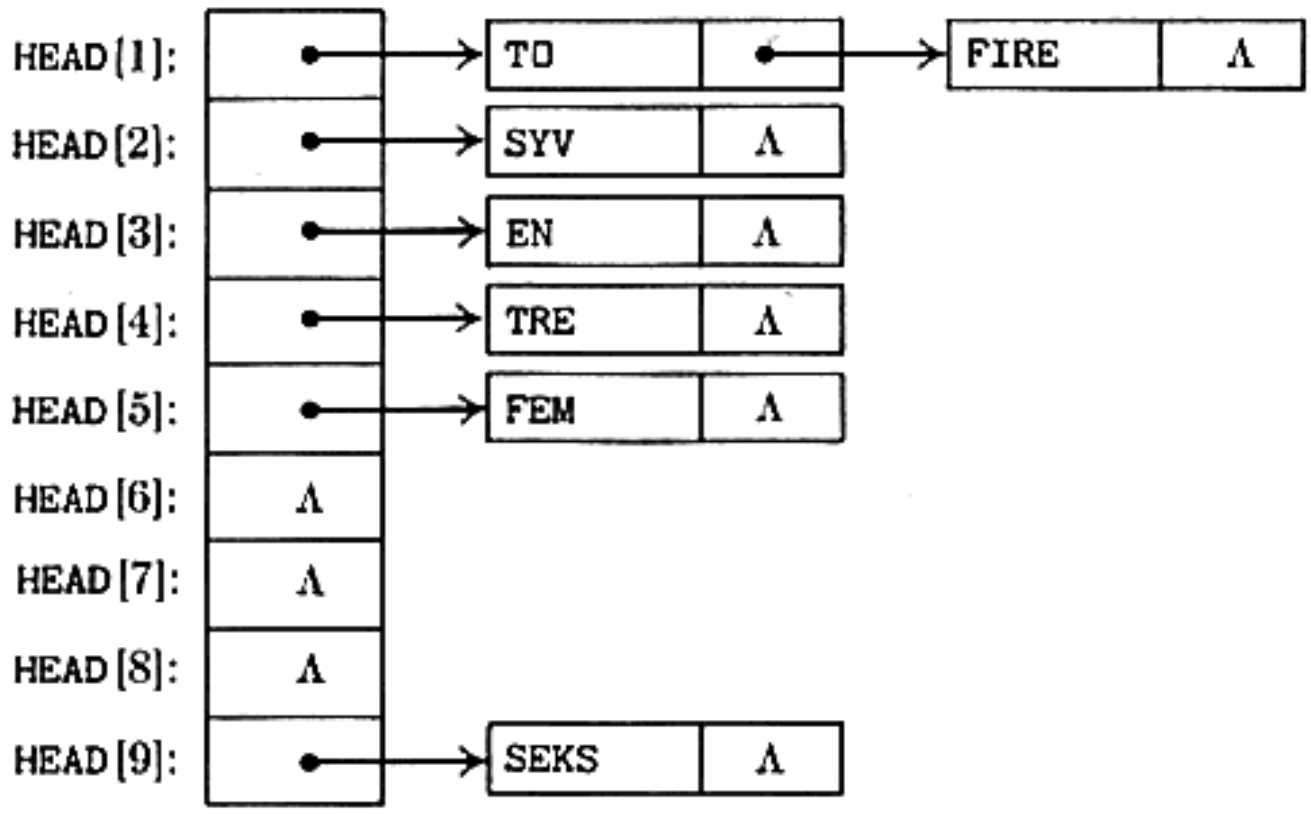

Fig. 38. Separate chaining.

to make the lists ascending, the TO and FIRE nodes of Fig. 38 would be interchanged, and all the Λ links would be replaced by pointers to a dummy record whose key is ∞. (Cf. Algorithm 6.1T.) Alternatively we can make use of the "self-organizing file" concept discussed in Section 6.1; instead of keeping the lists in order by key, they may be kept in order according to the time of most recent occurrence.

For the sake of speed we would like to make M rather large. But when M is large, many of the lists will be empty and much of the space for the M list heads will be wasted. This suggests another approach, when the records are small: We can overlap the record storage with the list heads, making room for a total of M records and M links instead of for N records and $M + N$ links. Sometimes it is possible to make one pass over all the data to find out which list heads will be used, then to make another pass inserting all the "overflow" records into the empty slots. But this is often impractical or impossible, and we would rather have a technique that processes each record only once when it first enters the system. The following algorithm, due to F. A. Williams [*CACM* **2**, 6 (June 1959), 21–24], is a convenient way to solve the problem.

Algorithm C (*Chained scatter table search and insertion*). This algorithm searches an M-node table, looking for a given key K. If K is not in the table and the table is not full, K is inserted.

The nodes of the table are denoted by TABLE[i], for $0 \le i \le M$, and they are of two distinguishable types, *empty* and *occupied*. An occupied node contains a key field KEY[i], a link field LINK[i], and possibly other fields.

The algorithm makes use of a hash function $h(K)$. An auxiliary variable R is also used, to help find empty spaces; when the table is empty, we have R $= M + 1$, and as insertions are made it will always be true that TABLE[j] is occupied for all j in the range R $\le j \le M$. By convention, TABLE[0] will always be empty.

C1. [Hash.] Set $i \leftarrow h(K) + 1$. (Now $1 \le i \le M$.)

C2. [Is there a list?] If TABLE[i] is empty, go to C6. (Otherwise TABLE[i] is occupied; we will look at the list of occupied nodes which starts here.)

C3. [Compare.] If $K =$ KEY[i], the algorithm terminates successfully.

C4. [Advance to next.] If LINK[i] $\neq 0$, set $i \leftarrow$ LINK[i] and go back to step C3.

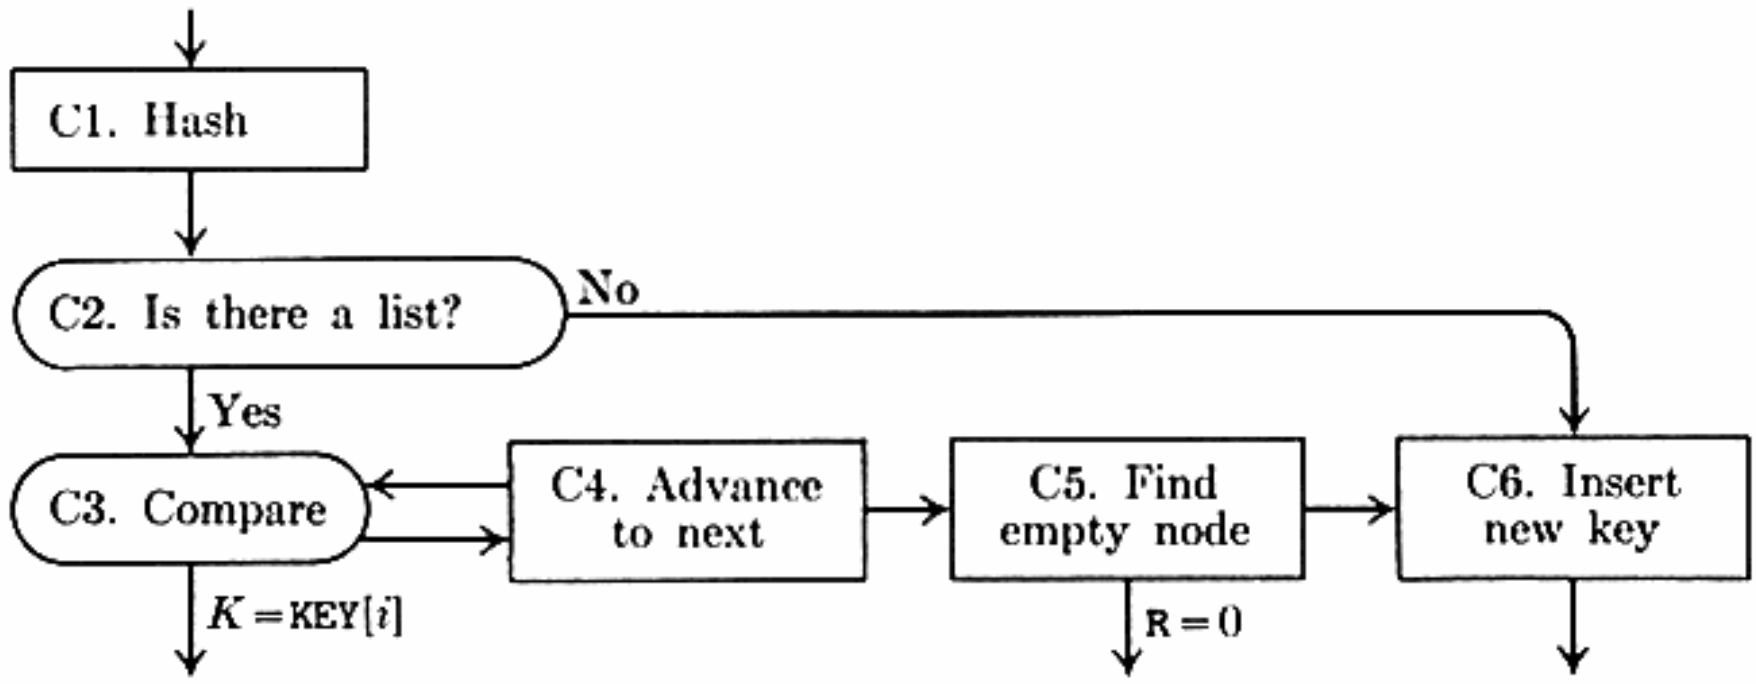

Fig. 39. Chained scatter table search and insertion.

C5. [Find empty node.] (The search was unsuccessful, and we want to find an empty position in the table.) Decrease R one or more times until finding a value such that TABLE[R] is empty. If R = 0, the algorithm terminates with overflow (there are no empty nodes left); otherwise set LINK[i] $\leftarrow$ R, $i \leftarrow$ R.

C6. [Insert new key.] Mark TABLE[i] as an occupied node, with KEY[i] $\leftarrow K$ and LINK[i] $\leftarrow 0$. ∎

This algorithm allows several lists to coalesce, so that records need not be moved after they have been inserted into the table. For example, see Fig. 40, where SEKS appears in the list containing TO and FIRE since the latter had already been inserted into position 9.

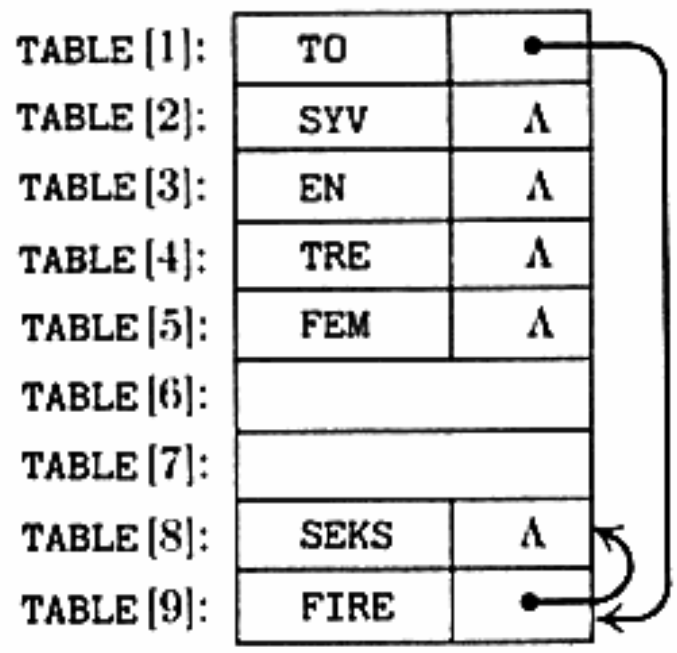

Fig. 40. Coalesced chaining.

In order to see how this algorithm compares with others in this chapter, we can write the following MIX program. The analysis worked out below indicates that the lists of occupied cells tend to be short, and the program has been designed with this fact in mind.

Program C (*Chained scatter table search and insertion*). For convenience, the keys are assumed to be only three bytes long, and nodes are represented as follows:

empty	—	1	0	0	0	0
occupied	+	LINK		KEY		

(13)

The table size M is assumed to be prime; TABLE[i] is stored in location TABLE$+i$. rI1 $\equiv i$, rA $\equiv K$.

```
01  KEY     EQU   3:5
02  LINK    EQU   0:2
03  START   LDX   K                    1          C1. Hash.

05          DIV   =M=                  1
06          STX   *+1(0:2)             1
07          ENT1  *                    1          i ← h(k)
08          INC1  1                    1                  + 1.
09          LDA   K                    1
10          LD2   TABLE,1(LINK)        1          C2. Is there a list?
11          J2N   6F                   1          To C6 if TABLE[i] empty.
12          CMPA  TABLE,1(KEY)         A          C3. Compare.
13          JE    SUCCESS              A          Exit if K = KEY[i].
14          J2Z   5F                   A − S1     To C5 if LINK[i] = 0.
15  4H      ENT1  0,2                  C − 1      C4. Advance to next.
16          CMPA  TABLE,1(KEY)         C − 1      C3. Compare.
17          JE    SUCCESS              C − 1      Exit if K = KEY[i].
18          LD2   TABLE,1(LINK)        C − 1 − S2
19          J2NZ  4B                   C − 1 − S2 Advance if LINK[i] ≠ 0.
20  5H      LD2   R                      A − S    C5. Find empty node.
21          DEC2  1                      T        R ← R − 1.
22          LDX   TABLE,2                T
23          JXNN  *-2                    T        Repeat until TABLE[R] empty.
24          J2Z   OVERFLOW             A − S      Exit if no empty nodes left.
25          ST2   TABLE,1(LINK)        A − S      LINK[i] ← R.
26          ENT1  0,2                  A − S      i ← R.
27          ST2   R                    A − S      Update R in memory.
28  6H      STZ   TABLE,1(LINK)        1 − S      C6. Insert new key.
29          STA   TABLE,1(KEY)         1 − S      KEY[i] ← K. ∎
```

The running time of this program depends on

C = number of table entries probed while searching;

$A = 1$ if the initial probe found an occupied node;

$S = 1$ if successful, 0 if unsuccessful;

$T =$ number of table entries probed while looking for an empty space.

Here $S = S1 + S2$, where $S1 = 1$ if successful on the first try. The total running time for the searching phase of Program C is $(7C + 4A + 17 - 3S + 2S1)u$, and the insertion of a new key when $S = 0$ takes an additional $(8A + 4T + 4)u$.

Suppose there are N keys in the table at the start of this program, and let

$$\alpha = N/M = \text{load factor of the table.} \tag{14}$$

Then the average value of A in an unsuccessful search is obviously α, if the hash function is random; and exercise 39 proves that the average value of C in an unsuccessful search is

$$C'_N = 1 + \frac{1}{4}\left(\left(1 + \frac{2}{M}\right)^N - 1 - \frac{2N}{M}\right) \approx 1 + \tfrac{1}{4}(e^{2\alpha} - 1 - 2\alpha). \tag{15}$$

Thus when the table is half full, the average number of probes made in an unsuccessful search is about $\frac{1}{4}(e + 2) \approx 1.18$; and even when the table gets completely full, the average number of probes made just before inserting the final item will be only about $\frac{1}{4}(e^2 + 1) \approx 2.10$. The standard deviation is also small, as shown in exercise 40. These statistics prove that *the lists stay short even though the algorithm occasionally allows them to coalesce*, when the hash function is random. Of course C can be as high as N, if the hash function is bad or if we are extremely unlucky.

In a successful search, we always have $A = 1$. The average number of probes during a successful search may be computed by summing the quantity $C + A$ over the first N unsuccessful searches and dividing by N, if we assume that each key is equally likely. Thus we obtain

$$C_N = \frac{1}{N}\sum_{0\le k<N}\left(C'_k + \frac{k}{M}\right) = 1 + \frac{1}{8}\,\frac{M}{N}\left(\left(1 + \frac{2}{M}\right)^N - 1 - \frac{2N}{M}\right) + \frac{1}{4}\,\frac{N-1}{M}$$

$$\approx 1 + \frac{1}{8\alpha}(e^{2\alpha} - 1 - 2\alpha) + \tfrac{1}{4}\alpha \tag{16}$$

as the average number of probes in a random successful search. Even a full table will require only about 1.80 probes, on the average, to find an item! Similarly (see exercise 42), the average value of $S1$ turns out to be

$$S1_N = 1 - \tfrac{1}{2}((N-1)/M) \approx 1 - \tfrac{1}{2}\alpha. \tag{17}$$

At first glance it may appear that step C5 is inefficient, since it has to search sequentially for an empty position. But actually the total number of table probes made in step C5 as a table is being built will never exceed the number of items in the table; so we make an average of at most one of these probes per insertion! Exercise 41 proves that T is approximately αe^{α} in a random unsuccessful search.

It would be possible to modify Algorithm C so that no two lists coalesce, but then it would become necessary to move records around. For example,

consider the situation in Fig. 40 just before we wanted to insert SEKS into position 9; in order to keep the lists separate, it would be necessary to move FIRE, and for this purpose it would be necessary to discover which node points to FIRE. We could solve this problem without providing two-way linkage by using circular lists, as suggested by Allen Newell in 1962, since the lists are short; but that would probably slow down the main search loop because step C4 would be more complicated. Exercise 34 shows that the average number of probes, when lists aren't coalesced, is reduced to

$$C'_N = \left(1 - \frac{1}{M}\right)^N + \frac{N}{M} \approx e^{-\alpha} + \alpha \qquad \text{(unsuccessful search)}; \qquad (18)$$

$$C_N = \quad 1 + \frac{N-1}{2M} \quad \approx 1 + \tfrac{1}{2}\alpha \qquad \text{(successful search)}. \qquad (19)$$

This is not enough of an improvement over (15) and (16) to warrant changing the algorithm.

On the other hand, Butler Lampson has observed that most of the space actually needed for links can actually be saved in the chaining method, if we avoid coalescing the lists. This leads to an interesting algorithm which is discussed in exercise 13.

Note that chaining can be used when $N > M$, so overflow is not a serious problem. If separate lists are used, formulas (18) and (19) are valid for $\alpha > 1$. When the lists coalesce as in Algorithm C, we can link extra items into an auxiliary storage pool; L. Guibas has proved that the average number of probes to insert the $(M + L + 1)$st item is then $(L/2M + \frac{1}{4})((1 + 2/M)^M - 1) + \frac{1}{2}$.

Collision resolution by "open addressing." Another way to resolve the problem of collisions is to do away with the links entirely, simply looking at various entries of the table one by one until either finding the key K or finding an empty position. The idea is to formulate some rule by which every key K determines a "probe sequence," namely a sequence of table positions which are to be inspected whenever K is inserted or looked up. If we encounter an open position while searching for K, using the probe sequence determined by K, we can conclude that K is not in the table, since the same sequence of probes will be made every time K is processed. This general class of methods was named *open addressing* by W. W. Peterson [*IBM J. Research & Development* **1** (1957), 130–146].

The simplest open addressing scheme, known as *linear probing*, uses the cyclic probe sequence

$$h(K),\ h(K) - 1,\ \ldots,\ 0,\ M - 1,\ M - 2,\ \ldots,\ h(K) + 1 \qquad (20)$$

as in the following algorithm.

Algorithm L (*Open scatter table search and insertion*). This algorithm searches an M-node table, looking for a given key K. If K is not in the table and the table is not full, K is inserted.

The nodes of the table are denoted by TABLE[i], for $0 \le i < M$, and they are of two distinguishable types, *empty* and *occupied*. An occupied node contains a key, called KEY[i], and possibly other fields. An auxiliary variable N is used to keep track of how many nodes are occupied; this variable is considered to be part of the table, and it is increased by 1 whenever a new key is inserted.

This algorithm makes use of a hash function $h(K)$, and it uses the linear probing sequence (20) to address the table. Modifications of that sequence are discussed below.

L1. [Hash.] Set $i \leftarrow h(K)$. (Now $0 \le i < M$.)

L2. [Compare.] If TABLE[i] is empty, go to L4. Otherwise if KEY[i] $= K$, the algorithm terminates successfully.

L3. [Advance to next.] Set $i \leftarrow i - 1$; if now $i < 0$, set $i \leftarrow i + M$. Go back to step L2.

L4. [Insert.] (The search was unsuccessful.) If N $= M - 1$, the algorithm terminates with overflow. (This algorithm considers the table to be full when N $= M - 1$, not when N $= M$; see exercise 15.) Otherwise set N $\leftarrow$ N $+ 1$, mark TABLE[i] occupied, and set KEY[i] $\leftarrow K$. ∎

Figure 41 shows what happens when the seven example keys (11) are inserted by Algorithm L, using the respective hash codes 2, 7, 1, 8, 2, 8, 1: The last three keys, FEM, SEKS, and SYV, have been displaced from their initial locations $h(K)$.

0	FEM

7	TO
8	FIRE

Fig. 41. Linear open addressing.

Program L (*Open scatter table search and insertion*). This program deals with full-word keys; but a key of 0 is not allowed, since 0 is used to signal an empty position in the table. (Alternatively, we could require the keys to be nonnegative, letting empty positions contain -1.) The table size M is assumed to be prime, and TABLE[i] is stored in location TABLE $+ i$ for $0 \le i < M$. For speed in the inner loop, location TABLE $- 1$ is assumed to contain 0. Location VACANCIES is assumed to contain the value $M - 1 -$ N; and rA $\equiv K$, rI1 $\equiv i$.

In order to speed up the inner loop of this program, the test "$i < 0$" has been removed from the loop so that only the essential parts of steps L2 and L3 remain. The total running time for the searching phase comes to $(7C + 9E + 21 - 4S)u$, and the insertion after an unsuccessful search adds an extra $9u$.

```
01  START  LDX   K              1          L1. Hash.

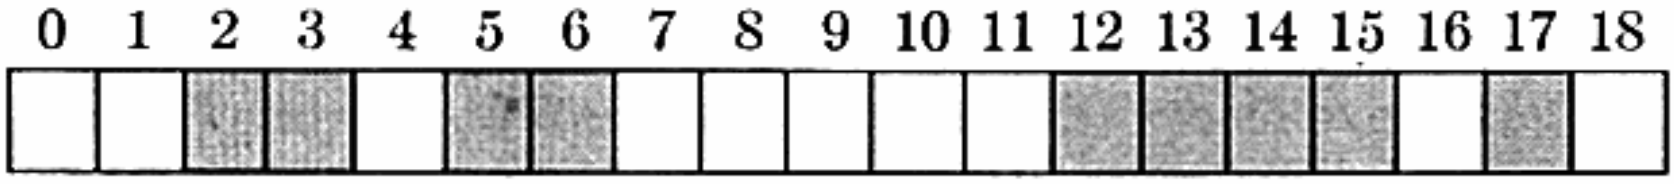
10  2H     CMPA  TABLE,1        C + E      L2. Compare.,
11         JE    SUCCESS        C + E      Exit if K = KEY[i].
12         LDX   TABLE,1        C + E − S
13         JXNZ  3B             C + E − S  To L3 if TABLE[i] empty.
14         J1N   8B             E + 1 − S  To L3 with i ← M if i = −1.
15  4H     LDX   VACANCIES      1 − S      L4. Insert.
16         JXZ   OVERFLOW       1 − S      Exit with overflow if N = M − 1.
17         DECX  1              1 − S
18         STX   VACANCIES      1 − S      Increase N by 1.
19         STA   TABLE,1        1 − S      TABLE[i] ← K. ∎
```

As in Program C, the variable C denotes the number of probes, and S tells whether or not the search was successful. We may ignore the variable E, which is 1 only if a spurious probe of TABLE[−1] has been made, since its average value is $(C - 1)/M$.

Experience with linear probing shows that the algorithm works fine until the table begins to get full; but eventually the process slows down, with long drawn-out searches becoming increasingly frequent. The reason for this behavior can be understood by considering the following hypothetical scatter table with $M = 19$, $N = 9$:



(21)

Shaded squares represent occupied positions. The next key K to be inserted into the table will go into one of the ten empty spaces, but these are not equally likely; in fact, K will be inserted into position 11 if $11 \le h(K) \le 15$, while it will fall into position 8 only if $h(K) = 8$. Therefore position 11 is five times as likely as position 8; long lists tend to grow even longer.

This phenomenon isn't enough by itself to account for the relatively poor behavior of linear probing, since a similar thing occurs in Algorithm C. (A list of length 4 is four times as likely to grow in Algorithm C as a list of length 1.) The real problem occurs when a cell like 4 or 16 is filled in (21); then two separate lists are combined, while the lists in Algorithm C never grow by more than one step at a time. Consequently the performance of linear probing degrades rapidly when N approaches M.

We shall prove later in this section that the average number of probes needed by Algorithm L is approximately

$$C'_N \approx \frac{1}{2}\left(1 + \left(\frac{1}{1-\alpha}\right)^2\right) \qquad \text{(unsuccessful search)}; \tag{22}$$

$$C_N \approx \frac{1}{2}\left(1 + \frac{1}{1-\alpha}\right) \qquad \text{(successful search)}, \tag{23}$$

where $\alpha = N/M$ is the load factor of the table. So Program L is almost as fast as Program C, when the table is less than 75 percent full, in spite of the fact that Program C deals with unrealistically short keys. On the other hand, when α approaches 1 the best thing we can say about Program L is that it works, slowly but surely. In fact, when $N = M - 1$, there is only one vacant space in the table, so the average number of probes in an unsuccessful search is $(M + 1)/2$; we shall also prove that the average number of probes in a successful search is approximately $\sqrt{\pi M/8}$ when the table is full.

The pileup phenomenon which makes linear probing costly on a nearly full table is aggravated by the use of division hashing, if consecutive key values $\{K, K + 1, K + 2, \ldots\}$ are likely to occur, since these keys will have consecutive hash codes. Multiplicative hashing will break up these clusters satisfactorily. Note that multiplicative hashing is slightly awkward for the chained method, since we generally would want to use at least $(m + 1)$-bit link fields when $M = 2^m$ in order to distinguish rapidly between Λ and a valid link. This wasted bit position is no problem with open addressing since there are no links.

Another way to protect against the consecutive hash code problem is to set $i \leftarrow i - c$ in step L3, instead of $i \leftarrow i - 1$. Any positive value of c will do, so long as it is *relatively prime* to M, since the probe sequence will still examine every position of the table in this case. Such a change will make Program L somewhat slower. It doesn't alter the pileup phenomenon, since groups of c-apart records will still be formed; equations (22) and (23) will still apply, but the appearance of consecutive keys $\{K, K + 1, K + 2, \ldots\}$ will now actually be a help instead of a hindrance.

Although a fixed value of c does not reduce the pileup phenomenon, we can improve the situation nicely by letting c depend on K! This idea leads to an important modification of Algorithm L, first discovered by Guy de Balbine [Ph.D. thesis, Calif. Inst. of Technology (1968), 149–150]:

Algorithm D (*Open addressing with double hashing*). This algorithm is almost identical to Algorithm L, but it probes the table in a slightly different fashion by making use of two hash functions $h_1(K)$ and $h_2(K)$. As usual $h_1(K)$ produces a value between 0 and $M - 1$, inclusive; but $h_2(K)$ must produce a value between 1 and $M - 1$ that is *relatively prime* to M. (For example, if M is prime, $h_2(K)$ can be *any* value between 1 and $M - 1$ inclusive; or if $M = 2^m$, $h_2(K)$ can be any *odd* value between 1 and $2^m - 1$.)

D1. [First hash.] Set $i \leftarrow h_1(K)$.

D2. [First probe.] If TABLE[i] is empty, go to D6. Otherwise if KEY[i] $= K$, the algorithm terminates successfully.

D3. [Second hash.] Set $c \leftarrow h_2(K)$.

D4. [Advance to next.] Set $i \leftarrow i - c$; if now $i < 0$, set $i \leftarrow i + M$.

D5. [Compare.] If TABLE[i] is empty, go to D6. Otherwise if KEY[i] $= K$, the algorithm terminates successfully. Otherwise go back to D4.

D6. [Insert.] If N $= M - 1$, the algorithm terminates with overflow. Otherwise set N $\leftarrow$ N $+ 1$, mark TABLE[i] occupied, and set KEY[i] $\leftarrow K$. ∎

Several possibilities have been suggested for computing $h_2(K)$. If M is prime and $h_1(K) = K \bmod M$, we might let $h_2(K) = 1 + (K \bmod (M - 1))$; but since $M - 1$ is even, it would be better to let $h_2(K) = 1 + (K \bmod (M - 2))$. This suggests choosing M so that M and $M - 2$ are "twin primes" like 1021 and 1019. Alternatively, we could set $h_2(K) = 1 + (\lfloor K/M \rfloor \bmod (M - 2))$, since the quotient $\lfloor K/M \rfloor$ might be available in a register as a by-product of the computation of $h_1(K)$.

If $M = 2^m$ and we are using multiplicative hashing, $h_2(K)$ can be computed simply by shifting left m more bits and "oring in" a 1, so that the coding sequence (5) would be followed by

```
ENTA   0        Clear rA.
SLB    m        Shift rAX m bits left.          (24)
ORR    =1=      rA ← rA ∨ 1.
```

This is faster than the division method.

In each of the techniques suggested above, $h_1(K)$ and $h_2(K)$ are "independent," in the sense that different keys will have the same value for both h_1 and h_2 with probability $O(1/M^2)$ instead of $O(1/M)$. Empirical tests show that the behavior of Algorithm D with independent hash functions is essentially indistinguishable from the number of probes which would be required if the keys were inserted at random into the table; there is practically no "piling up" or "clustering" as in Algorithm L.

It is also possible to let $h_2(K)$ depend on $h_1(K)$, as suggested by Gary Knott in 1968; for example, if M is prime we could let

$$h_2(K) = \begin{cases} 1, & \text{if} \quad h_1(K) = 0; \\ M - h_1(K), & \text{if} \quad h_1(K) > 0. \end{cases} \tag{25}$$

This would be faster than doing another division, but we shall see that it does cause a certain amount of *secondary clustering*, requiring slightly more probes because of the increased chance that two or more keys will follow the same path. The formulas derived below can be used to determine whether the gain in hashing time outweighs the loss of probing time.

Algorithms L and D are very similar, yet there are enough differences that it is instructive to compare the running time of the corresponding MIX programs.

Program D (*Open addressing with double hashing*). Since this program is substantially like Program L, it is presented without comments. rI2 $\equiv c - 1$.

```
01    START  LDX    K              1
02           ENTA   0              1

19           JE     SUCCESS        C - 1
20           LDX    TABLE,1        C - 1 - S2
21           JXNZ   3B             C - 1 - S2
22     4H    LDX    VACANCIES      1 - S
23           JXZ    OVERFLOW       1 - S
24           DECX   1              1 - S
25           STX    VACANCIES      1 - S
26           LDA    K              1 - S
27           STA    TABLE, 1       1 - S
```

The frequency counts A, C, $S1$, $S2$ in this program have a similar interpretation to those in Program C above. The other variable B will be about $\frac{1}{2}(C - 1)$ on the average. (If we restricted the range of $h_2(K)$ to, say, $1 \le h_2(K) \le \frac{1}{2}M$, B would be only about $\frac{1}{4}(C - 1)$; this increase of speed will probably *not* be offset by a noticeable increase in the number of probes.) When there are $N = \alpha M$ keys in the table, the average value of A is, of course, α in an unsuccessful search, and $A = 1$ in a successful search. As in Algorithm C, the average value of $S1$ in a successful search is $1 - \frac{1}{2}((N - 1)/M) \approx 1 - \frac{1}{2}\alpha$. The average number of probes is difficult to determine exactly, but empirical tests show good agreement with formulas derived below for "uniform probing," namely

$$C'_N = \frac{M+1}{M+1-N} \approx (1-\alpha)^{-1} \quad \text{(unsuccessful search)}, \tag{26}$$

$$C_N = \frac{M+1}{N}(H_{M+1} - H_{M+1-N}) \approx -\alpha^{-1}\ln(1-\alpha) \quad \text{(successful search)}, \tag{27}$$

when $h_1(K)$ and $h_2(K)$ are independent. When $h_2(K)$ depends on $h_1(K)$ as in (25), the secondary clustering causes these formulas to be increased to

$$C'_N = \frac{M+1}{M+1-N} - \frac{N}{M+1} + H_{M+1} - H_{M+1-N} + O(M^{-1}) \approx (1-\alpha)^{-1} - \alpha - \ln(1-\alpha); \tag{28}$$

$$C_N = 1 + H_{M+1} - H_{M+1-N} - \frac{N}{2(M+1)} - (H_{M+1} - H_{M+1-N})/N + O(N^{-1}) \approx 1 - \ln(1-\alpha) - \tfrac{1}{2}\alpha. \tag{29}$$

(See exercise 44.) Note that as the table gets full, these values of C_N approach $H_{M+1} - 1$ and $H_{M+1} - \frac{1}{2}$, respectively, when $N = M$; this is much better than we observed in Algorithm L, but not as good as in the chaining methods.

Since each probe takes slightly less time in Algorithm L, double hashing is advantageous only when the table gets full. Figure 42 compares the average running time of Program L, Program D, and a modified Program D which involves secondary clustering, replacing the rather slow calculation of $h_2(K)$ in lines 10–13 by the three instructions

```
ENN2 -M-1,1          c ← M − i.
J1NZ *+2                                   (30)
ENT2 0               If i = 0, c ← 1.
```

In this case, secondary clustering is preferable to independent double hashing.

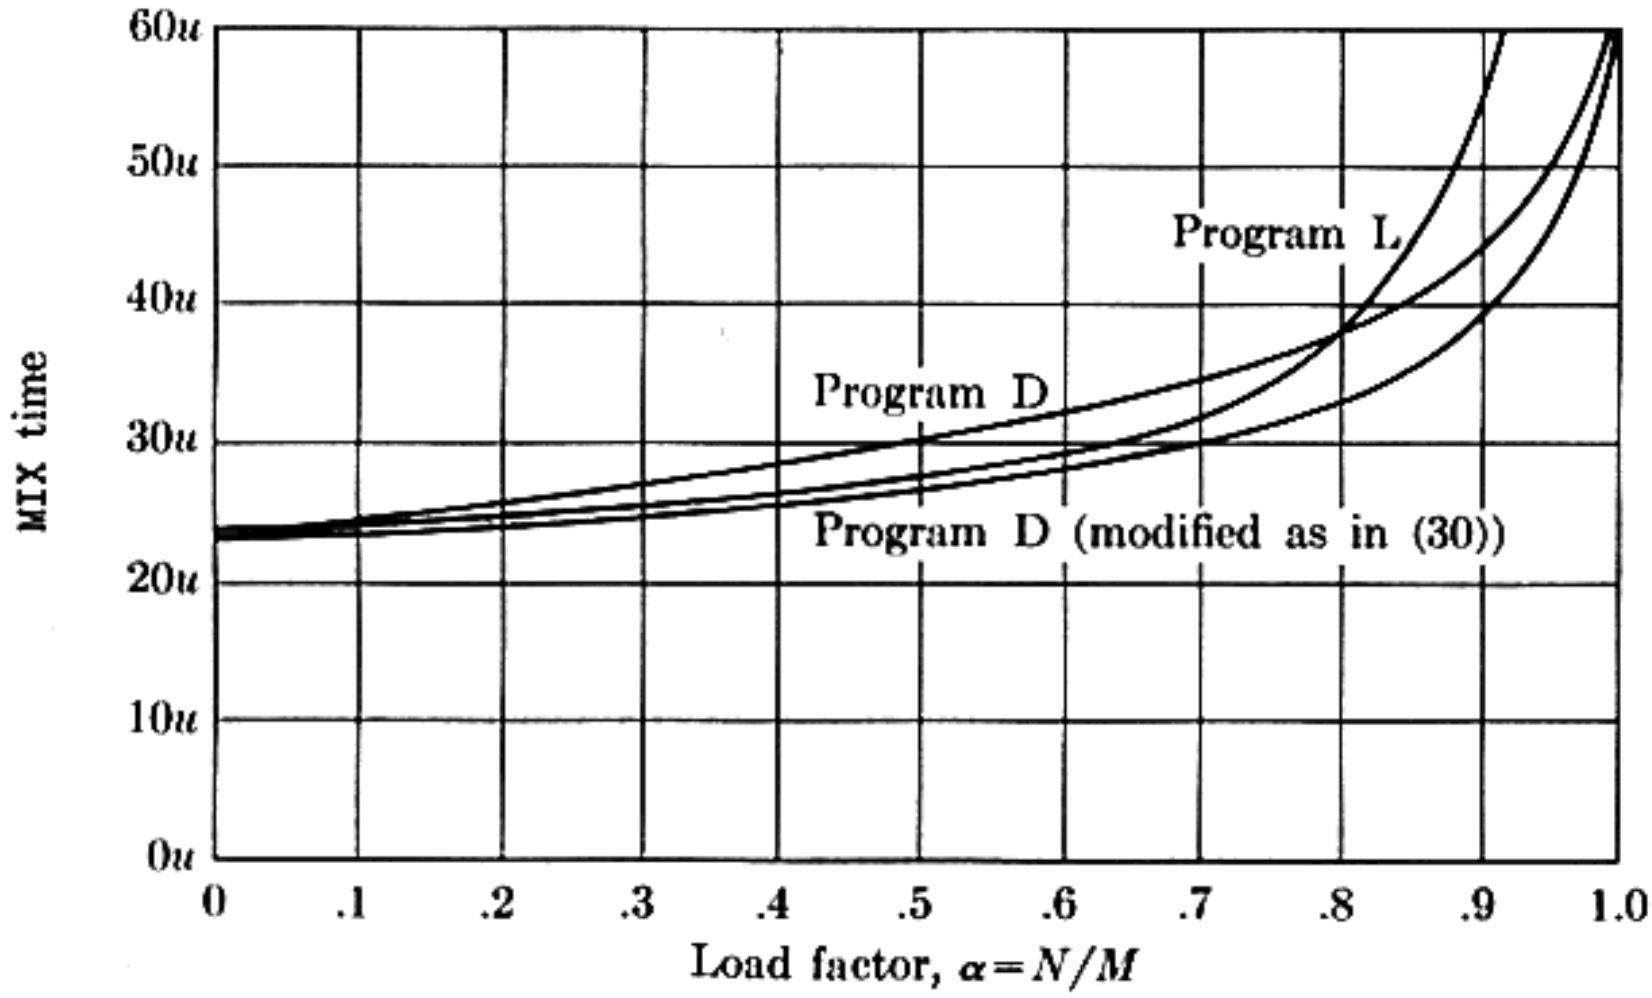

Fig. 42. The running time for successful searching by three open addressing schemes.

On a binary computer, we could speed up the computation of $h_2(K)$ in another way, replacing lines 10–13 by, say,

```
AND  =511=           rA ← rA mod 512.
STA  *+1(0:2)                              (31)
ENT2 *               c ← rA + 1.
```

if M is a prime greater than 512. This idea (suggested by Bell and Kaman, *CACM* **13** (1970), 675–677, who discovered Algorithm D independently) avoids secondary clustering without the expense of another division.

Many other probe sequences have been proposed as improvements on Algorithm L, but none seem to be superior to Algorithm D except possibly the method described in exercise 20.

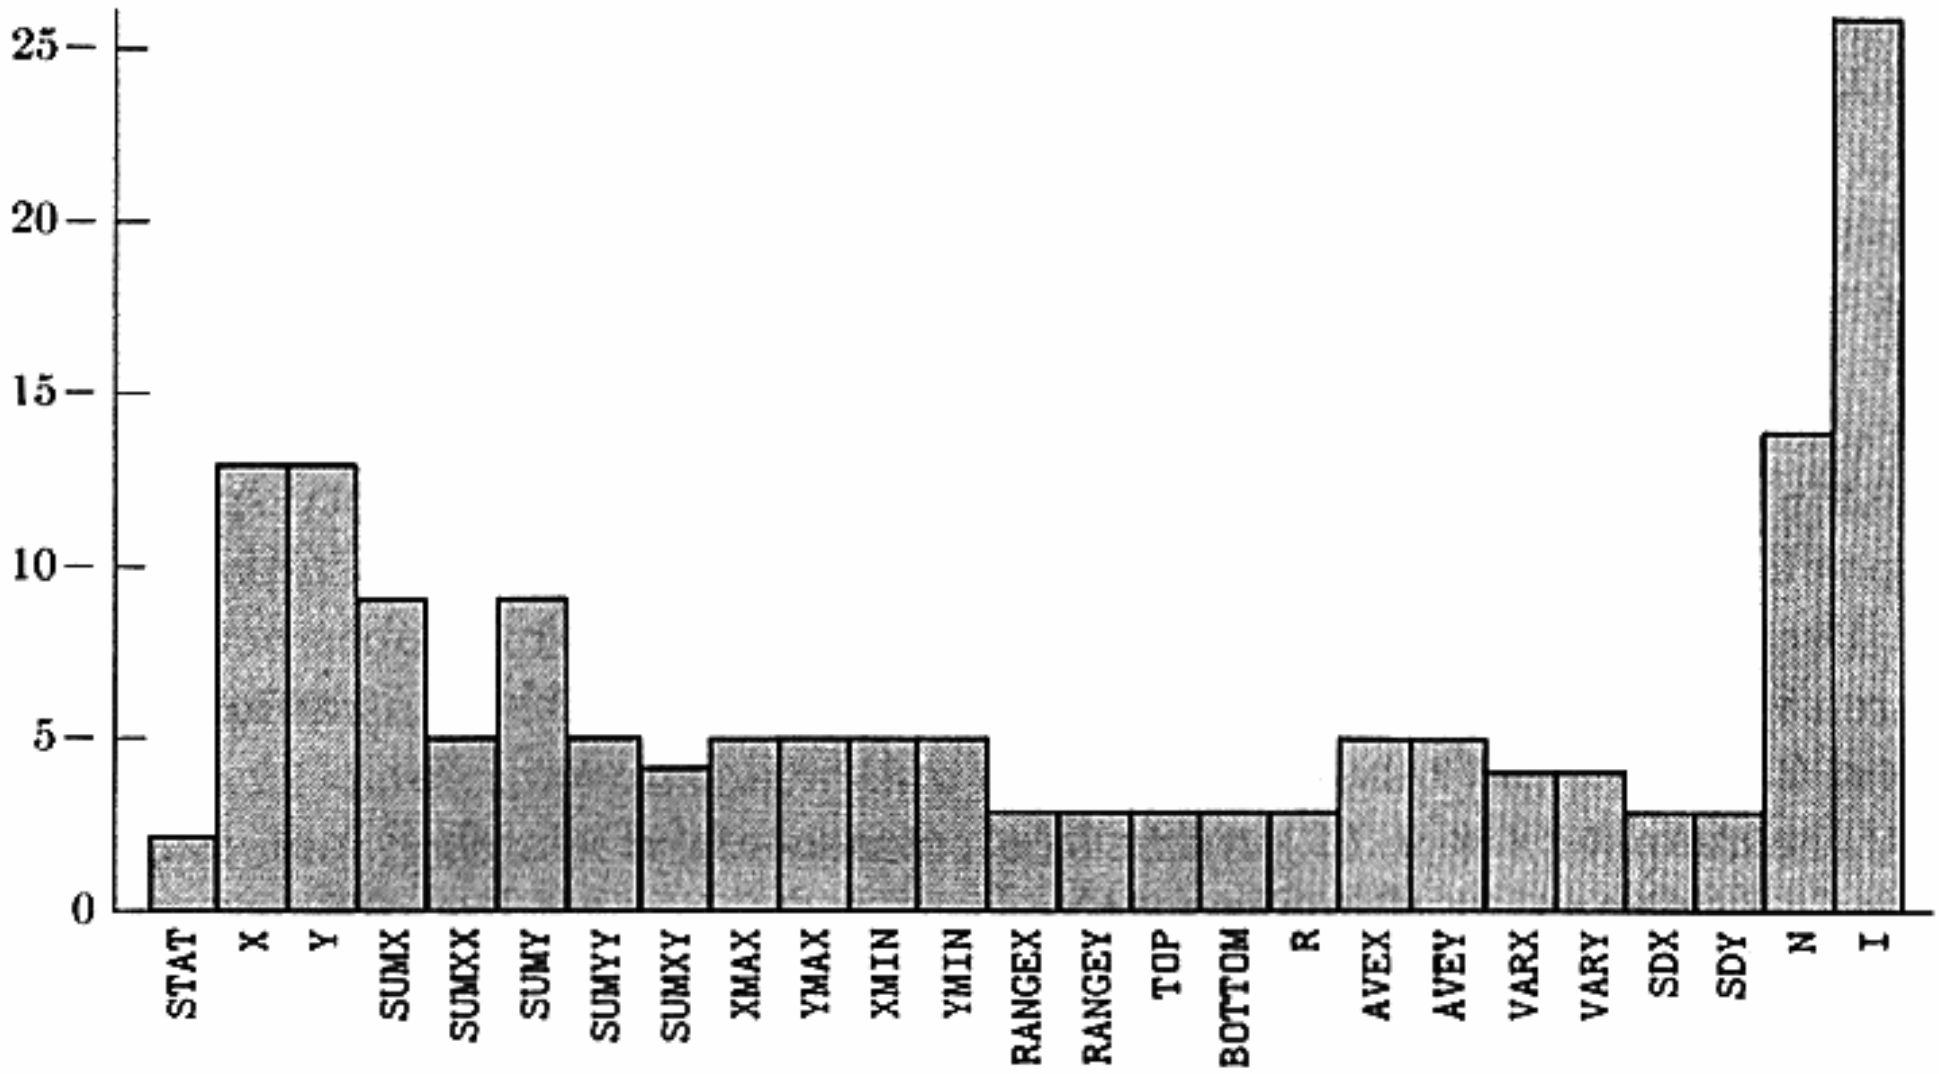

Fig. 43. The number of times a compiler typically searches for variable names. The names are listed from left to right in order of their first appearance.

Brent's Variation. Richard P. Brent has discovered a way to modify Algorithm D so that the average successful search time remains bounded as the table gets full. His method is based on the fact that successful searches are much more common than insertions, in many applications; therefore he proposes doing more work when inserting an item, moving records in order to reduce the expected retrieval time. [*CACM* **15** (1972), to appear.]

For example, Fig. 43 shows the number of times each identifier was actually found to appear, in a typical PL/I procedure. This data indicates that a PL/I compiler which uses a hash table to keep track of variable names will be looking up many of the names five or more times but inserting them only once. Similarly, Bell and Kaman found that a COBOL compiler used its symbol table algorithm 10988 times while compiling a program, but made only 735 insertions into the table; this is an average of about 14 successful searches per unsuccessful search. Sometimes a table is actually created only once (for example, a table of symbolic opcodes in an assembler), and it is used thereafter purely for retrieval.

Brent's idea is to change the insertion process in Algorithm D as follows. Suppose an unsuccessful search has probed locations

$$p_0, p_1, \cdots, p_{t-1}, p_t,$$

where $p_j = \big(h_1(K) - jh_2(K)\big) \bmod M$ and TABLE$[p_t]$ is empty. If $t \leq 1$, we insert K in position p_t as usual; but if $t \geq 2$, we compute $c_0 = h_2(K_0)$, where $K_0 =$ KEY$[p_0]$, and see if TABLE$[(p_0 - c_0) \bmod M]$ is empty. If it is, we set it to

TABLE[p_0] and then insert K in position p_0. This increases the retrieval time for K_0 by one step, but it decreases the retrieval time for K by $t \geq 2$ steps, so it results in a net improvement. Similarly, if TABLE[$(p_0 - c_0) \bmod M$] is occupied and $t \geq 3$, we try TABLE[$(p_0 - 2c_0) \bmod M$]; if that is full too, we compute $c_1 = h_2(\text{KEY}[p_1])$ and try TABLE[$(p_1 - c_1) \bmod M$]; etc. In general, let $c_j = h_2(\text{KEY}[p_j])$ and $p_{j,k} = (p_j - kc_j) \bmod M$; if we have found TABLE[$p_{j,k}$] occupied for all indices j, k such that $j + k < r$, and if $t \geq r + 1$, we look at TABLE[$p_{0,r}$], TABLE[$p_{1,r-1}$], . . . , TABLE[$p_{r-1,1}$]. If the first empty space occurs at position $p_{j,r-j}$ we set TABLE[$p_{j,r-j}$] $\leftarrow$ TABLE[p_j] and insert K in position p_j.

Brent's analysis indicates that the average number of probes per successful search is reduced as shown in Fig. 44, on page 539, with a maximum value of about 2.49.

The number $t + 1$ of probes in an unsuccessful search is not reduced by Brent's variation; it remains at the level indicated by Eq. (26), approaching $\frac{1}{2}(M + 1)$ as the table gets full. The average number of times h_2 needs to be computed per insertion is $\alpha^2 + \alpha^5 + \frac{1}{3}\alpha^6 + \cdots$, according to Brent's analysis, eventually approaching the order of $\sqrt{M}$; and the number of additional table positions probed while deciding how to make the insertion is about $\alpha^2 + \alpha^4 + \frac{4}{3}\alpha^5 + \alpha^6 + \cdots$.

Deletions. Many computer programmers have great faith in algorithms, and they are surprised to find that *the obvious way to delete records from a scatter table doesn't work*. For example, if we try to delete the key EN from Fig. 41, we can't simply mark that table position empty, because another key FEM would suddenly be forgotten! (Recall that EN and FEM both hashed to the same location. When looking up FEM, we would find an empty place, indicating an unsuccessful search.) A similar problem occurs with Algorithm C, due to the coalescing of lists; imagine the deletion of both TO and FIRE from Fig. 40.

In general, we can handle deletions by putting a special code value in the corresponding cell, so that there are three kinds of table entries: empty, occupied, and deleted. When searching for a key, we should skip over deleted cells, as if they were occupied. If the search is unsuccessful, the key can be inserted in place of the first deleted or empty position that was encountered.

But this idea is workable only when deletions are very rare, because the entries of the table never become empty again once they have been occupied. After a long sequence of repeated insertions and deletions, all of the empty spaces will eventually disappear, and every unsuccessful search will take M probes! Furthermore the time per probe will be increased, since we will have to test whether i has returned to its starting value in step D4; and the number of probes in a successful search will drift upward from C_N to C'_N.

When linear probing is being used (i.e., Algorithm L), it is possible to do deletions in a way that avoids such a sorry state of affairs, if we are willing to do some extra work for the deletion.

Algorithm R (*Deletion with linear probing*). Assuming that an open scatter table has been constructed by Algorithm L, this algorithm deletes the record from a given position TABLE[i].

R1. [Empty a cell.] Mark TABLE[i] empty, and set $j \leftarrow i$.

R2. [Decrease i.] Set $i \leftarrow i - 1$, and if this makes i negative set $i \leftarrow i + M$.

R3. [Inspect TABLE[i].] If TABLE[i] is empty, the algorithm terminates. Otherwise set $r \leftarrow h(\text{KEY}[i])$, the original hash address of the key now stored at position i. If $i \le r < j$ or if $r < j < i$ or $j < i \le r$ (in other words, if r lies cyclically between i and j), go back to R2.

R4. [Move a record.] Set TABLE[j] $\leftarrow$ TABLE[i], and return to step R1. ▮

Exercise 22 shows that this algorithm causes no degradation in performance, i.e., the average number of probes predicted in Eqs. (22) and (23) remains the same. (A similar result for tree insertion was proved in Theorem 6.2.2H.) But the validity of Algorithm R depends heavily on the fact that linear probing is involved, and no analogous deletion procedure for use with Algorithm D is possible.

Of course when chaining is used with separate lists for each possible hash value, deletion causes no problems since it is simply a deletion from a linked linear list. Deletion with Algorithm C is discussed in exercise 23.

***Analysis of the algorithms.** It is especially important to know the average behavior of a hashing method, because we are committed to trusting in the laws of probability whenever we hash. The worst case of these algorithms is almost unthinkably bad, so we need to be reassured that the average behavior is very good.

Before we get into the analysis of linear probing, etc., let us consider a very approximate model of the situation, which may be called *uniform hashing* (cf. W. W. Peterson, *IBM J. Research & Development* **1** (1957), 135–136). In this model, we assume that the keys go into random locations of the table, so that each of the $\binom{M}{N}$ possible configurations of N occupied cells and $M - N$ empty cells is equally likely. This model ignores any effect of primary or secondary clustering; the occupancy of each cell in the table is essentially independent of the others. For this model the probability that exactly r probes are needed to insert the $(N + 1)$st item is the number of configurations in which $r - 1$ given cells are occupied and another is empty, divided by $\binom{M}{N}$, namely

$$P_r = \binom{M - r}{N - r + 1} \Big/ \binom{M}{N};$$

therefore the average number of probes for uniform hashing is

$$C'_N = \sum_{1 \le r \le M} rP_r = M + 1 - \sum_{1 \le r \le M} (M + 1 - r)P_r$$

$$= M + 1 - \sum_{1 \le r \le M} (M + 1 - r) \binom{M - r}{M - N - 1} \Big/ \binom{M}{N}$$

$$= M + 1 - \sum_{1 \le r \le M} (M - N) \binom{M+1-r}{M-N} \Big/ \binom{M}{N} \tag{32}$$

$$= M + 1 - (M - N) \binom{M+1}{M-N+1} \Big/ \binom{M}{N}$$

$$= M + 1 - (M - N) \frac{M+1}{M-N+1} = \frac{M+1}{M-N+1}, \quad \text{for} \quad 1 \le N < M.$$

(We have already solved essentially the same problem in connection with random sampling, in exercise 3.4.2–5.) Setting $\alpha = N/M$, this exact formula for C'_N is approximately equal to

$$\frac{1}{1-\alpha} = 1 + \alpha + \alpha^2 + \alpha^3 + \cdots, \tag{33}$$

a series which has a rough intuitive interpretation: With probability α we need more than one probe, with probability α^2 we need more than two, etc. The corresponding average number of probes for a successful search is

$$\begin{aligned} C_N = \frac{1}{N} \sum_{0 \le k < N} C'_k &= \frac{M+1}{N} \left(\frac{1}{M+1} + \frac{1}{M} + \cdots + \frac{1}{M-N+2} \right) \\ &= \frac{M+1}{N} (H_{M+1} - H_{M-N+1}) \approx \frac{1}{\alpha} \log \frac{1}{1-\alpha}. \end{aligned} \tag{34}$$

As remarked above, extensive tests show that Algorithm D with two independent hash functions behaves essentially like uniform hashing, for all practical purposes.

This completes the analysis of uniform hashing. In order to study linear probing and other types of collision resolution, we need to set up the theory in a different, more realistic way. The probabilistic model we shall use for this purpose assumes that each of the M^N possible "hash sequences"

$$a_1 \, a_2 \ldots a_N, \qquad 0 \le a_j < M, \tag{35}$$

is equally likely, where a_j denotes the initial hash address of the jth key inserted into the table. The average number of probes in a successful search, given any particular searching algorithm, will be denoted by C_N as above; this is assumed to be the average number of probes needed to find the kth key, averaged over $1 \le k \le N$ with each key equally likely, and averaged over all hash sequences (35) with each sequence equally likely. Similarly, the average number of probes needed when the Nth key is inserted, considering all sequences (35) to be equally likely, will be denoted by C'_{N-1}; this is the average number of probes in an unsuccessful search starting with $N - 1$ elements in the table. When open addressing is used,

$$C_N = \frac{1}{N} \sum_{0 \le k < N} C'_k, \tag{36}$$

so that we can deduce one quantity from the other as we have done in (34).

Strictly speaking, there are two defects even in this more accurate model. In the first place, the different hash sequences aren't all equally probable, because the keys themselves are distinct. This makes the probability that $a_1 = a_2$ slightly less than $1/M$; but the difference is usually negligible since the set of all possible keys is typically very large compared to M. (See exercise 24.) Furthermore a good hash function will exploit the nonrandomness of typical data, making it even less likely that $a_1 = a_2$; as a result, our estimates for the number of probes will be pessimistic. Another inaccuracy in the model is indicated in Fig. 43: Keys that occur earlier are (with some exceptions) more likely to be looked up than keys that occur later. Therefore our estimate of C_N tends to be doubly pessimistic, and the algorithms should perform slightly better in practice than our analysis predicts.

With these precautions, we are ready to make an "exact" analysis of linear probing.* Let $f(M, N)$ be the number of hash sequences (35) such that position 0 of the table will be empty after the keys have been inserted by Algorithm L. The circular symmetry of linear probing implies that position 0 is empty just as often as any other position, so it is empty with probability $1 - N/M$; in other words

$$f(M, N) = \left(1 - \frac{N}{M}\right) M^N. \tag{37}$$

Now let $g(M, N, k)$ be the number of hash sequences (35) such that the algorithm leaves position 0 empty, positions 1 through k occupied, and position $k + 1$ empty. We have

$$g(M, N, k) = \binom{N}{k} f(k + 1, k)\ f(M - k - 1, N - k), \tag{38}$$

because all such hash sequences are composed of two subsequences, one (containing k elements $a_i \le k$) that leaves position 0 empty and positions 1 through k occupied and one (containing $N - k$ elements $a_j \ge k + 1$) that leaves position $k + 1$ empty; there are $f(k + 1, k)$ subsequences of the former type and $f(M - k - 1, N - k)$ of the latter, and there are $\binom{N}{k}$ ways to intersperse two such subsequences. Finally let P_k be the probability that exactly $k + 1$ probes will be needed when the $(N + 1)$st key is inserted; it follows (see exercise 25) that

$$P_k = M^{-N}(g(M, N, k) + g(M, N, k + 1) + \cdots + g(M, N, N)). \tag{39}$$

Now $C'_N = \sum_{0 \le k \le N} (k + 1)P_k$; putting this equation together with (36)–(39) and simplifying yields the following result.

---

* The author cannot resist inserting a biographical note at this point: I first formulated the following derivation in 1962, shortly after beginning work on *The Art of Computer Programming*. Since this was the first nontrivial algorithm I had ever analyzed satisfactorily, it has had a strong influence on the structure of these books. Little did I know that more than ten years would go by before this derivation got into print!

Theorem K. *The average number of probes needed by Algorithm L, assuming that all M^N hash sequences (35) are equally likely, is*

$$C_N = \tfrac{1}{2}(1 + Q_0(M, N-1)) \qquad \text{(successful search)}, \tag{40}$$

$$C'_N = \tfrac{1}{2}(1 + Q_1(M, N)) \qquad \text{(unsuccessful search)}, \tag{41}$$

where

$$Q_r(M, N) = \binom{r}{0} + \binom{r+1}{1}\frac{N}{M} + \binom{r+2}{2}\frac{N(N-1)}{M^2} + \cdots$$

$$= \sum_{k\ge 0}\binom{r+k}{k}\frac{N}{M}\,\frac{N-1}{M}\cdots\frac{N-k+1}{M}. \tag{42}$$

Proof. Details of the calculation are worked out in exercise 27. ∎

The rather strange-looking function $Q_r(M, N)$ which appears in this theorem is really not hard to deal with. We have

$$N^k - \binom{k}{2}N^{k-1} \le N(N-1)\cdots(N-k+1) \le N^k;$$

hence if $N/M = \alpha$,

$$\sum_{k\ge 0}\binom{r+k}{k}\left(N^k - \binom{k}{2}N^{k-1}\right)\Big/ M^k \le Q_r(M, N) \le \sum_{k\ge 0}\binom{r+k}{k}N^k/M^k,$$

$$\sum_{k\ge 0}\binom{r+k}{k}\alpha^k - \frac{\alpha}{M}\sum_{k\ge 0}\binom{r+k}{k}\binom{k}{2}\alpha^{k-2} \le Q_r(M, \alpha M) \le \sum_{k\ge 0}\binom{r+k}{k}\alpha^k,$$

i.e.,

$$\frac{1}{(1-\alpha)^{r+1}} - \frac{1}{M}\binom{r+2}{2}\frac{\alpha}{(1-\alpha)^{r+3}} \le Q_r(M, \alpha M) \le \frac{1}{(1-\alpha)^{r+1}}. \tag{43}$$

This relation gives us a good estimate of $Q_r(M, N)$ when M is large and α is not too close to 1. (The lower bound is a better approximation than the upper bound.) When α approaches 1, these formulas become useless, but fortunately $Q_0(M, M-1)$ is the function $Q(M)$ whose asymptotic behavior was studied in great detail in Section 1.2.11.3; and $Q_1(M, M-1)$ is simply equal to M (see exercise 50).

Another approach to the analysis of linear probing has been taken by G. Schay, Jr. and W. G. Spruth [*CACM* **5** (1962), 459–462]. Although their method yields only an approximation to the exact formulas in Theorem K, it sheds further light on the algorithm, so we shall sketch it briefly here. First let us consider a surprising property of linear probing which was first noticed by W. W. Peterson in 1957:

Theorem P. *The average number of probes in a successful search by Algorithm L is independent of the order in which the keys were inserted; it depends only on the number of keys which hash to each address.*

In other words, any rearrangement of a hash sequence $a_1\, a_2 \ldots a_N$ yields a hash sequence with the same average displacement of keys from their hash addresses. (We are assuming, as stated earlier, that all keys in the table have equal importance. If some keys are more frequently accessed than others, the proof can be extended to show that an optimal arrangement occurs if we insert them in decreasing order of frequency, by the method of Theorem 6.1S.)

Proof. It suffices to show that the total number of probes needed to insert keys for the hash sequence $a_1\, a_2 \ldots a_N$ is the same as the total number needed for $a_1 \ldots a_{i-1} a_{i+1} a_i a_{i+2} \ldots a_N$, $1 \le i < N$. There is clearly no difference unless the $(i+1)$st key in the second sequence falls into the position occupied by the ith in the first sequence. But then the ith and $(i+1)$st merely exchange places, so the number of probes for the $(i+1)$st is decreased by the same amount that the number for the ith is increased. ∎

Theorem P tells us that the average search length for a hash sequence $a_1\, a_2 \ldots a_N$ can be determined from the numbers $b_0\, b_1 \ldots b_{M-1}$, where b_j is the number of a's that equal j. From this sequence we can determine the "carry sequence" $c_0\, c_1 \ldots c_{M-1}$, where c_j is the number of keys for which both locations j and $j-1$ are probed as the key is inserted. This sequence is determined by the rule

$$c_j = \begin{cases} 0, & \text{if } \quad b_j = c_{(j+1) \bmod M} = 0; \\ b_j + c_{(j+1) \bmod M} - 1, & \text{otherwise.} \end{cases} \tag{44}$$

For example, let $M = 10$, $N = 8$, and $b_0 \ldots b_9 = 0\ 3\ 2\ 0\ 1\ 0\ 0\ 0\ 2$; then $c_0 \ldots c_9 = 2\ 3\ 1\ 0\ 0\ 0\ 0\ 1\ 2\ 3$, since one key needs to be "carried over" from position 2 to position 1, three from position 1 to position 0, two of these from position 0 to position 9, etc. We have $b_0 + b_1 + \cdots + b_{M-1} = N$, and the average number of probes needed for retrieval of the N keys is

$$1 + (c_0 + c_1 + \cdots + c_{M-1})/N. \tag{45}$$

Rule (44) seems to be a circular definition of the c's in terms of themselves, but actually there is a unique solution to the stated equations whenever $N < M$ (see exercise 32).

Schay and Spruth used this idea to determine the probability q_k that $c_j = k$, in terms of the probability p_k that $b_j = k$. (These probabilities are independent of j.) Thus

$$\begin{aligned} q_0 &= p_0 q_0 + p_1 q_0 + p_0 q_1, \\ q_1 &= p_2 q_0 + p_1 q_1 + p_0 q_2, \\ q_2 &= p_3 q_0 + p_2 q_1 + p_1 q_2 + p_0 q_3, \end{aligned} \tag{46}$$

etc., since, for example, the probability that $c_j = 2$ is the probability that $b_j + c_{(j+1) \bmod M} = 3$. Let $B(z) = \sum p_k z^k$ and $C(z) = \sum q_k z^k$ be the generating functions for these probability distributions; the equations (46) are equivalent to

$$B(z)C(z) = p_0 q_0 + (q_0 - p_0 q_0)z + q_1 z^2 + \cdots = p_0 q_0 (1 - z) + zC(z).$$

Since $B(1) = 1$, we may write $B(z) = 1 + (z - 1)D(z)$, and it follows that

$$C(z) = \frac{p_0 q_0}{1 - D(z)} = \frac{1 - D(1)}{1 - D(z)}, \tag{47}$$

since $C(1) = 1$. The average number of probes needed for retrieval, according to (45), will therefore be

$$1 + \frac{M}{N} C'(1) = 1 + \frac{M}{N} \frac{D'(1)}{1 - D(1)} = 1 + \frac{M}{2N} \frac{B''(1)}{1 - B'(1)}. \tag{48}$$

Since we are assuming that each hash sequence $a_1 \ldots a_N$ is equally likely we, have

$$\begin{aligned} p_k &= \Pr(\text{exactly } k \text{ of the } a_i \text{ are equal to } j, \text{ for fixed } j) \\ &= \binom{N}{k} \left(\frac{1}{M}\right)^k \left(1 - \frac{1}{M}\right)^{N-k}; \end{aligned} \tag{49}$$

hence

$$B(z) = \left(1 + \frac{z - 1}{M}\right)^N, \qquad B'(1) = \frac{N}{M}, \qquad B''(1) = \frac{N(N - 1)}{M^2}, \tag{50}$$

and the average number of probes according to (48) will be

$$C_N = \frac{1}{2}\left(1 + \frac{M - 1}{M - N}\right). \tag{51}$$

Can the reader see why this answer is different from the result in Theorem K? (Cf. exercise 33.)

***Optimality considerations.** We have seen several examples of probe sequences for open addressing, and it is natural to ask for one that can be proved "best possible" in some meaningful sense. This problem has been set up in the following interesting way by J. D. Ullman [*JACM* **19** (1972), 569–575]: Instead of computing a "hash address" $h(K)$, we map each key K into an entire permutation of $\{0, 1, \ldots, M - 1\}$, which represents the probe sequence to use for K. Each of the $M!$ permutations is assigned a probability, and the generalized hash function is supposed to select each permutation with that probability. The question is, "What assignment of probabilities to permutations gives the best performance, in the sense that the corresponding average number of probes C_N or C'_N is minimized?"

For example, if we assign the probability $1/M!$ to each permutation, it is easy to see that we have exactly the behavior of *uniform hashing* which we have analyzed above in (32), (34). However, Ullman has found an example with $M = 4$, $N = 2$ for which C'_N is smaller than the value $\frac{5}{3}$ obtained with uniform hashing. His construction assigns zero probability to all but the following six permutations:

Permutation	Probability	Permutation	Probability	
0 1 2 3	$(1 + 2\epsilon)/6$	1 0 3 2	$(1 + 2\epsilon)/6$	
2 0 1 3	$(1 - \epsilon)/6$	2 1 0 3	$(1 - \epsilon)/6$	(52)
3 0 1 2	$(1 - \epsilon)/6$	3 1 0 2	$(1 - \epsilon)/6$	

Roughly speaking, the first choice favors 2 and 3, but the second choice is 0 or 1. The average number of probes needed to insert the third item turns out to be $\frac{5}{3} - \frac{1}{9}\epsilon + O(\epsilon^2)$, so we can improve on uniform hashing by taking ϵ to be a small positive value.

However, the corresponding value of C'_1 for these probabilities is $\frac{23}{18} + O(\epsilon)$, which is larger than $\frac{5}{4}$ (the uniform hashing value). Ullman has proved that any assignment of probabilities such that $C'_N < (M + 1)/(M + 1 - N)$ for some N always implies that $C'_n > (M + 1)/(M + 1 - n)$ for some $n < N$; you can't win all the time over uniform hashing.

Actually the number of probes C_N for a *successful* search is a better measure than C'_N. The permutations in (52) do not lead to an improved value of C_N for any N, and indeed it seems reasonable to conjecture that no assignment of probabilities will be able to make C_N less than the uniform value $((M + 1)/N) \times (H_{M+1} - H_{M+1-N})$.

This conjecture appears to be very difficult to prove, especially because there are many ways to assign probabilities to achieve the effect of uniform hashing; we do not need to assign $1/M!$ to each permutation. For example, the following assignment for $M = 4$ is equivalent to uniform hashing:

Permutation	Probability	Permutation	Probability	
0 1 2 3	1/6	0 2 1 3	1/12	
1 2 3 0	1/6	1 3 2 0	1/12	(53)
2 3 0 1	1/6	2 0 3 1	1/12	
3 0 1 2	1/6	3 1 0 2	1/12	

with zero probability assigned to the other 16 permutations.

The following theorem characterizes *all* assignments that produce the behavior of uniform hashing.

Theorem U. *An assignment of probabilities to permutations will make each of the* $\binom{M}{N}$ *configurations of empty and occupied cells equally likely after* N *insertions, for* $0 < N < M$, *if and only if the sum of probabilities assigned to all permutations whose first* N *elements are the members of a given* N*-element set is* $1/\binom{M}{N}$, *for all* N *and all* N*-element sets.*

For example, the sum of probabilities assigned to each of the $3!(M - 3)!$ permutations beginning with the numbers $\{0, 1, 2\}$ in some order must be $1/\binom{M}{3} = 3!(M - 3)!/M!$. Observe that the condition of this theorem holds in (53).

Proof. Let $A \le \{0, 1, \ldots, M-1\}$, and let $\prod(A)$ be the set of all permutations whose first $\|A\|$ elements are members of A, and let $S(A)$ be the sum of the probabilities assigned to these permutations. Let $P_k(A)$ be the probability that the first $\|A\|$ insertions of the open addressing procedure occupy the locations specified by A, and that the last insertion required exactly k probes; and let $P(A) = P_1(A) + P_2(A) + \cdots$. The proof is by induction on $N \ge 1$, assuming that

$$P(A) = S(A) = 1 \Big/ \binom{M}{n}$$

for all sets A with $\|A\| = n < N$. Let B be any N-element set. Then

$$P_k(B) = \sum_{\substack{A \subseteq B \\ \|A\|=k}} \sum_{\pi \in \prod(A)} \Pr(\pi) P(B \backslash \{\pi_k\}),$$

where $\Pr(\pi)$ is the probability assigned to permutation π and π_k is its kth element. By induction

$$P_k(B) = \sum_{\substack{A \subseteq B \\ \|A\|=k}} \frac{1}{\binom{M}{N-1}} \sum_{\pi \in \prod(A)} \Pr(\pi),$$

which equals

$$\binom{N}{k} \Big/ \binom{M}{N-1}\binom{M}{k}, \qquad \text{if} \qquad k < N;$$

hence

$$P(B) = \frac{1}{\binom{M}{N-1}} \left(S(B) + \sum_{1 \le k < N} \frac{\binom{N}{k}}{\binom{M}{k}} \right),$$

and this can be equal to $1/\binom{M}{N}$ if and only if $S(B)$ has the correct value. ∎

External searching. Hashing techniques lend themselves well to external searching on direct-access storage devices like disks or drums. For such applications, as in Section 6.2.4, we want to minimize the number of accesses to the file, and this has two major effects on the choice of algorithms:

1) It is reasonable to spend more time computing the hash function, since the penalty for bad hashing is much greater than the cost of the extra time needed to do a careful job.
2) The records are usually grouped into *buckets*, so that several records are fetched from the external memory each time.

The file is usually divided into M buckets containing b records each. Collisions now cause no problem unless more than b keys have the same hash address. The following three approaches to collision resolution seem to be best:

A) *Chaining with separate lists.* If more than b records fall into the same bucket, a link to an "overflow" record can be inserted at the end of the first bucket. These overflow records are kept in a special overflow area. There is usually no advantage in having buckets in the overflow area, since comparatively few overflows occur; thus, the extra records are usually linked together so that the $(b + k)$th record of a list requires $1 + k$ accesses. It is usually a good idea to leave some room for overflows on each "cylinder" of a disk file, so that most accesses are to the same cylinder.

Although this method of handling overflows seems inefficient, the number of overflows is statistically small enough that the average search time is very good. See Tables 2 and 3, which show the average number of accesses required as a function of the load factor

$$\alpha = N/Mb, \tag{54}$$

for fixed α as $M, N \to \infty$. Curiously when $\alpha = 1$ the asymptotic number of accesses for an unsuccessful search increases with increasing b.

Table 2

AVERAGE ACCESSES IN AN UNSUCCESSFUL SEARCH BY SEPARATE CHAINING

50	1.0000	1.0000	1.0000	1.0000	1.0000	1.0000	1.001	1.015	1.083	1.2

B) *Chaining with coalescing lists.* Instead of providing a separate overflow area, we can adapt Algorithm C to external files. A doubly linked list of available space can be used which links together each bucket that is not yet full. Under this scheme, every bucket contains a count of how many record positions are empty, and the bucket is removed from the doubly linked list only when this count becomes zero. A 'roving pointer' can be used to distribute overflows (cf. exercise 2.5–6), so that different lists tend to use different overflow buckets. It may be a good idea to have separate available-space lists for the buckets on each cylinder of a disk file.

This method has not yet been analyzed, but it should prove to be quite useful.

C) *Open addressing.* We can also do without links, using an "open" method. Linear probing is probably better than random probing when we consider external searching, because the increment c can often be chosen so that it minimizes latency delays between consecutive accesses. The approximate theoretical model of linear probing which was worked out above can be generalized to account for the influence of buckets, and it shows that linear probing is indeed satisfactory unless the table has gotten very full. For example, see Table 4; when the load factor is 90 percent and the bucket size is 50, the average

Table 4

AVERAGE ACCESSES IN A SUCCESSFUL SEARCH BY LINEAR PROBING

Bucket size, b	Load factor, α 10%	20%	30%	40%	50%	60%	70%	80%	90%	95%
1	1.0556	1.1250	1.2143	1.3333	1.5000	1.7500	2.167	3.000	5.500	10.5
2	1.0062	1.0242	1.0553	1.1033	1.1767	1.2930	1.494	1.903	3.147	5.6
3	1.0009	1.0066	1.0201	1.0450	1.0872	1.1584	1.286	1.554	2.378	4.0
4	1.0001	1.0021	1.0085	1.0227	1.0497	1.0984	1.190	1.386	2.000	3.2
5	1.0000	1.0007	1.0039	1.0124	1.0307	1.0661	1.136	1.289	1.777	2.7
10	1.0000	1.0000	1.0001	1.0011	1.0047	1.0154	1.042	1.110	1.345	1.8
20	1.0000	1.0000	1.0000	1.0000	1.0003	1.0020	1.010	1.036	1.144	1.4
50	1.0000	1.0000	1.0000	1.0000	1.0000	1.0000	1.001	1.005	1.040	1.1

number of accesses in a successful search is only 1.04. This is actually *better* than the 1.08 accesses required by the chaining method (A) with the same bucket size!

The analysis of methods (A) and (C) involves some very interesting mathematics; we shall merely summarize the results here, since the details are worked out in exercises 49 and 55. The formulas involve two functions strongly related to the Q-functions of Theorem K, namely

$$R(\alpha, n) = \frac{n}{n+1} + \frac{n^2\alpha}{(n+1)(n+2)} + \frac{n^3\alpha^2}{(n+1)(n+2)(n+3)} + \cdots, \quad (55)$$

and

$$t_n(\alpha) = e^{-n\alpha}\left(\frac{(\alpha n)^n}{(n+1)!} + 2\,\frac{(\alpha n)^{n+1}}{(n+2)!} + 3\,\frac{(\alpha n)^{n+2}}{(n+3)!} + \cdots\right)$$

$$= \frac{e^{-n\alpha}n^n\alpha^n}{n!}\,(1 - (1-\alpha)R(\alpha, n)). \tag{56}$$

In terms of these functions, the average number of accesses made by the chaining method (A) in an unsuccessful search is

$$C'_N = 1 + \alpha b t_b(\alpha) + O\left(\frac{1}{M}\right) \tag{57}$$

as $M, N \to \infty$, and the corresponding number in a successful search is

$$C_N = 1 + (1 - \tfrac{1}{2}b(1-\alpha))t_b(\alpha) + \frac{e^{-b\alpha}b^b\alpha^b}{2b!}\,R(\alpha, b) + O\left(\frac{1}{M}\right). \tag{58}$$

These are the quantities shown in Tables 2 and 3.

Since chaining method (A) requires a separate overflow area, we need to estimate how many overflows will occur. The average number of overflows will be $M(C'_N - 1) = Nt_b(\alpha)$, since $C'_N - 1$ is the average number of overflows in any given list. Therefore Table 2 can be used to deduce the amount of overflow space required. For fixed α, the standard deviation of the total number of overflows will be roughly proportional to $\sqrt{M}$ as $M \to \infty$.

Asymptotic values for C'_N and C_N appear in exercise 53, but the approximations aren't very good when b is small or α is large; fortunately the series for $R(\alpha, n)$ converges rather rapidly even when α is large, so the formulas can be evaluated exactly without much difficulty. The maximum values occur for $\alpha = 1$, when

$$\max C'_N = 1 + \frac{e^{-b}b^{b+1}}{b!} = \sqrt{\frac{b}{2\pi}} + 1 + O(b^{-1/2}), \tag{59}$$

$$\max C_N = 1 + \frac{e^{-b}b^b}{2b!}\,(R(b)+1) = \frac{5}{4} + \sqrt{\frac{2}{9\pi b}} + O(b^{-1}), \tag{60}$$

as $b \to \infty$, by Stirling's approximation and the analysis of the function $R(n) = R(1, n) - 1$ in Section 1.2.11.3.

The average number of access in a successful external search with *linear* probing has the remarkably simple expression

$$C_N \approx 1 + t_b(\alpha) + t_{2b}(\alpha) + t_{3b}(\alpha) + \cdots, \tag{61}$$

which can be understood as follows: The average total number of accesses to look up all N keys is NC_N, and this is $N + T_1 + T_2 + \cdots$, where T_k is the average number of keys which require more than k accesses. Theorem P says that we can enter the keys in any order without affecting C_N, and it follows that T_k is the average number of overflow records that would occur in the

chaining method if we had M/k buckets of size kb, namely $Nt_{kb}(\alpha)$ by what we said above. Further justification of Eq. (61) appears in exercise 55.

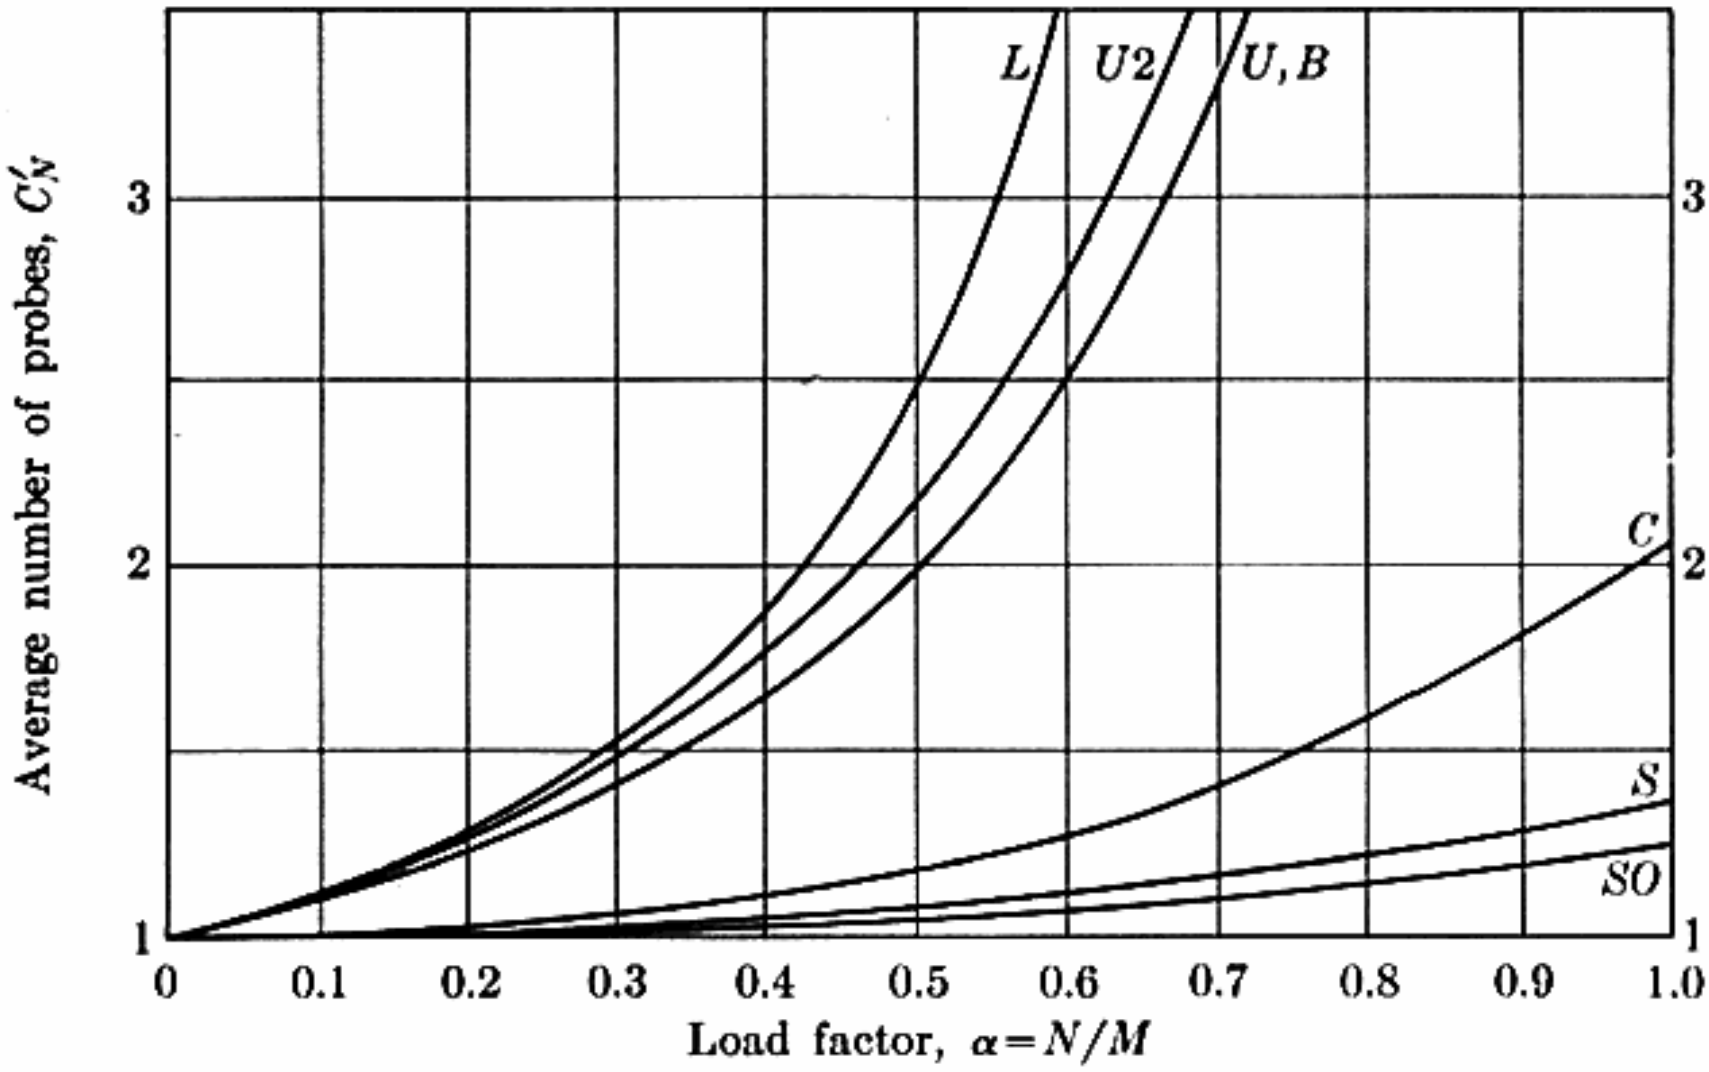
An excellent discussion of practical considerations involved in the design of external scatter tables has been given by Charles A. Olson, *Proc. ACM Nat'l Conf.* **24** (1969), 539–549. He includes several worked examples and points out that the number of overflow records will increase substantially if the file is subject to frequent insertion/deletion activity without relocating records; and he presents an analysis of this situation which was obtained jointly with J. A. de Peyster.

Comparison of the methods. We have now studied a large number of techniques for searching; how can we select the right one for a given application? It is difficult to summarize in a few words all the relevant details of the "trade-offs" involved in the choice of a search method, but the following things seem to be of primary importance with respect to the speed of searching and the requisite storage space.

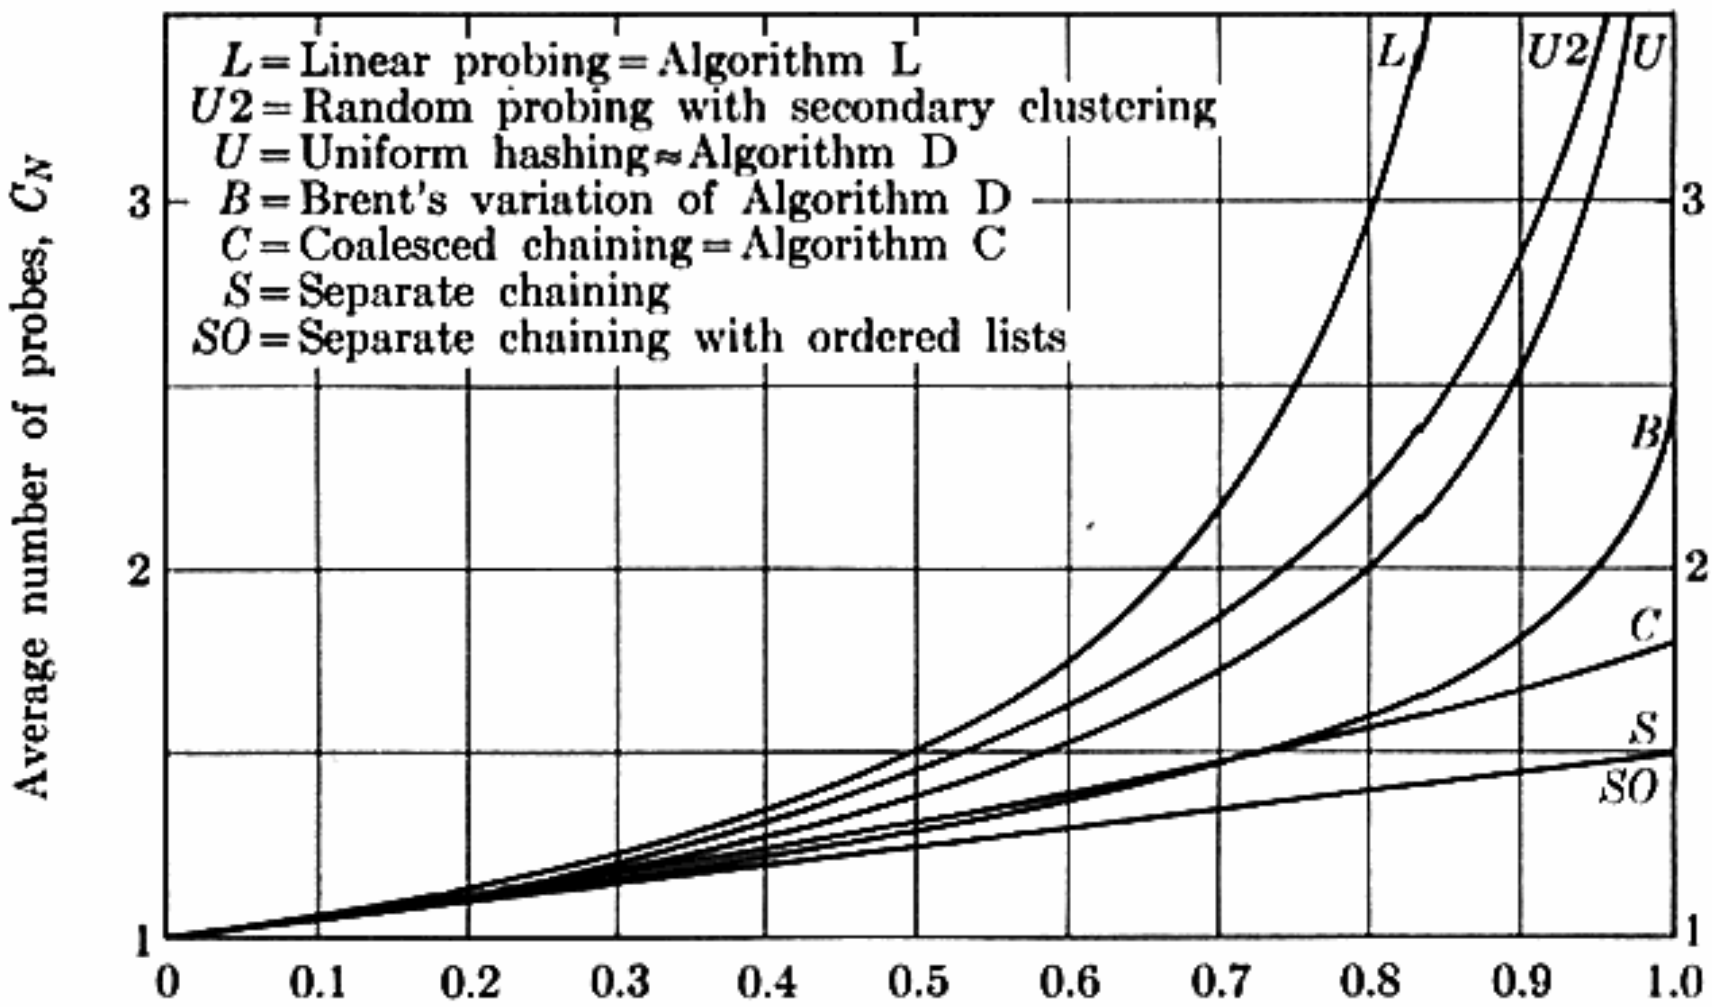
Figure 44 summarizes the analyses of this section, showing that the various methods for collision resolution lead to different numbers of probes. But this does not tell the whole story, since the time per probe varies in different methods, and the latter variation has a noticeable effect on the running time (as we have seen in Fig. 42). Linear probing accesses the table more frequently than the other methods shown in Fig. 44, but it has the advantage of simplicity. Furthermore, even linear probing isn't terribly bad: when the table is 90 percent full, Algorithm L requires an average of less than 5.5 probes to locate a random item in the table. (However, the average number of probes needed to insert a *new* item with Algorithm L is 50.5, with a 90-percent-full table.)

Figure 44 shows that the chaining methods are quite economical with respect to the number of probes, but the extra memory space needed for link fields sometimes makes open addressing more attractive for small records. For example, if we have to choose between a chained scatter table of capacity 500 and an open scatter table of capacity 1000, the latter is clearly preferable, since it allows efficient searching when 500 records are present and it is capable of absorbing twice as much data. On the other hand, sometimes the record size and format will allow space for link fields at virtually no extra cost. (Cf. exercise 65.)

How do hash methods compare with the other search strategies we have studied in this chapter? From the standpoint of speed we can argue that they are better, when the number of records is large, because the average search time for a hash method stays bounded as $N \longrightarrow \infty$ if we stipulate that the table never gets too full. For example, Program L will take only about 55 units of time for a successful search when the table is 90 percent full; this beats the fastest MIX binary search routine we have seen (exercise 6.2.1–24) when N is greater than 600 or so, at the cost of only 11 percent in storage space. Moreover the binary search is suitable only for fixed tables, while a scatter table allows efficient insertions.



(a) Unsuccessful search.



(b) Successful search

Fig. 44. Comparison of collision resolution methods: Limiting values of the average number of probes as $M \to \infty$.

We can also compare Program L to the tree-oriented search methods which allow dynamic insertions. Program L with a 90-percent-full table is faster than Program 6.2.2T when N is greater than about 90, and faster than Program 6.3D (exercise 6.3–9) when N is greater than about 75.

Only one search method in this chapter is efficient for successful searching with virtually no storage overhead, namely Brent's variation of Algorithm D. His method allows us to put N records into a table of size $M = N + 1$, and to

find any record in about $2\frac{1}{2}$ probes on the average. No extra space for link fields, etc., is needed; however, an unsuccessful search will be very slow, requiring about $\frac{1}{2}N$ probes.

Thus hashing has several advantages. On the other hand, there are three important respects in which scatter table searching is inferior to other methods we have discussed:

a) After an unsuccessful search in a scatter table, we know only that the desired key is not present. Search methods based on comparisons always yield more information, making it possible to find the largest key $\leq K$ and/or the smallest key $\geq K$; this is important in many applications (e.g., for interpolation of function values from a stored table). It is also possible to use comparison-based algorithms to locate all keys which lie *between* two given values K and K'. Furthermore the tree search algorithms of Section 6.2 make it easy to output the contents of a table in ascending order, without sorting it separately, and this is occasionally desirable.

b) The storage allocation for scatter tables is often somewhat difficult; we have to dedicate a certain area of the memory for use as the hash table, and it may not be obvious how much space should be allotted. If we provide too much memory, we may be wasting storage at the expense of other lists or other computer users; but if we don't provide enough room, the table will overflow. When a scatter table overflows, it is probably best to "rehash" it, i.e., to allocate a larger space and to change the hash function, reinserting every record into the larger table. F. R. A. Hopgood [*Comp. Bulletin* **11** (1968), 297–300] has suggested rehashing the table when it becomes α_0 percent full, replacing M by d_0M; suitable choices of these parameters α_0 and d_0 can be made by using the analyses above and characteristics of the data, so that the critical point at which it becomes cheaper to rehash can be determined. (Note that the method of chaining does not lead to any troublesome overflows, so it requires no rehashing; but the search time is proportional to N when M is fixed and N gets large.) By contrast, the tree search and insertion algorithms require no such painful rehashing; the trees grow no larger than necessary. In a virtual memory environment we probably ought to use tree search or digital tree search, instead of creating a large scatter table that requires bringing in a new page nearly every time we hash a key.

c) Finally, we need a great deal of faith in probability theory when we use hashing methods, since they are efficient only on the average, while their worst case is terrible! As in the case of random number generators, we are never completely sure that a hash function will perform properly when it is applied to a new set of data. Therefore scatter storage would be inappropriate for certain real-time applications such as air traffic control, where people's lives are at stake; the balanced tree algorithms of Sections 6.2.3 and 6.2.4 are much safer, since they provide guaranteed upper bounds on the search time.

History. The idea of hashing appears to have been originated by H. P. Luhn, who wrote an internal IBM memorandum suggesting the use of chaining, in

January 1953; this was also among the first applications of linked linear lists. He pointed out the desirability of using buckets containing more than one element, for external searching. Shortly afterwards, A. D. Lin carried Luhn's analysis a little further, and suggested a technique for handling overflows that used "degenerative addresses"; e.g., the overflows from primary bucket 2748 are put in secondary bucket 274; overflows from that bucket go to tertiary bucket 27, etc., assuming the presence of 10000 primary buckets, 1000 secondary buckets, 100 tertiary buckets, etc. The hash functions originally suggested by Luhn were digital in character, e.g., adding adjacent pairs of key digits mod 10, so that 31415926 would be compressed to 4548.

At about the same time the idea of hashing occurred independently to another group of IBMers: Gene M. Amdahl, Elaine M. Boehme, N. Rochester, and Arthur L. Samuel, who were building an assembly program for the IBM 701. In order to handle the collision problem, Amdahl originated the idea of open addressing with linear probing.

Hash coding was first described in the open literature by Arnold I. Dumey, *Computers and Automation* **5**, 12 (December 1956), 6–9. He was the first to mention the idea of dividing by a prime number and using the remainder as the hash address. Dumey's interesting article mentions chaining but not open addressing. A. P. Ershov of Russia independently discovered linear open addressing in 1957 [*Doklady Akad. Nauk SSSR* **118** (1958), 427–430]; he published empirical results about the number of probes, conjecturing correctly that the average number of probes per successful search is <2 when $N/M < 2/3$.

A classic article by W. W. Peterson, *IBM J. Research & Development* **1** (1957), 130–146, was the first major paper dealing with the problem of searching in large files. Peterson defined open addressing in general, analyzed the performance of uniform hashing, and gave numerous empirical statistics about the behavior of linear open addressing with various bucket sizes, noting the degradation in performance that occurred when items were deleted. Another comprehensive survey of the subject was published six years later by Werner Buchholz [*IBM Systems J.* **2** (1963), 86–111], who gave an especially good discussion of hash functions.

Up to this time linear probing was the only type of open addressing scheme that had appeared in the literature, but another scheme based on repeated random probing by independent hash functions had independently been developed by several people (see exercise 48). During the next few years hashing became very widely used, but hardly anything more was published about it. Then Robert Morris wrote a very influential survey of the subject [*CACM* **11** (1968), 38–44], in which he introduced the idea of random probing (with secondary clustering). Morris's paper touched off a flurry of activity which culminated in Algorithm D and its refinements.

It is interesting to note that the word "hashing" apparently never appeared in print, with its present meaning, until Morris's article was published in 1968, although it had already become common jargon in several parts of the world

by that time. The only previous occurrence of the word among approximately 60 relevant documents studied by the author as this section was being written was in an unpublished memorandum written by W. W. Peterson in 1961. Somehow the verb "to hash" magically became standard terminology for key transformation during the mid-1960's, yet nobody was rash enough to use such an undignified word publicly until 1968!

EXERCISES

1. [*20*] When the instruction 9H in Table 1 is reached, how small and how large can the contents of rI1 possibly be, assuming that bytes 1, 2, 3 of K contain alphabetic character codes less than 30?

2. [*20*] Find a reasonably common English word not in Table 1 that could be added to that table without changing the program.

3. [*23*] Explain why no program beginning with the five instructions

```
LD1  K(1:1)     or     LD1N  K(1:1)
LD2  K(2:2)     or     LD2N  K(2:2)
          INC1  a,2
          LD2   K(3:3)
          J2Z   9F
```

could be used in place of the more complicated program in Table 1, for any constant a, since unique addresses would not be produced for the given keys.

4. [*M30*] How many people should be invited to a party in order to make it likely that there are *three* with the same birthday?

5. [*15*] Mr. B. C. Dull was writing a FORTRAN compiler using a decimal MIX computer, and he needed a symbol table to keep track of the names of variables in the FORTRAN program being compiled. These names were restricted to be ten or less characters in length. He decided to use a scatter table with $M = 100$, and to use the fast hash function $h(K) =$ leftmost byte of K. Was this a good idea?

6. [*15*] Would it be wise to change the first two instructions of (3) to `LDA K; ENTX 0`?

7. [*HM30*] (*Polynomial hashing.*) The purpose of this exercise is to consider the construction of polynomials $P(x)$ such as (10), which convert n-bit keys into m-bit addresses, such that distinct keys differing in t or fewer bits will hash to different addresses. Given n and $t \le n$, and given an integer k such that n divides $2^k - 1$, we shall construct a polynomial whose degree m is a function of n, t, and k. (Usually n is increased, if necessary, so that k can be chosen to be reasonably small.)

Let S be the smallest set of integers such that $\{1, 2, \ldots, t\} \subseteq S$, and $(2j) \bmod n \in S$ for all $j \in S$. For example, when $n = 15$, $k = 4$, $t = 6$, we have $S = \{1, 2, 3, 4, 5, 6, 8, 10, 12, 9\}$. We now define the polynomial $P(x) = \prod_{j \in S}(x - \alpha^j)$, where α is an element of order n in the finite field $GF(2^k)$, and where the coefficients of $P(x)$ are computed in this field. The degree m of $P(x)$ is the number of elements of S. Since α^{2j} is a root of $P(x)$ whenever α^j is a root, it follows that the coefficients p_i of $P(x)$ satisfy $p_i^2 = p_i$, so they are all 0 or 1.

Prove that if $R(x) = r_{n-1}x^{n-1} + \cdots + r_1x + r_0$ is any nonzero polynomial modulo 2, with at most t nonzero coefficients, then $R(x)$ is not a multiple of $P(x)$, modulo 2. [It follows that the corresponding hash function behaves as advertised.]

8. [*M34*] (*The three-distance theorem.*) Let θ be an irrational number between 0 and 1, whose regular continued fraction representation in the notation of Section 4.5.3 is $\theta = /a_1, a_2, a_3, \ldots/$. Let $q_0 = 0$, $p_0 = 1$, $q_1 = 1$, $p_1 = 0$, and $q_{k+1} = a_kq_k + q_{k-1}$, $p_{k+1} = a_kp_k + p_{k-1}$, for $k \geq 1$. Let $\{x\}$ denote $x \bmod 1 = x - \lfloor x \rfloor$, and let $\{x\}^+$ denote $x - \lceil x \rceil + 1$. As the points $\{\theta\}$, $\{2\theta\}$, $\{3\theta\}$, ... are successively inserted into the interval [0, 1], let the line segments be numbered as they appear in such a way that the first segment of a given length is number 0, the next is number 1, etc. Prove that the following statements are all true: Interval number s of length $\{t\theta\}$, where $t = rq_k + q_{k-1}$ and $0 \leq r < a_k$ and k is even and $0 \leq s < q_k$, has left endpoint $\{s\theta\}$ and right endpoint $\{(s+t)\theta\}^+$. Interval number s of length $1 - \{t\theta\}$, where $t = rq_k + q_{k-1}$ and $0 \leq r < a_k$ and k is odd and $0 \leq s < q_k$, has left endpoint $\{(s+t)\theta\}$ and right endpoint $\{s\theta\}^+$. Every positive integer n can be uniquely represented as $n = rq_k + q_{k-1} + s$ for some $k \geq 1$, $1 \leq r \leq a_k$, $0 \leq s < q_k$. In terms of this representation, just before the point $\{n\theta\}$ is inserted the n intervals present are

the first s intervals (numbered $0, \ldots, s-1$) of length $\{(-1)^k(rq_k + q_{k-1})\theta\}$;
the first $n - q_k$ intervals (numbered $0, \ldots, n - q_k - 1$) of length $\{(-1)^kq_k\theta\}$;
the last $q_k - s$ intervals (numbered $s, \ldots, q_k - 1$) of length $\{(-1)^k((r-1)q_k + q_{k-1})\theta\}$.

The operation of inserting $\{n\theta\}$ removes interval number s of the latter type and converts it into interval number s of the first type, number $n - q_k$ of the second type.

9. [*M30*] When we successively insert the points $\{\theta\}$, $\{2\theta\}$, ... into the interval [0, 1], Theorem S asserts that each new point always breaks up one of the largest remaining intervals. If the interval $[a, c]$ is thereby broken into two parts $[a, b]$, $[b, c]$, we may call it a *bad break* if one of these parts is more than twice as long as the other, i.e. if $b - a > 2(c - b)$ or $c - b > 2(b - a)$.

Prove that bad breaks will occur for some $\{n\theta\}$ unless $\theta \bmod 1 = \phi^{-1}$ or ϕ^{-2}; and the latter values of θ *never* produce bad breaks.

10. [*M48*] (R. L. Graham.) Prove or disprove the following $3d$ *distance conjecture:* If $\theta, \alpha_1, \ldots, \alpha_d$ are real numbers with $\alpha_1 = 0$, and if $n_1, \ldots, n_d$ are positive integers, and if the points $\{n\theta + \alpha_i\}$ are inserted into the interval [0, 1] for $0 \leq n < n_i$, $1 \leq i \leq d$, the resulting $n_1 + \cdots + n_d$ (possibly empty) intervals have at most $3d$ different lengths.

11. [*16*] Successful searches are usually more frequent than unsuccessful ones. Would it therefore be a good idea to interchange lines 12–13 of Program C with lines 10–11?

▸ **12.** [*21*] Show that Program C can be rewritten so that there is only one conditional jump instruction in the inner loop. Compare the running time of the modified program with the original.

▸ **13.** [*24*] (*Abbreviated keys.*) Let $h(K)$ be a hash function, and let $q(K)$ be a function of K such that K can be determined once $h(K)$ and $q(K)$ are given. For example, in division hashing we may let $h(K) = K \bmod M$ and $q(K) = \lfloor K/M \rfloor$; in multiplicative hashing we may let $h(K)$ be the leading bits of $(AK/w) \bmod 1$, and $q(K)$ can be the other bits.

Show that when chaining is used without overlapping lists, we need only store $q(K)$ instead of K in each record. (This almost saves the space needed for the link fields.) Modify Algorithm C so that it allows such abbreviated keys by avoiding overlapping lists, yet uses no auxiliary storage locations for "overflow" records.

14. [*24*] (E. W. Elcock.) Show that it is possible to let a large scatter table *share memory* with any number of other linked lists. Let every word of the list area have a 2-bit TAG field, with the following interpretation:

TAG(P) = 0 indicates a word in the list of available space; LINK(P) points to the next available word.

TAG(P) = 1 indicates any word in use that is not part of the scatter table; the other fields of this word may have any desired format.

TAG(P) = 2 indicates a word in the scatter table; LINK(P) points to another word. Whenever we are processing a list that is not part of the scatter table and we access a word with TAG(P) = 2, we are supposed to set P ← LINK(P) until reaching a word with TAG(P) ≤ 1. (For efficiency we might also then change one of the prior links so that it will not be necessary to skip over the same scatter table entries again and again.)

Show how to define suitable algorithms for inserting and retrieving keys from such a combined table, assuming that words with TAG(P) = 2 also have another link field AUX(P).

15. [*16*] Why is it a good idea for Algorithm L and Algorithm D to signal overflow when $N = M - 1$ instead of when $N = M$?

16. [*10*] Program L says that K should not be zero. But doesn't it actually work even when K is zero?

17. [*15*] Why not simply define $h_2(K) = h_1(K)$ in (25), when $h_1(K) \neq 0$?

▸ **18.** [*21*] Is (31) better or worse than (30), as a substitute for lines 10–13 of Program D? Give your answer on the basis of the average values of A, $S1$, and C.

19. [*40*] Empirically test the effect of restricting the range of $h_2(K)$ in Algorithm D, so that (a) $1 \leq h_2(K) \leq r$ for $r = 1, 2, 3, \ldots, 10$; (b) $1 \leq h_2(K) \leq \rho M$ for $\rho = \frac{1}{10}, \frac{2}{10}, \ldots, \frac{9}{10}$.

20. [*M25*] (R. Krutar.) Change Algorithm D as follows, avoiding the hash function $h_2(K)$: In step D3, set $c \leftarrow 0$; and at the beginning of step D4, set $c \leftarrow c + 1$. Prove that if $M = 2^m$, the corresponding probe sequence $h_1(K)$, $(h_1(K) - 1) \bmod M, \ldots, (h_1(K) - \binom{M}{2}) \bmod M$ will be a permutation of $\{0, 1, \ldots, M - 1\}$. When this method is programmed for MIX, how does it compare with the three programs considered in Fig. 42, assuming that the behavior is like random probing with secondary clustering?

▸ **21.** [*20*] Suppose that we wish to delete a record from a table constructed by Algorithm D, marking it "deleted" as suggested in the text. Should we also decrease the variable N which is used to govern Algorithm D?

22. [*27*] Prove that Algorithm R leaves the table exactly as it would have been if KEY[i] had never been inserted in the first place.

▸ **23.** [*23*] Design an algorithm analogous to Algorithm R, for deleting entries from a chained scatter table that has been constructed by Algorithm C.

24. [*M20*] Suppose that the set of all possible keys that can occur has MP elements, where exactly P keys hash to a given address. (In practical cases, P is very large; e.g. if the keys are arbitrary 10-digit numbers and if $M = 10^3$, we have $P = 10^7$.) Assume that $M \geq 7$ and $N = 7$. If seven distinct keys are selected at random from the set of all possible keys, what is the exact probability that the hash sequence 1 2 6 2 1 6 1 will be obtained (i.e., that $h(K_1) = 1, h(K_2) = 2, \ldots, h(K_7) = 1$), as a function of M and P?

25. [*M19*] Explain why Eq. (39) is true.

26. [*M20*] How many hash sequences $a_1\, a_2 \ldots a_9$ yield the pattern of occupied cells (21), using linear probing?

27. [*M27*] Complete the proof of Theorem K. [*Hint:* Let

$$s(n, x, y) = \sum_{k \geq 0} \binom{n}{k} (x + k)^{k+1} (y - k)^{n-k-1} (y - n);$$

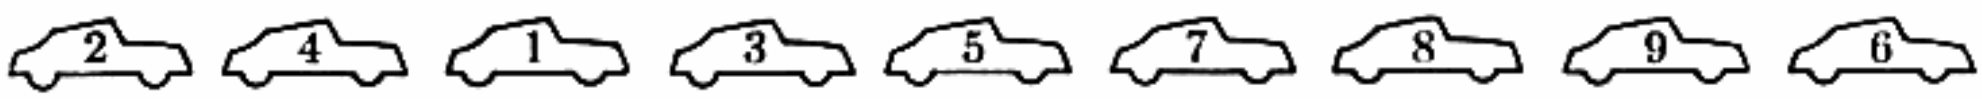
use Abel's binomial theorem, Eq. 1.2.6–16, to prove that $s(n, x, y) = x(x + y)^n + ns(n - 1, x + 1, y - 1)$.]

28. [*M30*] In the old days when computers were much slower than they are now, it was possible to watch the lights flashing and see how fast Algorithm L was running. When the table began to fill up, some entries would be processed very quickly, while others took a great deal of time.

This experience suggests that the standard deviation of C'_N is rather high, when linear probing is used. Find a formula which expresses the variance in terms of the Q_r functions defined in Theorem K, and estimate the variance when $N = \alpha M$ as $M \to \infty$.

29. [*M21*] (*The parking problem.*) A certain one-way street has m parking spaces in a row, numbered 1 through m. A man and his dozing wife drive by, and suddenly she wakes up and orders him to park immediately. He dutifully parks at the first available space; but if there are no places left that he can get to without backing up (i.e., if his wife awoke when the car approached space k, but spaces $k, k + 1, \ldots, m$ are all full), he expresses his regrets and drives on.

Suppose, in fact, that this happens for n different cars, where the jth wife wakes up just in time to park at space a_j. In how many of the sequences $a_1 \ldots a_n$ will all of the cars get safely parked, assuming that the street is initially empty and that nobody leaves after parking? For example, when $m = n = 9$ and $a_1 \ldots a_9 =$ 3 1 4 1 5 9 2 6 5, the cars get parked as follows:



[*Hint:* Use the analysis of linear probing.]

30. [*M28*] (John Riordan.) When $n = m$ in the parking problem of exercise 29, show that all cars get parked if and only if there exists a permutation $p_1\, p_2 \ldots p_n$ of $\{1, 2, \ldots, n\}$ such that $a_j \leq p_j$ for all j.

31. [*M40*] When $n = m$ in the parking problem of exercise 29, the number of solutions turns out to be $(n + 1)^{n-1}$; and from exercise 2.3.4.4–22 we know this is the same as the number of free trees on $n + 1$ labeled vertices! Find an interesting connection between parking sequences and trees.

32. [*M26*] Prove that the system of equations (44) has a unique solution $(c_0, c_1, \ldots, c_{M-1})$, whenever $b_0, b_1, \ldots, b_{M-1}$ are nonnegative integers whose sum is less than M. Design an algorithm which finds that solution.

▸**33.** [*M23*] Explain why (51) is only an approximation to the true average number of probes made by Algorithm L. [What was there about the derivation of (51) that wasn't rigorously exact?]

▸**34.** [*M22*] The purpose of this exercise is to investigate the average number of probes in a chained scatter table when the lists are kept separate as in Fig. 38. (a) What is P_{Nk}, the probability that a given list has length k, when the M^N hash sequences (35) are equally likely? (b) Find the generating function $P_N(z) = \sum_{k\geq 0} P_{Nk} z^k$. (c) Express the average number of probes for successful and unsuccessful search in terms of this generating function. (Assume that an unsuccessful search in a list of length k requires $k + \delta_{k0}$ probes.)

35. [*M21*] Continuing exercise 34, what is the average number of probes in an unsuccessful search when the individual lists are kept in order by their key values?

36. [*M22*] Find the variance of (18), the number of probes in separate chaining when the search is unsuccessful.

▸**37.** [*M29*] Find the variance of (19), the number of probes in separate chaining when the search is successful.

38. [*M32*] (*Tree hashing.*) A clever programmer might try to use binary search trees instead of linear lists in the chaining method, thereby combining Algorithm 6.2.2T with hashing. Analyze the average number of probes that would be required by this compound algorithm, for both successful and unsuccessful searches. [*Hint:* Cf. Eq. 5.2.1–11.]

39. [*M30*] The purpose of this exercise is to analyze the average number of probes in Algorithm C (chaining with coalescing lists). Let $c(k_1, k_2, k_3, \ldots)$ be the number of hash sequences (35) that cause Algorithm C to form exactly k_1 lists of length 1, k_2 of length 2, etc., when $k_1 + 2k_2 + 3k_3 + \cdots = N$. Find a recurrence relation which defines these numbers $c(k_1, k_2, k_3, \ldots)$, and use it to determine a simple formula for the sum

$$S_N = \sum_{\substack{j\geq 1 \\ k_1+2k_2+\cdots=N}} \binom{j}{2} k_j c(k_1, k_2, \ldots).$$

How is S_N related to the number of probes in an unsuccessful search by Algorithm C?

40. [*M33*] Find the variance of (15), the number of probes used by Algorithm C in an unsuccessful search.

41. [*M40*] Analyze T_N, the average number of times R is decreased by 1 when the $(N + 1)$st item is being inserted by Algorithm C.

▸**42.** [*M20*] Derive (17).

43. [*M42*] Analyze a modification of Algorithm C that uses a table of size $M' > M$. Only the first M locations are used for hasing, so the first $M' - M$ empty nodes found in step C5 will be in the extra locations of the table. For fixed M', what choice of M in the range $1 \leq M \leq M'$ leads to the best performance?

44. [*M43*] (*Random probing with secondary clustering.*) The object of this exercise is to determine the expected number of probes in the open addressing scheme with probe sequence

$$h(K),\quad (h(K)+p_1) \bmod M,\quad (h(K)+p_2) \bmod M,\quad \ldots,\quad (h(K)+p_{M-1}) \bmod M,$$

where $p_1\, p_2 \ldots p_{M-1}$ is a randomly chosen permutation of $\{1, 2, \ldots, M-1\}$ that depends on $h(K)$. In other words, all keys with the same value of $h(K)$ follow the same probe sequence, and the $(M-1)!^M$ possible choices of M probe sequences with this property are equally likely.

This situation can be accurately modeled by the following experimental procedure performed on an initially empty linear array of size m. Do the following operation n times:

> With probability p, occupy the leftmost empty position. Otherwise (i.e., with probability $q = 1 - p$), select any table position except the leftmost, with each of these $m - 1$ positions equally likely. If the selected position is empty, occupy it; otherwise select *any* empty position (including the leftmost) and occupy it, considering each of the empty positions equally likely.

For example when $m = 5$ and $n = 3$, the array configuration after the above experiment will be (occupied, occupied, empty, occupied, empty) with probability

$$\tfrac{7}{192}qqq + \tfrac{1}{6}pqq + \tfrac{1}{6}qpq + \tfrac{11}{64}qqp + \tfrac{1}{3}ppq + \tfrac{1}{4}pqp + \tfrac{1}{4}qpp.$$

(This procedure corresponds to random probing with secondary clustering, when $p = 1/m$, since we can renumber the table entries so that a particular probe sequence is 0, 1, 2, . . . and all the others are random.)

Find a formula for the average number of occupied positions at the left of the array (i.e., 2 in the above example). Also find the asymptotic value of this quantity when $p = 1/m$, $n = \alpha(m+1)$, and $m \to \infty$.

45. [*M48*] Solve the analog of exercise 44 with *tertiary clustering*, when the probe sequence begins $h_1(K)$, $((h_1(K) + h_2(K)) \bmod M$, and the succeeding probes are randomly chosen depending only on $h_1(K)$ and $h_2(K)$. (Thus the $(M-2)!^{M(M-1)}$ possible choices of $M(M-1)$ probe sequences with this property are considered to be equally likely.) Is this procedure asymptotically equivalent to uniform probing?

46. [*M42*] Determine C'_N and C_N for the open addressing method which uses the probe sequence

$$h(K), 0, 1, \ldots, h(K)-1, h(K)+1, \ldots, M-1.$$

47. [*M25*] Find the average number of probes needed by open addressing when the probe sequence is

$$h(K), h(K)-1, h(K)+1, h(K)-2, h(K)+2, \ldots.$$

This probe sequence was once suggested because all the distances between consecutive probes are distinct when M is even. [*Hint:* Find the trick and this problem is easy.]

▶**48.** [*M21*] Analyze the open addressing method that probes locations $h_1(K)$, $h_2(K)$, $h_3(K)$, . . . , given an infinite sequence of mutually independent random hash functions

$h_n(K)$. Note that it is possible to probe the same location twice, e.g. if $h_1(K) = h_2(K)$, but this is rather unlikely.

49. [*HM24*] Generalizing exercise 34 to the case of b records per bucket, determine the average number of probes (i.e., file accesses) C_N and C'_N, for chaining with separate lists, assuming that a list containing k elements requires $\min(1, k - b + 1)$ probes in an unsuccessful search. Instead of using the exact probability P_{Nk} as in exercise 34, use the *Poisson approximation*

$$\binom{N}{k}\left(\frac{1}{M}\right)^k\left(1-\frac{1}{M}\right)^{N-k} = \frac{N}{M}\,\frac{N-1}{M}\cdots\frac{N-k+1}{M}\left(1-\frac{1}{M}\right)^N\left(1-\frac{1}{M}\right)^{-k}\frac{1}{k!}$$
$$= e^{-\rho}\rho^k/k! + O(M^{-1}),$$

which is valid for $N = \rho M$ as $M \to \infty$.

50. [*M20*] Show that $Q_1(M, N) = M - (M - N - 1)Q_0(M, N)$, in the notation of (42). [*Hint:* Prove first that $Q_1(M, N) = (N + 1)Q_0(M, N) - NQ_0(M, N - 1)$.]

51. [*HM16*] Express the function $R(\alpha, n)$ defined in (55) in terms of the function Q_0 defined in (42).

52. [*HM20*] Prove that $Q_0(M, N) = \int_0^\infty e^{-t}(1 + t/M)^N\,dt$.

53. [*HM20*] Prove that the function $R(\alpha, n)$ can be expressed in terms of the incomplete gamma function, and use the result of exercise 1.2.11.3–9 to find the asymptotic value of $R(\alpha, n)$ to $O(n^{-2})$ as $n \to \infty$, for fixed $\alpha < 1$.

54. [*40*] Experiment with the behavior of Algorithm C when it has been adapted to external searching as described in the text.

55. [*HM43*] Generalize the Schay-Spruth model, discussed after Theorem P, to the case of M buckets of size b. Prove that $C(z)$ is equal to $Q(z)/(B(z) - z^b)$, where $Q(z)$ is polynomial of degree b and $Q(1) = 0$. Show that the average number of probes is

$$1 + \frac{M}{N}C'(1) = 1 + \frac{1}{b}\left(\frac{1}{1-q_1} + \cdots + \frac{1}{1-q_{b-1}} - \frac{1}{2}\,\frac{B''(1) - b(b-1)}{B'(1) - b}\right),$$

where $q_1, \ldots, q_{b-1}$ are the roots of $Q(z)/(z - 1)$. Replacing the binomial probability distribution $B(z)$ by the Poisson approximation $P(z) = e^{b\alpha(z-1)}$, where $\alpha = N/Mb$, and using Lagrange's inversion formula (cf. Eq. 2.3.4.4–9 and exercise 4.7–8), reduce your answer to Eq. (61).

56. [*M48*] Generalize Theorem K, obtaining an exact analysis of linear probing with buckets of size b.

57. [*M47*] Does the uniform assignment of probabilities to probe sequences give the minimum value of C_N, over all open addressing methods?

58. [*M21*] (S. C. Johnson.) Find ten permutations on {0, 1, 2, 3, 4} that are equivalent to uniform hashing in the sense of Theorem U.

59. [*M25*] Prove that if an assignment of probabilities to permutations is equivalent to uniform hashing, in the sense of Theorem U, the number of permutations with nonzero probabilities exceeds M^a for any fixed exponent a, when M is sufficiently large.

60. [*M48*] Let us say that an open addressing scheme involves *single hashing* if it uses exactly M probe sequences, one beginning with each possible value of $h(K)$, each of which occurs with probability $1/M$.

Are the best single-hashing schemes (in the sense of minimum C_N) asymptotically better than the random ones analyzed in exercise 44?

61. [*M46*] Is the method analyzed in exercise 46 the worst possible single-hashing scheme? (Cf. exercise 60.)

62. [*M49*] How good can a single-hashing scheme be when the increments $p_1\, p_2 \ldots p_{M-1}$ in the notation of exercise 44 are fixed for all K? (Examples of such methods are linear probing and the sequences considered in exercises 20 and 47.)

63. [*M25*] If repeated random insertions and deletions are made in a scatter table, how many independent insertions are needed on the average before all M locations have become occupied at one time or another?

64. [*M46*] Analyze the expected behavior of Algorithm R. How many times will step R4 be performed, on the average?

▸**65.** [*20*] (*Variable-length keys.*) Many applications of scatter tables deal with keys that can be any number of characters long. In such cases we can't simply store the key in the table as in the programs of this section. What would be a good way to deal with variable-length keys in a scatter table on the MIX computer?

6.5. RETRIEVAL ON SECONDARY KEYS

We have now completed our study of searching for "primary keys," i.e., for keys which uniquely specify a record in a file. But it is sometimes necessary to conduct a search based on the values of other fields in the records besides the primary key; these other fields are often called "secondary keys" or "attributes" of the record. For example, in an enrollment file which contains information about the students at a university, it may be desirable to search for all sophomores from Ohio who are not majoring in mathematics or statistics; or to search for all unmarried French-speaking graduate student women; etc.

In general, we assume that each record contains several attributes, and we want to search for all records that have certain values of certain attributes. The specification of which records are desired is called a *query*. Queries are usually restricted to at most the following three types:

a) A *simple query* which gives a specific value of a specific attribute; e.g., MAJOR = MATHEMATICS; or RESIDENCE.STATE = OHIO.

b) A *range query* which gives a specific range of values for a specific attribute; e.g., COST $<$ \$18.00; or $21 \leq$ AGE ≤ 23.

c) A *Boolean query* which consists of the previous types combined with the operations AND, OR, NOT; e.g.,

```
(CLASS = SOPHOMORE) AND (RESIDENCE.STATE = OHIO)
      AND NOT ((MAJOR = MATHEMATICS) OR (MAJOR = STATISTICS)).
```

The problem of discovering efficient search techniques for these three types of queries is already quite difficult, and therefore queries of more complicated types are usually not considered. For example, a railroad company might have a file giving the current status of all its freight cars; a query such as "find all empty refrigerator cars within 500 miles of Seattle" would not be explicitly allowed, unless "distance from Seattle" were an attribute stored within each record instead of a complicated function to be deduced from other attributes. And the use of logical quantifiers, in addition to AND, OR, and NOT, would introduce further complications, limited only by the imagination of the query-poser; given a file of baseball statistics, for example, we might ask for the longest consecutive hitting streak in night games. These examples are complicated, but they can still be handled by taking one pass through a suitably-arranged file; other queries are even more difficult, e.g. to find all pairs of records that have the same values on five or more attributes (without specifying which attributes must match). Such queries may be regarded as general programming tasks which are beyond the scope of this discussion, although they can often be broken down into subproblems of the kind considered here.

Before we begin to study the various techniques for secondary key retrieval, it is important to put the subject in a proper economic context. Although a vast number of applications fit into the general framework of the three types of queries outlined above, not many of these applications are really suited to the

sophisticated techniques we shall be studying, and some of them are better done by hand than by machine! Computers have increased the speed of scientific calculations by a factor of 10^7 or 10^8, but they have provided nowhere near this gain in efficiency with respect to problems of information handling. When large quantities of data are involved, today's computers are still constrained to working at mechanical (instead of electronic) speeds, so there is no dramatic increase in performance per unit cost when a computer system replaces a manual system. We shouldn't expect too much of a computer just because it performs certain other tasks so well.

People climb Mt. Everest "because it is there" and because tools have been developed which make the climb possible; similarly, when faced with a mountain of data, people are tempted to use a computer to find the answer to the most difficult queries they can dream up, in an "on-line, real-time" environment, without properly balancing the cost. The desired calculations are possible, but they're not right for everyone's application.

For example, consider the following simple approach to secondary key retrieval: After *batching* a number of queries, we can do a sequential search through the entire file, retrieving all the relevant records. ("Batching" means that we accumulate a number of queries before doing anything about them.) This method is quite satisfactory if the file isn't too large and if the queries don't have to be handled immediately. It can be used even with tape files, and it only ties up the computer at odd intervals, so it will tend to be very economical in terms of equipment costs. Moreover, it will even handle computational queries of the "distance to Seattle" type discussed above.

Another simple way to facilitate secondary key retrieval is to let *people* do part of the work, by providing them with suitable printed indexes to the information. This method is often the most reasonable and economical way to proceed (provided, of course, that the old paper is recycled whenever a new index is printed).

The applications which are not satisfactorily handled by the above simple schemes involve very large files for which quick responses to queries are important. Such a situation would occur, for example, if the file were continuously being queried by a number of simultaneous users, or if the queries were being generated by machine instead of by people. Our goal in this section will be to see how well we can do secondary key retrieval with conventional computers, under various assumptions about the file structure.

A lot of good ideas have been developed for dealing with the problem, but (as the reader will have guessed from all these precautionary remarks) the algorithms are by no means as good as those available for primary key retrieval. Because of the wide variety of files and applications, we will not be able to give a complete discussion of all the possibilities that have been considered, or to analyze the behavior of each algorithm in typical environments. The remainder of this section presents the basic approaches which have been proposed, and it is left to the reader's imagination to decide what combination of techniques is most appropriate in each particular case.

Inverted files. The first important class of techniques for secondary key retrieval is based on the idea of an "inverted file." This does not mean that the file is turned upside down, it means that the roles of records and attributes are reversed. Instead of listing the attributes of a given record, we list the records having a given attribute.

We encounter inverted files (under other names) quite often in our daily lives. For example, the inverted file corresponding to a Russian-English dictionary is an English-Russian dictionary. The inverted file corresponding to this book is the index which appears at the close of the book. Accountants traditionally use "double-entry bookkeeping," where all transactions are entered both in a cash account and in a customer account, so that the current cash position and customer liability are both readily accessible.

In general, an inverted file usually doesn't stand by itself, it is to be used together with the original uninverted file; it provides duplicate, redundant information in order to speed up secondary key retrieval. The components of an inverted file are called *inverted lists*, namely the lists of all records having a given value of some attribute.

Like all lists, the inverted lists can be represented in many ways within a computer, and different modes of representation are appropriate at different times. Some secondary key fields have only two values (e.g., a 'sex' attribute), and the corresponding inverted lists are quite long; but other fields typically have a great many values with few duplications (e.g., a 'telephone number' attribute).

Imagine, for example, that we want to store the information in a telephone directory so that all entries can be retrieved on the basis of either name, phone number, or residence address. One solution is simply to make three separate files, oriented to retrieval on each type of key. Another idea is to combine these files, for example by making three hash tables which serve as the list heads for the chaining method. In the latter scheme, each record of the file would be an element of three lists, and it would therefore contain three link fields; this is the so-called *Multilist* method which is discussed further below. A third possibility is to combine the three files into one super file, by analogy with library card catalogues in which author cards, title cards, and subject cards are all alphabetized together.

A consideration of the format used in the index to this book leads to further ideas on inverted list representation. For secondary key fields in which there are typically five or so entries per attribute value, we can simply make a short sequential list of the record locations (analogous to page locations in a book index), following the key value. If related records tend to be clustered consecutively, a "range specification" code (e.g., pages 200 through 214) could be useful. If the records in the file tend to be reallocated frequently, it may be better to use primary keys instead of record locations in the inverted files, so that no updating needs to be done when the locations change; for example, references to Bible passages are always given by chapter and verse, and the index to some books is based on paragraph numbers instead of page numbers.

None of these ideas is especially appropriate for the case of a two-valued attribute like 'SEX'. In such a case only one inverted list is needed, of course, since the non-males will be female and conversely. If each value relates to about half the items of the file, the inverted list will be horribly long, but we can solve the problem rather nicely on a binary computer by using a bit string representation, with each bit specifying the value of a particular record. Thus the bit string 01001011101 $\cdots$ might mean that the first record in the file refers to a male, the second female, the next two male, etc. (Cf. also the discussion of prime number representation at the end of Section 6.1.)

The above methods suffice to handle simple queries about specific attribute values. A slight extension makes it possible to treat range queries, except that some comparison-based search scheme (Section 6.2) must be used instead of hashing.

For Boolean queries like "(MAJOR = MATHEMATICS) AND (RESIDENCE.STATE = OHIO)", we need to intersect two inverted lists. This can be done in several ways; for example, if both lists are ordered, one pass through each one will pick out all common entries. Alternatively, we could select the *shortest* list and look up each of its records, checking the other attributes; but this method works only for AND's, not for OR's, and it is unattractive on external files because it requires many accesses to records that will not satisfy the query.

The same considerations show that a Multilist organization as described above is inefficient for Boolean queries, on an external file, since it implies many unnecessary accesses. For example, imagine what would happen if the index to this book were organized in a Multilist manner. This would mean that each entry of the index would refer only to the last page on which its particular subject was mentioned; then on every page there would be a further reference, for each subject on that page, to the previous occurrence of that subject. In order to find all pages relevant to "[Analysis of algorithms] and [(External sorting) or (External searching)]", it would be necessary to turn many pages. On the other hand, the same query can be resolved by looking at only two pages of the real index as it actually appears, doing simple operations on the inverted lists in order to find the small subset of pages which satisfy the query.

When an inverted list is represented as a bit string, Boolean combinations of simple queries are, of course, rather easily performed, because computers can manipulate bit strings at relatively high speed. For mixed queries in which some attributes are represented as sequential lists of record numbers while other attributes are represented as bit strings, it is not difficult to convert the sequential lists into bit strings, then to perform the Boolean operations on these bit strings.

A quantitative example of a hypothetical application may be helpful at this point. Assume that we have 1,000,000 records of 40 characters each, and that our file is stored on MIXTEC disks, as described in Section 5.4.9. The file itself therefore fills two disk packs, and the inverted lists will probably fill several more. Each track contains 5000 characters = 30,000 bits, so an inverted list for a particular attribute will take up at most 34 tracks. (This maximum

number of tracks occurs when the bitstring representation is the shortest possible one.) Suppose that we have a rather involved query that refers to a Boolean combination of 10 inverted lists; in the worst case we will have to read 340 tracks of information from the inverted file, for a total read time of 340×25 ms $= 8.5$ sec. The average latency delay will be about one half of this, but by careful programming it may be possible to eliminate the latency. By storing the first track of each bitstring list in one cylinder, and the second track of each list in the next, etc., most of the seek time will be eliminated, so we can estimate the seek time as at most about 34×26 ms ≈ 0.9 sec (or twice this if two different disk packs are involved). Finally, if k records satisfy the query, it will take about $k \times (60$ ms (seek) $+ 12.5$ ms (latency) $+ 0.2$ ms (read)) extra time to fetch each one for subsequent processing. Thus an optimistic estimate of the total expected time to process this rather complicated query is $< (10 + .073k)$ seconds. This may be contrasted with about 210 seconds to read through the entire file at top speed under the same assumptions without using any inverted lists.

This example shows that space optimization is closely related to time optimization in a disk memory; the time to process the inverted lists is roughly the time needed to seek and to read them.

The above discussion has more or less assumed that the file is not growing or shrinking as we query it; what should we do if frequent updates are necessary? In many applications it is sufficient to batch a number of requests for updates, and to take care of them in dull moments when no queries need to be answered. Alternatively, if updating the file has high priority, the method of B-trees (Section 6.2.4) is attractive. The entire collection of inverted lists could be made into one huge B-tree, with special conventions for the leaves so that the branch nodes contain key values while the leaves contain both keys and lists of pointers of records.

We have glossed over another point in the above discussion, namely the difficult subject of Boolean combinations of range queries. For example, suppose that the records of the file refer to North American cities, and that the query asks for all cities with

$$(21.49° \le \texttt{LATITUDE} \le 37.41°) \texttt{ AND } (70.34° \le \texttt{LONGITUDE} \le 75.72°).$$

No really nice data structures seem to be available for such "orthogonal range queries." (Reference to a map will show that many cities satisfy this LATITUDE range, and many satisfy the LONGITUDE range, but hardly any cities lie in both ranges.) Perhaps the best approach is to partition the set of all possible LATITUDE and LONGITUDE values rather coarsely, with only a few classes per attribute (e.g., by truncating to the next lower multiple of 5°), then to have one inverted list for each combined (LATITUDE, LONGITUDE) class. This is like having maps

with one page for each local region. Using 5° intervals, the above query would refer to eight pages, namely (20°, 70°), (25°, 70°), . . . , (35°, 75°). The range query needs to be processed for each of these pages, either by going to a finer partition within the page or by direct reference to the records themselves, depending on the number of records corresponding to that page. In a sense this is a tree structure with two-dimensional branching at each internal node.

Another tree-structured approach to orthogonal range queries has been proposed by Bruce McNutt. Suppose, for example, that we wish to handle queries like "What is the nearest city to point x?", given the value of x. Each node of McNutt's proposed binary search tree corresponds to a city y and a "test radius" r; the left subtree of this node corresponds to all cities z entered subsequently into this part of the tree such that the distance from y to z is $\leq r + \delta$, and the right subtree similarly is for distances $\geq r - \delta$. Here δ is a given tolerance; cities between $r - \delta$ and $r + \delta$ away from y must be entered in *both* subtrees. Searching in such a "post-office tree" makes it possible to locate all cities within distance δ of a given point. (See Fig. 45.)

Several experiments based on this idea were conducted in 1972 by McNutt and Edward Pring, using the 231 most populous cities in the continental United States, in random order, as an example data base. They let the test radii shrink in a regular manner, replacing r by $0.67r$ when going to the left, and by $0.57r$ when going to the right, except that r was left unchanged when taking the second of two consecutive right branches. The result was that 610 nodes were required in the tree for $\delta = 20$ miles, and 1600 nodes were required for $\delta = 35$ miles. The top levels of their smaller tree are shown in Fig. 45. (In the remaining levels of this tree, Orlando FL appeared below both Jacksonville and Miami. Some cities occurred quite often; e.g., 17 of the nodes were for Brockton MA!)

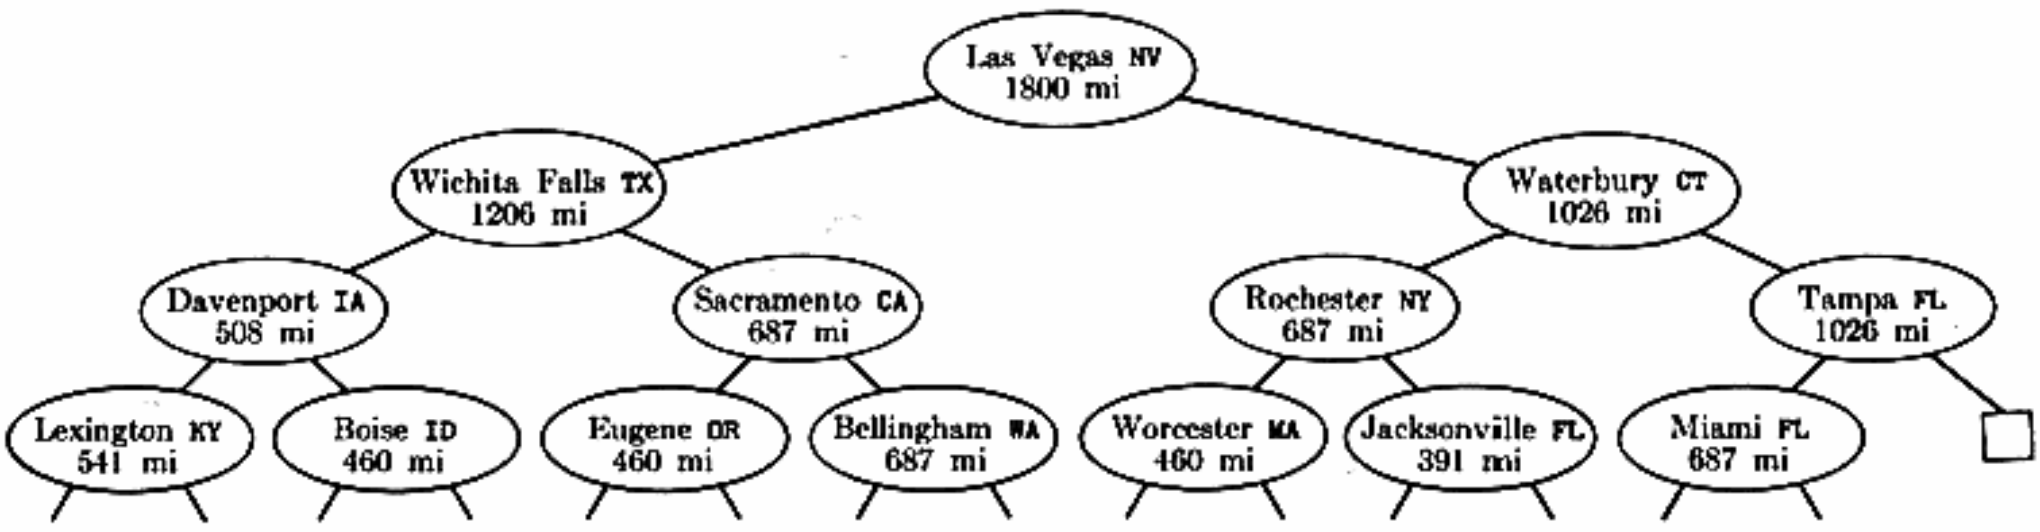


Fig. 45. The top levels of an example "post-office tree." To search for all cities near a given point x, start at the root: If x is within 1800 miles of Las Vegas, go left, otherwise go to the right; then repeat the process until encountering a terminal node. The method of tree construction ensures that all cities within 20 miles of x will be encountered during this search.

Table 1 A FILE WITH BINARY ATTRIBUTES

Reference: *McCall's Cook Book* (New York: Random House, 1963), Chapter 9.

Compound attributes. It is possible to combine two or more attributes into one super attribute. For example, a "(CLASS, MAJOR) attribute" could be created by combining the CLASS and MAJOR fields of a university enrollment file. In this way queries can often be satisfied by taking the union of disjoint, short lists instead of the intersection of longer lists.

The idea of attribute combination has been further developed by V. Y. Lum [*CACM* **13** (1970), 660–665], who suggests ordering the inverted lists of combined attributes lexicographically from left to right, and making multiple copies, with the individual attributes permuted in a clever way. For example, suppose that we have three attributes A, B, C; we can form three combined attributes

$$(A, B, C), \quad (B, C, A), \quad (C, A, B) \tag{1}$$

and construct ordered inverted lists for each of these. (Thus in the first list, the records occur in order of their A values, with all records of the same A value in order by B and then by C.) This organization makes it possible to satisfy queries based on any combination of the three attributes; e.g., all records having specified values for A and C will appear contiguously in the third list.

Similarly, from four attributes A, B, C, D, we can form the six combined attributes

$$(A, B, C, D), \quad (B, C, D, A), \quad (B, D, A, C), \quad (C, A, D, B), \quad (C, D, A, B), \quad (D, A, B, C), \tag{2}$$

which suffice to answer all combinations of simple queries relating to the simultaneous values of one, two, three, or four of the attributes. There is a general procedure for constructing $\binom{n}{k}$ combined attributes from n attributes, where $k \le \frac{1}{2}n$, such that all records having specified combinations of $\le k$ or $\ge n - k$ of the attribute values will appear consecutively in one of the combined attribute lists (see exercise 1). Alternatively, we can get by with fewer combinations when some attributes have a limited number of values. For example if D is simply a two-valued attribute, the three combinations

$$(D, A, B, C), \quad (D, B, C, A), \quad (D, C, A, B), \tag{3}$$

obtained by placing D in front of (1), will be almost as good as (2) with only half the redundancy, since queries that do not depend on D can be treated by looking in just two places in one of the lists.

Binary attributes. It is instructive to consider the special case in which all attributes are two-valued. In a sense this is the *opposite* of combining attributes, since we can represent any value as a binary number and regard the individual bits of that number as separate attributes. Table 1 shows a typical file involving "yes-no" attributes; in this case the records stand for selected cookie recipes, and the attributes specify which ingredients are used. For example, Almond Lace Wafers are made from butter, flour, milk, nuts, and granulated sugar.

If we think of Table 1 as a matrix of zeros and ones, the transpose of the matrix is the "inverted" file, in bitstring form.

The right-hand column of Table 1 is used to indicate special items that occur only rarely. These could be coded in a more efficient way than to devote an entire column to each one; the "Cornstarch" column could be similarly treated. Dually, we could find a more efficient way to encode the "Flour" column, since flour occurs in everything except Meringues. For the present, however, let us sidestep these considerations and simply ignore the "Special ingredients" column.

Let us define a *basic query* in a binary attribute file as a request for all records having 0's in certain columns, 1's in other columns, and arbitrary values in the remaining columns. Using "*" to stand for an arbitrary value, we can represent any basic query as a sequence of 0's, 1's, and *'s. For example, consider a man who is in the mood for some coconut cookies, but he is allergic to chocolate, hates anise, and has run out of vanilla extract; he can formulate the query

```
* 0 * * * * 0 * * 1 * * * * * * * * * * * * * * * * * 0.    (4)
```

Table 1 now says that Dream Bars are just the thing.

Before we consider the general problem of organizing a file for basic queries, it is important to look at the special case where no 0's are specified, only 1's and *'s. This may be called an *inclusive query*, because it asks for all records which include a certain set of attributes, if we assume that 1's denote attributes that are present and that 0's denote attributes that are absent. For example, the recipes in Table 1 which call for both baking powder and baking soda are Glazed Gingersnaps and Old-Fashioned Sugar Cookies.

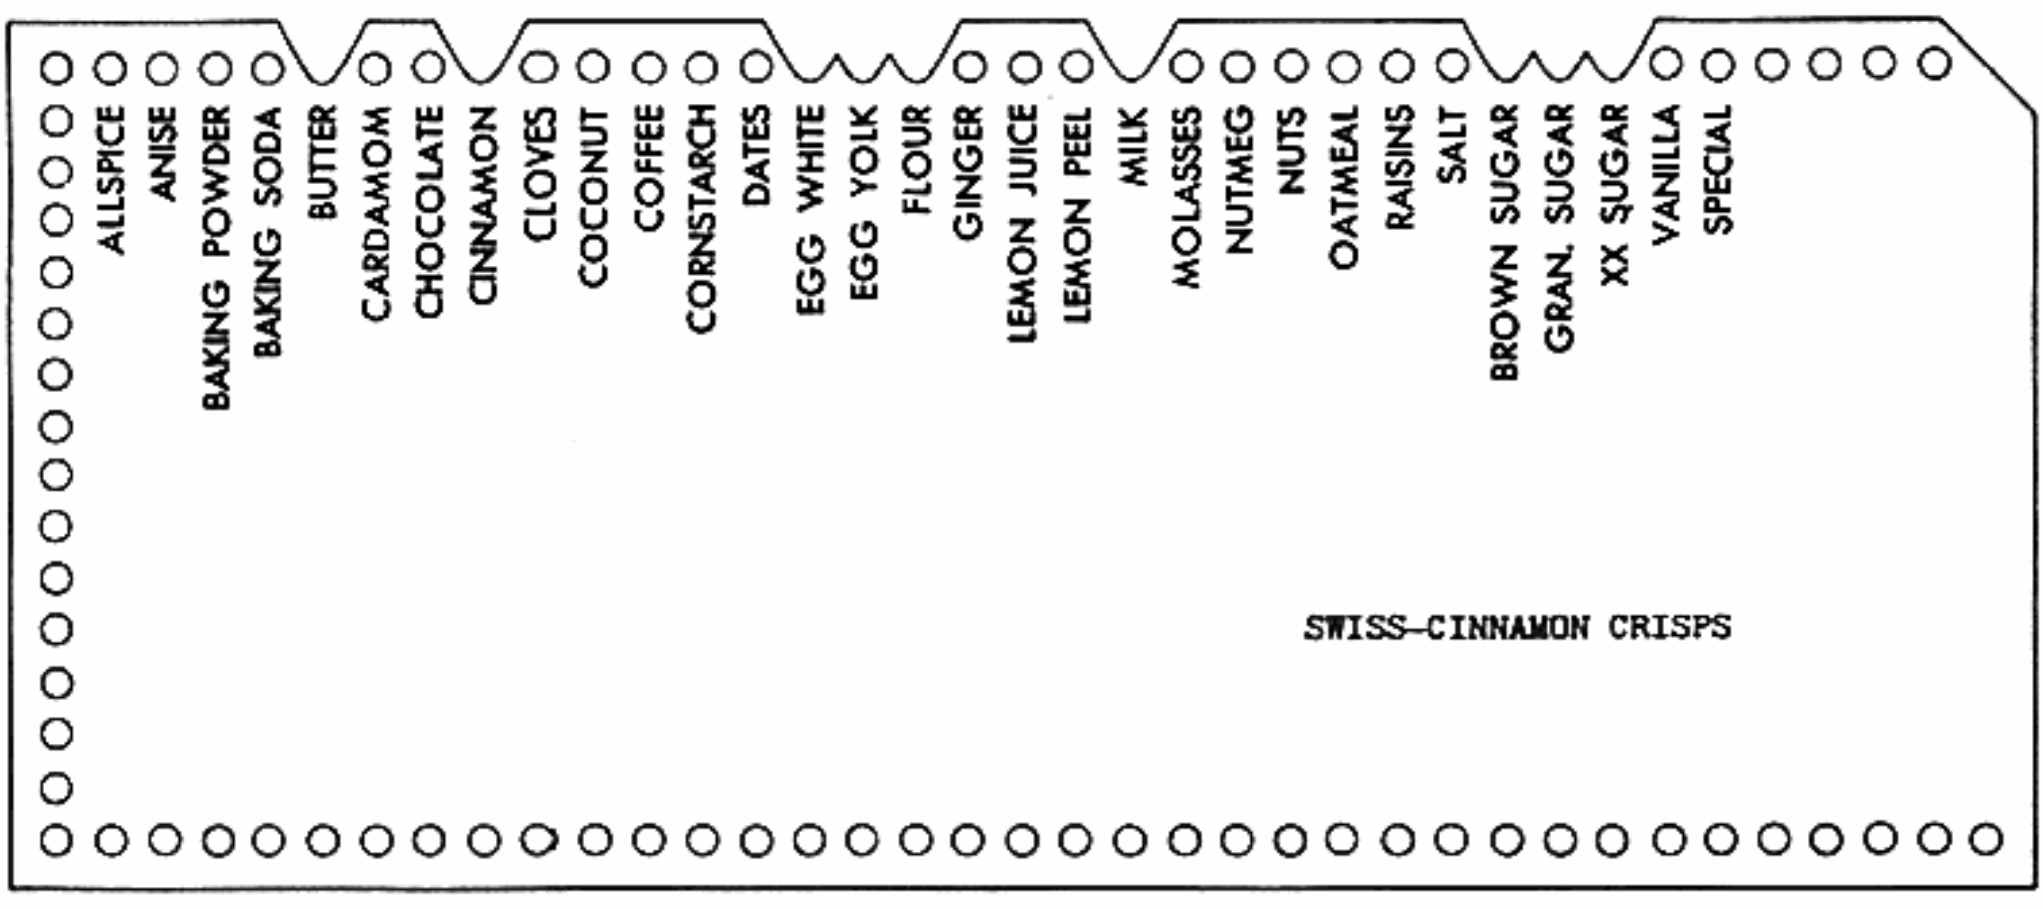

Fig. 46. An edge-notched card.

In some applications it is sufficient to provide for the special case of inclusive queries. This occurs, for example, in the case of many manual card-filing systems, such as "edge-notched cards" or "feature cards." An edge-notched card system corresponding to Table 1 would have one card for every recipe, with holes cut out for each ingredient (see Fig. 46). In order to process an inclusive query, the file of cards is arranged into a neat deck and needles are put in each column position corresponding to an attribute that is to be included. After raising the needles, all cards having the appropriate attributes will drop out.

A feature-card system works on the inverse file in a similar way. In this case there is one card for every attribute, and holes are punched in designated positions on the surface of the card for every record possessing that attribute. An ordinary 80-column card can therefore be used to tell which of $12 \times 80 = 960$ records have a given attribute. To process an inclusive query, the feature cards for the specified attributes are selected and put together; then light will shine through all positions corresponding to the desired records. This operation is analogous to the treatment of Boolean queries by intersecting inverted bit strings as explained above.

Superimposed coding. The reason these manual card systems are of special interest to us is that ingenious schemes have been devised to save space on edge-notched cards; the same principles can be applied in the representation of computer files. Superimposed coding is a technique similar to hashing, and it was actually invented several years before hashing itself was discovered. The idea is to map attributes into random k-bit codes in an n-bit field, and to superimpose the codes for each attribute that is present in a record. An inclusive query for some set of attributes can be converted into an inclusive query for the corresponding superimposed bit codes. A few extra records may satisfy this query, but the number of such "false drops" can be statistically controlled. [Cf. Calvin N. Mooers, *Amer. Chem. Soc. Meeting* **112** (September, 1947), 14E–15E; *American Documentation* **2** (1951), 20–32.]

As an example of superimposed coding, let's consider Table 1 again, but only the flavorings instead of the basic ingredients like baking powder, shortening, eggs, and flour. Table 2 shows what happens if we assign random 2-bit codes in a 10-bit field to each of the flavoring attributes and superimpose the coding. For example, the entry for Chocolate Chip Cookies is obtained by superimposing the codes for chocolate, nuts, and vanilla:

$$0010001000 \vee 0000100100 \vee 0000001001 = 0010101101.$$

The superimposition of these codes also yields some spurious attributes, in this case allspice, candied cherries, currant jelly, peanut butter, and pepper; these will cause false drops to occur on certain queries (and they also suggest the creation of a new recipe called False Drop Cookies!).

Table 2

AN EXAMPLE OF SUPERIMPOSED CODING

Codes for individual flavorings

Almond extract	0100000001	Dates	1000000100
Allspice	0000100001	Ginger	0000110000
Anise seed	0000011000	Honey	0000000011

Chocolate	0010001000	Nuts	0000100100
Cinnamon	1000000010	Oranges	0100000100
Citron	0100000010	Peanut butter	0000000101
Cloves	0001100000	Pepper	0010000100
Coconut	0001010000	Prunes	0010000010
Coffee	0001000100	Raisins	0101000000
Currant jelly	0010000001	Vanilla extract	0000001001

Superimposed codes

Almond Lace Wafers	0000100100	Lebkuchen Rounds	1011110111
Applesauce-Spice Squares	1111111111	Meringues	1000101100
Banana-Oatmeal Cookies	1000111111	Moravian Spice Cookies	1001110011
Chocolate Chip Cookies	0010101101	Oatmeal-Date Bars	1000100100
Coconut Macaroons	0001111101	Old-Fashioned Sugar Cookies	0000011011
Cream-Cheese Cookies	0010001001	Peanut-Butter Pinwheels	0010001101
Delicious Prune Bars	0111110110	Petticoat Tails	0000001001
Double-Chocolate Drops	0010101100	Pfeffernuesse	1111111111
Dream Bars	0001111101	Scotch Oatmeal Shortbread	0000001001
Filled Turnovers	1011101101	Shortbread Stars	0000000000
Finska Kakor	0100100101	Springerle	0011011000
Glazed Gingersnaps	1001110010	Spritz Cookies	0000001001
Hermits	1101010110	Swedish Kringler	0000000000
Jewel Cookies	0010101101	Swiss-Cinnamon Crisps	1000000010
Jumbles	1000001011	Toffee Bars	0010111101
Kris Kringles	1011100101	Vanilla-Nut Icebox Cookies	0000101101

Superimposed coding actually doesn't work very well in Table 2, because that table is a small example with lots of attributes present. In fact, Applesauce-Spice Squares will drop out for *every* query, since it was obtained by superimposing seven codes that cover all ten positions; and Pfefferneusse is even worse, obtained by superimposing twelve codes! On the other hand Table 2 works surprisingly well in some respects; e.g., for the query "Vanilla extract", only the record for Pfefferneusse comes out as a false drop.

A more appropriate example of superimposed coding occurs if we have, say, a 32-bit field and a set of $\binom{32}{3} = 4960$ different attributes, where each record is allowed to possess up to six attributes and each attribute is encoded by specifying 3 of the 32 bits. In this situation, if we assume that each record has six randomly selected attributes, the probability of a false drop in an inclusive query

$$\begin{aligned} &\text{on one attribute is} && .0806933;\\ &\text{on two attributes is} && .0070878;\\ &\text{on three attributes is} && .0006709;\\ &\text{on four attributes is} && .0000679;\\ &\text{on five attributes is} && .0000073;\\ &\text{on six attributes is} && .0000008. \end{aligned} \tag{5}$$

Thus if there are M records which do not actually satisfy a two-attribute query, about $.007M$ will have a superimposed code that spuriously matches all code bits of the two specified attributes.. (These probabilities are computed in exercise 4.) The total number of bits needed in the inverted file is only 32 times the number of records, which is less than half the number of bits needed to specify the attributes themselves in the original file.

Malcolm C. Harrison [*CACM* **14** (1971), 777–779] has observed that superimposed coding can be used to speed up *text searching*. Assume that we want to locate all occurrences of a particular string of characters in a long body of text, without building an extensive table as in Algorithm 6.3P; and assume, for example, that the text is diyided into individual lines $c_1c_2 \ldots c_{50}$ of 50 characters each. Harrison suggests encoding each of the 49 pairs c_1c_2, c_2c_3, . . . , $c_{49}c_{50}$ by hashing each of them into a number between 0 and 127, say; then the "signature" of the line $c_1c_2 \ldots c_{50}$ is the string of 128 bits $b_0b_1 \ldots b_{127}$, where $b_i = 1$ if and only if $h(c_jc_{j+1}) = i$ for some j.

If now we want to search for all occurrences of the word NEEDLE in a large text file called HAYSTACK, we simply look for all lines whose signature contains 1-bits in positions h(NE), h(EE), h(ED), h(DL), and h(LE). Assuming that the hash function is random, the probability that a random line contains all these bits in its signature is only 0.00341 (cf. exercise 4); hence the intersection of five inverted-list bit strings will rapidly identify all the lines containing NEEDLE, together with a few false drops.

The assumption of randomness is not really justified in this application, since typical text has so much redundancy; the distribution of bigrams, i.e. of two-letter combinations in words, is highly biased. For example, it will probably be very helpful to discard all pairs c_jc_{j+1} containing a blank character, since blanks are usually much more common than any other symbol.

Another interesting application of superimposed coding to search problems has been suggested by Burton H. Bloom [*CACM* **13** (1970), 422–426]; his method actually applies to *primary* key retrieval, although it is most appropriate for us to discuss it in this section. Imagine a search application with a large data base

in which no calculation needs to be done if the search was unsuccessful. For example, we might want to check somebody's credit rating or passport number, etc., and if no record for him appears in the file we don't have to investigate further. Similarly in an application to computerized typesetting, we might have a simple algorithm that hyphenates most words correctly, but it fails on some 50,000 exceptional words; if we don't find the word in the exception file we are free to use the simple algorithm.

In such situations it is possible to maintain a bit table in internal memory so that most keys not in the file can be recognized as absent without making *any* references to the external memory. Here's how: Let the internal bit table be $b_0 b_1 \ldots b_{m-1}$, where M is rather large. For each key K_j in the file, compute k independent hash functions $h_1(K_j), \ldots, h_k(K_j)$, and set the corresponding k b's equal to 1. (These k values need not be distinct.) Thus $b_i = 1$ if and only if $h_l(K_j) = i$ for some j and l. Now to determine if a search argument K is in the external file, first test whether or not $b_{h_l(K)} = 1$ for $1 \le l \le k$; if not, there is no need to access the external memory, but if so, a conventional search will probably find K if k and M have been chosen properly. The chance of a false drop when there are N records in the file is approximately $(1 - e^{-kN/M})^k$. In a sense, Bloom's method treats the entire file as one record, with the primary keys as the attributes which are present, and with superimposed coding in a huge M-bit field.

Still another variation of superimposed coding has been developed by Richard A. Gustafson [Ph.D. thesis (Univ. South Carolina, 1969)]. Suppose that we have N records and that each record possesses six attributes chosen from a set of 10,000 possible attributes. The records may, for example, stand for technical articles and the attributes may be keywords describing the article. Let h be a hash function which maps each attribute into a number between 0 and 15. If a record has attributes $a_1, a_2, \ldots, a_6$, Gustafson suggests mapping the record into the 16-bit number $b_0 b_1 \ldots b_{15}$, where $b_i = 1$ if and only if $h(a_j) = i$ for some j; and furthermore if this method results in only k of the b's equal to 1, for $k < 6$, another $6 - k$ 1's are supplied by some random method (not necessarily depending on the record itself). There are $\binom{16}{9} = 8008$ sixteen-bit codes in which exactly six 1 bits are present, and with luck about $N/8008$ records will be mapped into each value. We can keep 8008 lists of records, directly calculating the address corresponding to $b_0 b_1 \ldots b_{15}$ using a suitable formula. In fact, if the 1's occur in positions $0 \le p_1 < p_2 < \cdots < p_6$, the function

$$\binom{p_1}{1} + \binom{p_2}{2} + \cdots + \binom{p_6}{6}$$

will convert each string $b_0 b_1 \ldots b_1$ into a unique number between 0 and 8007, as we have seen in exercises 1.2.6–56, 2.2.6–7.

Now if we want to find all records having three particular attributes A_1, A_2, A_3, we compute $h(A_1)$, $h(A_2)$, $h(A_3)$; assuming that these three values are distinct, we need only look at the records stored in the $\binom{13}{3} = 286$ lists whose

bit code $b_0 b_1 \ldots b_{15}$ contains 1's in those three positions. In other words, only $286/8008 \approx 3.5$ percent of the records need to be examined in the search.

Combinatorial hashing. The idea underlying Gustafson's method just described is to find some way to map the records into memory locations so that comparatively few locations are relevant to a particular query. But his method applies only to inclusive queries when the individual records possess few attributes. Another type of mapping, designed to handle arbitrary basic queries like (4) consisting of 0's, 1's, and *'s, was discovered by Ronald L. Rivest in 1971.

Suppose first that we have 1,000,000 records each containing 10 secondary keys, where each secondary key has a fairly large number of possible values. We can map the records whose secondary keys are $(K_1, K_2, \ldots, K_{10})$ into the 20-bit number

$$h(K_1)h(K_2)\ldots h(K_{10}), \tag{6}$$

where h is a hash function taking each secondary key into a 2-bit value, and (6) stands for the juxtaposition of these ten pairs of bits. This scheme maps 1,000,000 records into $2^{20} = 1{,}048{,}576$ possible values, and we can consider the total mapping as a hash function with $M = 2^{20}$; chaining can be used to resolve collisions. If we want to retrieve all records having specified values of any five secondary keys, we need to look at only 2^{10} lists [corresponding to the five unspecified bit pairs in (6)], so only about $1000 = \sqrt{N}$ records need to be examined on the average. (A similar approach has been suggested by M. Arisawa, *J. Inf. Proc. Soc. Japan* **12** (1971), 163–167.)

Rivest has developed this idea further so that in many cases we have the following situation. Assume that there are $N \approx 2^n$ records, each having m secondary keys. Each record is mapped into an n-bit hash address, in such a way that a query which leaves the values of k keys unspecified corresponds to approximately $N^{k/m}$ hash addresses. All the other methods we have discussed in this section (except Gustafson's) require order N steps for retrieval, although the constant of proportionality is small; for large enough N, Rivest's method will be faster, and it requires no inverted files.

But we have to define an appropriate mapping, before we can apply this technique. Here is an example with small parameters, when $m = 4$ and $n = 3$ and when all secondary keys are binary-valued; we can map 4-bit records into eight addresses as follows:

$$\begin{array}{llll} * \ 0 \ 0 \ 0 \to 1 & & 0 \ 1 \ * \ 0 \to 5 \\ * \ 1 \ 1 \ 1 \to 2 & & 1 \ 0 \ * \ 1 \to 6 \\ 0 \ * \ 0 \ 1 \to 3 & & 0 \ 0 \ 1 \ * \to 7 \\ 1 \ * \ 1 \ 0 \to 4 & & 1 \ 1 \ 0 \ * \to 8 \end{array} \tag{7}$$

An examination of this table reveals that all records corresponding to the query 0 * * * are mapped into locations 1, 2, 3, 5, and 7; and similarly *any* basic query with three *'s corresponds to exactly five locations. The basic queries with two *'s each correspond to three locations; and the basic queries with one * cor-

respond to either one or two locations, $(8 \times 1 + 24 \times 2)/32 = 1.75$ on the average. Thus we have

Number of unspecified bits in the query	Number of locations to search
4	$8 = 8^{4/4}$
3	$5 \approx 8^{3/4}$
2	$3 \approx 8^{2/4}$
1	$1.75 \approx 8^{1/4}$
0	$1 = 8^{0/4}$

(8)

Of course this is such a small example, we could handle it more easily by brute force. But it leads to nontrivial applications, since we can use it also when $m = 4r$ and $n = 3r$, mapping $4r$-bit records into $2^{3r} \approx N$ locations by dividing the secondary keys into r groups of 4 bits each and applying (7) in each group. The resulting mapping has the desired property: *A query that leaves k of the m bits unspecified will correspond to approximately $N^{k/m}$ locations.* (See exercise 6.)

Some further mappings designed by Rivest appear in exercise 7; they can be used in combination with (7) to produce combinatorial hash functions for cases with $1 \leq m/n \leq 2$. In practice, buckets of size b would be used, and we would take $N \approx 2^n b$; the case $b = 1$ has been used in the above discussion for simplicity in exposition.

***Balanced filing schemes.** Another combinatorial approach to information retrieval, based on "balanced incomplete block designs," has been the subject of considerable investigation. Although the subject is very interesting from a mathematical point of view, it has unfortunately not yet proved to be very useful by comparison with the other methods described above. A brief introduction to the theory will be presented here in order to indicate the flavor of the results, in hopes that some reader might think of a good way to put the ideas to practical use.

A *Steiner triple system* is an arrangement of v objects into unordered triples in such a way that every pair of objects occurs in exactly one triple. For example, when $v = 7$ there is essentially only one Steiner triple system, namely

Triple	Pairs included
{1, 2, 4}	{1, 2}, {1, 4}, {2, 4}
{2, 3, 5}	{2, 3}, {2, 5}, {3, 5}
{3, 4, 6}	{3, 4}, {3, 6}, {4, 6}
{4, 5, 0}	{0, 4}, {0, 5}, {4, 5}
{5, 6, 1}	{1, 5}, {1, 6}, {5, 6}
{6, 0, 2}	{0, 2}, {0, 6}, {2, 6}
{0, 1, 3}	{0, 1}, {0, 3}, {1, 3}

(9)

Since there are $\frac{1}{2}v(v-1)$ pairs of objects and three pairs per triple, there must be $\frac{1}{6}v(v-1)$ triples in all; and since each object must be paired with $v-1$

others, each object must appear in exactly $\frac{1}{2}(v-1)$ triples. These conditions imply that a Steiner triple system can't exist unless $\frac{1}{6}v(v-1)$ and $\frac{1}{2}(v-1)$ are integers, and this is equivalent to saying that v is odd and not congruent to 2 modulo 3, i.e.,

$$v \bmod 6 = 1 \text{ or } 3. \tag{10}$$

Conversely, T. P. Kirkman proved in 1847 that Steiner triple systems do exist for all $v \geq 1$ such that (10) holds. His interesting construction is given in exercise 10.

Steiner triple systems can be used to reduce the redundancy of combined inverted file indexes. For example, consider again the cookie recipe file of Table 1, and convert the rightmost column into a 31st attribute which is 1 if any special ingredients are necessary, 0 otherwise. Assume that we want to answer all inclusive queries on pairs of attributes, e.g., "What recipes use both coconut and raisins?" We could make up an inverted list for each of these $\binom{31}{2} = 465$ possible queries. But it would turn out that this takes a lot of space since Pfeffernuesse (for example) would appear in $\binom{17}{2} = 136$ of the lists, and a record with all 31 attributes would appear in every list! A Steiner triple system can be used to make a slight improvement in this situation. There is a Steiner triple system on 31 objects, with 155 triples and each pair of objects occurring in exactly one of the triples. We can associate four lists with each triple $\{a, b, c\}$, one list for all records having attributes a, b, $\bar{c}$ (i.e., not c); another for a, $\bar{b}$, c; another for $\bar{a}$, b, c; and another for records having all three attributes a, b, c. This guarantees that no record will be included in more than 155 of the inverted lists, and it saves space whenever a record has three attributes corresponding to a triple of the system.

Triple systems are special cases of block designs which have blocks of three or more objects. For example, there is a way to arrange 31 objects into sextuples so that every pair of objects appears in exactly one sextuple:

{1, 5, 17, 22, 23, 25}	{ 7, 11, 23, 28, 29, 0}	{13, 17, 29, 3, 4, 6}	{20, 24, 5, 10, 11, 13}	{26, 30, 11, 16, 17, 19}
{2, 6, 18, 23, 24, 26}	{ 8, 12, 24, 29, 30, 1}	{14, 18, 30, 4, 5, 7}	{21, 25, 6, 11, 12, 14}	{27, 0, 12, 17, 18, 20}
{3, 7, 19, 24, 25, 27}	{ 9, 13, 25, 30, 0, 2}	{15, 19, 0, 5, 6, 8}	{22, 26, 7, 12, 13, 15}	{28, 1, 13, 18, 19, 21}
{4, 8, 20, 25, 26, 28}	{10, 14, 26, 0, 1, 3}	{16, 20, 1, 6, 7, 9}	{23, 27, 8, 13, 14, 16}	{29, 2, 14, 19, 20, 22}
{5, 9, 21, 26, 27, 29}	{11, 15, 27, 1, 2, 4}	{17, 21, 2, 7, 8, 10}	{24, 28, 9, 14, 15, 17}	{30, 3, 15, 20, 21, 23}
{6, 10, 22, 27, 28, 30}	{12, 16, 28, 2, 3, 5}	{18, 22, 3, 8, 9, 11}	{25, 29, 10, 15, 16, 18}	{ 0, 4, 16, 21, 22, 24}
		{19, 23, 4, 9, 10, 12}		

(11)

(This design is formed from the first block by addition mod 31. To verify that it has the stated property, note that the 30 values $(a_i - a_j) \bmod 31$, for $i \neq j$, are distinct, where $(a_1, a_2, \ldots, a_6) = (1, 5, 17, 22, 23, 25)$. To find the sextuple containing a given pair (x, y), choose i and j such that $a_i - a_j \equiv x - y$ (modulo 31); now if $k = (x - a_i) \bmod 31$, we have $(a_i + k) \bmod 31 = x$ and $(a_j + k) \bmod 31 = y$.)

We can use the above design to store the inverted lists in such a way that no record can appear more than 31 times. Each sextuple $\{a, b, c, d, e, f\}$ is associated with 57 lists, for the various possibilities of records having two or

more of the attributes a, b, c, d, e, f, namely $(a, b, \bar{c}, \bar{d}, \bar{e}, \bar{f})$, $(a, \bar{b}, c, \bar{d}, \bar{e}, \bar{f})$, . . . , (a, b, c, d, e, f); and the answer to each inclusive 2-attribute query is the disjoint union of 16 appropriate lists in the appropriate sextuple. For this design, Pfefferneuse would be stored in 29 of the 31 blocks, since that record has two of the six attributes in all but blocks {19, 23, 4, 9, 10, 12} and {13, 17, 29, 3, 4, 6} if we number the columns from 0 to 30.

A similar idea can be used to cut down redundancy of compound inverted lists when we wish to process basic queries instead of inclusive queries. For example, suppose that we have records with five secondary keys K_1, K_2, K_3, K_4, K_5, each of which has four possible values {0, 1, 2, 3}. In order to answer queries about records that have $K_i = a$ and $K_j = b$, given a and b and $i \neq j$, we could form inverted lists for all 160 such queries; each record would then appear in ten of these inverted lists. An alternative is to make use of the following configuration of ordered quintuples based on a combinatorial pattern known as "mutually orthogonal latin squares":

$$\begin{array}{llll} (0,0,0,0,0) & (1,0,1,2,3) & (2,0,2,3,1) & (3,0,3,1,2) \\ (0,1,1,1,1) & (1,1,0,3,2) & (2,1,3,2,0) & (3,1,2,0,3) \\ (0,2,2,2,2) & (1,2,3,0,1) & (2,2,0,1,3) & (3,2,1,3,0) \\ (0,3,3,3,3) & (1,3,2,1,0) & (2,3,1,0,2) & (3,3,0,2,1) \end{array} \tag{12}$$

Here if we look at any two of the five components, we will see all 16 possible ordered pairs of values occurring exactly once in those components. We can associate with block (a, b, c, d, e) of this configuration the records which satisfy at least two of the conditions $K_1 = a$, $K_2 = b$, . . . , $K_5 = e$. In this way each of the 16 blocks will be associated with 376 of the 1024 possible records, so the average redundancy is lowered from 10 to $16 \times 376/1024 = 5\frac{7}{8}$.

The theory of block designs, latin squares, etc. is developed in detail in Marshall Hall, Jr.'s book *Combinatorial Theory* (Waltham, Mass.: Blaisdell, 1967). Although these combinatorial configurations are very beautiful, their only real application to information retrieval so far has been to decrease the redundancy incurred when compound inverted lists are being used; and David K. Chow [*Information and Control* **15** (1969), 377–396] has observed that this type of decrease can be obtained even without using combinatorial designs.

A short history and bibliography. The first published article dealing with a technique for secondary key retrieval was by L. R. Johnson in *CACM* **4** (1961), 218–222. The Multilist system was independently developed by Noah S. Prywes, H. J. Gray, W. I. Landauer, D. Lefkowitz and S. Litwin at about the same time; cf. *IEEE Trans. on Communication and Electronics* **68** (1963), 488–492. Another rather early publication which influenced later work was by D. R. Davis and A. D. Lin, *CACM* **8** (1965), 243–246.

Since then a large literature on the subject has grown up, but most of it deals with the user interface and with programming language considerations, which are not within the scope of this book. In addition to the papers already

cited, the following published articles were found to be most helpful to the author as this section was being written: Jack Minker and Jerome Sable, *Ann. Rev. of Information Science and Technology* **2** (1967), 123–160; Robert E. Bleier, *Proc. ACM Nat. Conf.* **22** (1967), 41–49; Jerome A. Feldman and Paul D. Rovner, *CACM* **12** (1969), 439–449; Burton H. Bloom, *Proc. ACM Nat. Conf.* **24** (1969), 83–95; H. S. Heaps and L. H. Thiel, *Information Storage and Retrieval* **6** (1970), 137–153; Vincent Y. Lum and Huei Ling, *Proc. ACM Nat. Conf.* **26** (1971), 349–356. A good survey of manual card-filing systems appears in *Methods of Information Handling* by C. P. Bourne (New York: Wiley, 1963), Chapter 5. "Balanced filing schemes" were originally developed by C. T. Abraham, S. P. Ghosh and D. K. Ray-Chaudhuri in 1965; perhaps the best summary of this work and its subsequent extensions appears in an article by R. C. Bose and Gary G. Koch, *SIAM J. Appl. Math.* **17** (1969), 1203–1214.

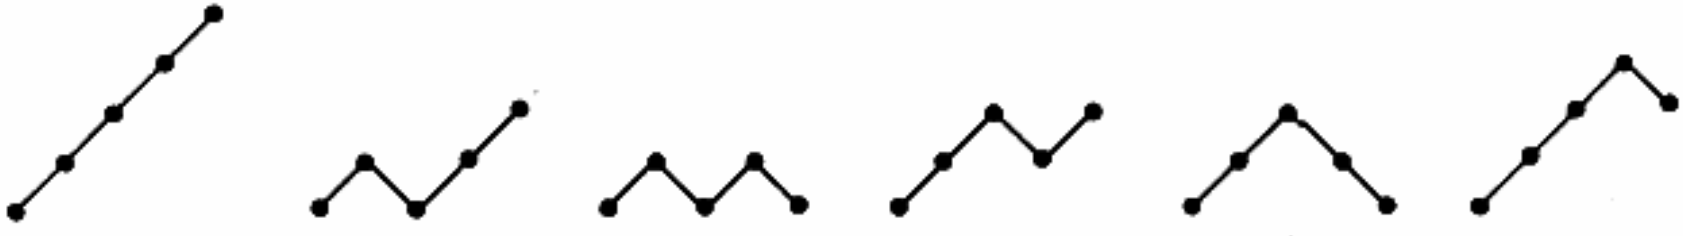
In this section we have discussed a fairly large number of interesting ideas that are helpful in quite different situations. Since many of these techniques were introduced shortly before this section was written, further advances will probably be forthcoming soon.

It is interesting to note that the human brain is much better at secondary key retrieval than computers are; in fact, it is rather easy for us to recognize faces, or melodies, etc., from only fragmentary information, while computers have barely been able to do this at all. Therefore it is not unlikely that a completely new approach to machine design will someday be discovered, which solves the problem of secondary key retrieval once and for all, making this entire section obsolete.

EXERCISES

▶ **1.** [*M27*] Let $0 \le k \le \frac{1}{2}n$. Prove that the following construction produces $\binom{n}{k}$ permutations of $\{1, 2, \ldots, n\}$, such that every t-element subset of $\{1, 2, \ldots, n\}$ appears as the first t elements of at least one of the permutations, for $t \le k$ or $t \ge n - k$: Consider a path in the plane from $(0, 0)$ to (n, r) where $r \ge n - 2k$, in which the ith step is from $(i - 1, j)$ to $(i, j + 1)$ or to $(i, j - 1)$; the latter possibility is allowed only if $j \ge 1$, so that the path never goes below the x-axis. There are exactly $\binom{n}{k}$ such paths. For each path of this kind, a permutation is constructed as follows, using three lists that are initially empty: For $i = 1, 2, \ldots, n$, if the ith step of the path goes up, put the number i into list B; if the step goes down, put i into list A and move the currently largest element of list B into list C. The resulting permutation is equal to the final contents of list A, then list B, then list C, each list in increasing order.

For example, when $n = 4$ and $k = 2$, the six paths and permutations defined by this procedure are



(Vertical lines show the division between lists A, B, and C. These six permutations correspond to the compound attributes in (2).)

Hint: Represent each t-element subset S by a path that goes from $(0, 0)$ to $(n, n - 2t)$, whose ith step runs from $(i - 1, j)$ to $(i, j + 1)$ if $i \notin S$ and to $(i, j - 1)$ if $i \in S$. Convert every such path into an appropriate path having the special form stated above.

2. [*M25*] (Sakti P. Ghosh.) Find the minimum possible length l of a list $r_1 r_2 \ldots r_l$ of references to records, such that the set of all responses to any of the inclusive queries `**1`, `*1*`, `1**`, `*11`, `1*1`, `11*`, `111` on three binary-valued secondary keys will appear in consecutive locations $r_i \ldots r_j$.

3. [*19*] In Table 2, what inclusive queries will cause (a) Old-Fashioned Sugar Cookies, (b) Oatmeal-Date Bars, to be obtained among the false drops?

4. [*M30*] Find exact formulas for the probabilities in (5), assuming that each record has r distinct attributes chosen randomly from among the $\binom{n}{k}$ k-bit codes in an n-bit field and that the query involves q distinct but otherwise random attributes. (Don't be alarmed if the formulas do not simplify.)

5. [*40*] Experiment with various ways to avoid the redundancy of text when using Harrison's technique for substring searching.

▶ **6.** [*M20*] The total number of m-bit basic queries with k bits specified is $s = \binom{m}{k}2^k$. If a combinatorial hashing function like that in (7) converts these queries into $l_1, l_2, \ldots, l_s$ locations, respectively, $L(k) = (l_1 + l_2 + \cdots + l_s)/s$ is the average number of locations per query. [For example, in (7) we have $L(3) = 1.75$.]

Consider now a composite hash function on an $(m_1 + m_2)$-bit field, formed by mapping the first m_1 bits with one hash function and the remaining m_2 with another, where $L_1(k)$ and $L_2(k)$ are the corresponding average numbers of locations per query. Find a formula that expresses $L(k)$, for the composite function, in terms of L_1 and L_2.

7. [*M24*] (R. L. Rivest.) Find the functions $L(k)$, as defined in the previous exercise, for the following combinatorial hash functions:

(a) $m = 3, n = 2$

$$\begin{aligned} 0\ 0\ * &\to 1\\ 1\ *\ 0 &\to 2\\ *\ 1\ 1 &\to 3\\ 1\ 0\ 1 &\to 4\\ 0\ 1\ 0 &\to 4 \end{aligned}$$

(b) $m = 4, n = 2$

$$\begin{aligned} 0\ 0\ *\ * &\to 1\\ *\ 1\ *\ 0 &\to 2\\ *\ 1\ 1\ 1 &\to 3\\ 1\ 0\ 1\ * &\to 3\\ *\ 1\ 0\ 1 &\to 4\\ 1\ 0\ 0\ * &\to 4 \end{aligned}$$

8. [*M47*] Develop further useful classes of combinatorial hash functions like (7).

9. [*M20*] Prove that when $v = 3^n$, the set of all triples of the form

$$\{(a_1 \ldots a_{k-1}\,0\,b_1 \ldots b_{n-k})_3,\ (a_1 \ldots a_{k-1}\,1\,c_1 \ldots c_{n-k})_3,\ (a_1 \ldots a_{k-1}\,2\,d_1 \ldots d_{n-k})_3\},\qquad 1 \le k \le n,$$

forms a Steiner triple system, where the a's, b's, c's, and d's range over all combinations of 0's, 1's, and 2's such that $b_i + c_i + d_i \equiv 0$ (modulo 3).

10. [*M32*] (Thomas P. Kirkman, *Cambridge and Dublin Math. Journal* **2** (1847), 191–204.) Let us say that a Kirkman triple system of order v is an arrangement of

$v+1$ objects $\{x_0, x_1, \ldots, x_v\}$ into triples such that every pair $\{x_i, x_j\}$ for $i \neq j$ occurs in exactly one triple, except that the v pairs $\{x_i, x_{(i+1) \bmod v}\}$ do not ever occur in the same triple, for $0 \leq i < v$. For example,

$$\{x_0, x_2, x_4\},\ \{x_1, x_3, x_4\}$$

is a Kirkman triple system of order 4.

a) Prove that a Kirkman triple system can exist only when $v \bmod 6 = 0$ or 4.

b) Given a Steiner triple system S on v objects $\{x_1, \ldots, x_v\}$, prove that the following construction yields another one S' on $2v+1$ objects and a Kirkman triple system K' of order $2v-2$: The triples of S' are those of S plus

i) $\{x_i, y_j, y_k\}$ where $j+k \equiv i$ (modulo v) and $j < k$, $1 \leq i, j, k \leq v$;

ii) $\{x_i, y_j, z\}$ where $2j \equiv i$ (modulo v), $1 \leq i, j \leq v$.

The triples of K' are those of S' minus all those containing y_1 and/or y_v.

c) Given a Kirkman triple system K on $\{x_0, x_1, \ldots, x_v\}$, where $v = 2u$, prove that the following construction yields a Steiner triple system S' on $2v+1$ objects and a Kirkman triple system K' of order $2v-2$: The triples of S' are those of K plus

i) $\{x_i, x_{(i+1) \bmod v}, y_{i+1}\}$, $0 \leq i < v$;

ii) $\{x_i, y_j, y_k\}$, $j+k \equiv 2i+1$ (modulo $v-1$), $1 \leq j < k-1 \leq v-2$, $1 \leq i \leq v-2$;

iii) $\{x_i, y_j, y_v\}$, $2j \equiv 2i+1$ (modulo $v-1$), $1 \leq j \leq v-1$, $1 \leq i \leq v-2$;

iv) $\{x_0, y_{2j}, y_{2j+1}\}$, $\{x_{v-1}, y_{2j-1}, y_{2j}\}$, $\{x_v, y_j, y_{v-j}\}$, for $1 \leq j < u$;

v) $\{x_v, y_u, y_v\}$.

The triples of K' are those of S' minus all those containing y_1 and/or y_{v-1}.

d) Use the preceding results to prove that Kirkman triple systems of order v exist for all $v \geq 0$ of the form $6k$ or $6k+4$, and Steiner triple systems or v objects exist for all $v \geq 1$ of the form $6k+1$ or $6k+3$.

11. [*M25*] The text describes the use of Steiner triple systems in connection with inclusive queries; in order to extend this to all basic queries it is natural to define the following concept. A *complemented triple system* of order v is an arrangement of $2v$ objects $\{x_1, \ldots, x_v, \bar{x}_1, \ldots, \bar{x}_v\}$ into triples such that every pair of objects occurs together is exactly one triple, except that complementary pairs $\{x_i, \bar{x}_i\}$ never occur together. For example,

$$\{x_1, x_2, x_3\},\ \{x_1, \bar{x}_2, \bar{x}_3\},\ \{\bar{x}_1, x_2, \bar{x}_3\},\ \{\bar{x}_1, \bar{x}_2, x_3\}$$

is a complemented triple system of order three.

Prove that complemented triple systems of order v exist for all $v \geq 0$ not of the form $3k+2$.

12. [*M23*] Continuing exercise 11, construct a complemented *quadruple* system of order 7.

13. [*M25*] Construct quadruple systems with $v = 4^n$ elements, analogous to the triple systems of exercise 9.

14. [*25*] Discuss the problem of deleting nodes from post-office trees like Fig. 45.

ANSWERS TO EXERCISES

"I have answered three questions, and that is enough,"
Said his father. "Don't give yourself airs!
Do you think I can listen all day to such stuff?
Be off, or I'll kick you down-stairs!"

— LEWIS CARROLL (Alice's Adventures in Wonderland, Chapter 5)

NOTES ON THE EXERCISES

1. An average problem for a mathematically inclined reader.

3. See W. J. LeVeque, *Topics in Number Theory* **2** (Reading, Mass.: Addison-Wesley, 1956), Chapter 3. (*Note:* One of the men who read a preliminary draft of the manuscript for this book reported that he had discovered a truly remarkable proof, which the margin of his copy was too small to contain.)

CHAPTER 5

1. Let $p(1) \ldots p(n)$ and $q(1) \ldots q(n)$ be different permutations satisfying the conditions, and let i be minimal with $p(i) \neq q(i)$. Then $p(i) = q(j)$ and $q(i) = p(k)$ for some j, k, i. Since $K_{p(i)} \leq K_{p(k)} = K_{q(i)} \leq K_{q(j)} = K_{p(i)}$ we have $K_{p(i)} = K_{q(i)}$; hence by stability $p(i) < p(k) = q(i) < q(j) = p(i)$, a contradiction.

2. Yes, if the sorting operations were all stable. (If they were not stable we cannot say.) Mr. A and Mr. C certainly have the same result; and so does Mr. B, since the stability shows that equal major keys in his result are accompanied by minor keys in nondecreasing order.

Formally, assume that Mr. B obtains the result $R_{p(1)}, \ldots, R_{p(N)} = R'_1, \ldots, R'_N$ after sorting the minor keys, then $R'_{q(1)}, \ldots, R'_{q(N)} = R_{p(q(1))}, \ldots, R_{p(q(N))}$ after sorting the major keys; we want to show that

$$(K_{p(q(i))}, k_{p(q(i))}) \leq (K_{p(q(i+1))}, k_{p(q(i+1))})$$

for $1 \leq i < N$. If $K_{p(q(i))} \neq K_{p(q(i+1))}$, we have $K_{p(q(i))} < K_{p(q(i+1))}$; and if $K_{p(q(i))} = K_{p(q(i+1))}$, then $K'_{q(i)} = K'_{q(i+1)}$, hence $q(i) < q(i+1)$, hence $k'_{q(i)} \leq k'_{q(i+1)}$, i.e., $k_{p(q(i))} \leq k_{p(q(i+1))}$.

3. We can always bring all records with equal keys together, preserving their relative order, treating these groups of records as a unit in further operations; hence we may assume that all keys are distinct. Let $a < b < c < a$; then we can arrange things so that the first three keys are *abc*, *bca*, or *cab*. Now if $N - 1$ distinct keys can be sorted, so can N; for if $K_1 < \cdots < K_{N-1} > K_N$ we always have either $K_{i-1} < K_N < K_i$ for some i, or $K_N < K_1$.

4. Overflow is possible, and it can lead to a false equality indication. He should have written, e.g., `LDA A; CMPA B` and tested the comparison indicator. (The inability to make full-word comparisons by subtraction is a problem on many computers; it is the chief reason for including `CMPA, . . . , CMPX` in `MIX`'s repertoire.)

5.

```
COMPARE  STJ   9F
1H       LDX   A,1
         CMPX  B,1
         JNE   9F
         DEC1  1
         J1P   1B
9H       JMP   *
```

6. Solution 1, based on the identity $\min(a, b) = \frac{1}{2}(a + b - |a - b|)$:

```
LDA   A
SRAX  5
DIV   =2=
STA   A1     a = 2a1 + a2
STX   A2     |a2| ≤ 1
LDA   B
SRAX  5
DIV   =2=
STA   B1     b = 2b1 + b2
STX   B2     |b2| ≤ 1
LDA   A1
SUB   B1     no overflow possible
STA   AB1    a1 - b1
LDA   A2
SUB   B2
STA   AB2    a2 - b2
SRAX  1
ADD   AB1
ENTX  1
SLAX  5
MUL   AB2
STX   AB3          (a2 - b2) sign (a - b)
LDA   A2
ADD   B2
SUB   AB3
SRAX  5
DIV   =2=
ADD   A1
ADD   B1           no overflow possible
SUB   AB1(1:5)
STA   C
```

Solution 2, based on the fact that indexing can cause interchanges in a tricky way:

```
LDA   A
STA   C
STA   TA
LDA   B
STA   TB
```

Now duplicate the following code k times, where $2^k > 10^{10}$:

```
LDA   TA          LDA   TB          INC1  0,2
SRAX  5           SRAX  5           INC1  0,2
DIV   =2=         DIV   =2=         INC1  0,2

7. $\sum_j \binom{r+j-1}{j}(-1)^j\binom{N}{r+j}x^{r+j}$, by the method of inclusion and exclusion (exercise 1.3.3–26). This is $r\binom{N}{r}\int_0^x t^{r-1}(1-t)^{N-r}\,dt$, a "beta distribution."

8. Sort it, then count. (Some sorting methods make it convenient to drop records whose keys are duplicated elsewhere in the file.)

9. Assign each person an identification number, which must appear on all forms concerning him. Sort the information forms and the tax forms separately, with this identification number as the key. Denote the sorted tax forms by $R_1, \ldots, R_N$, with keys $K_1 < \cdots < K_N$. (There should be no two tax forms with equal keys.) Add a new $(N+1)$st record whose key is ∞, and set $i \leftarrow 1$. Then, for each record in the information file, check if it has been reported, as follows: Let K denote the key on the information form being processed.

a) If $K > K_i$, increase i by 1 and repeat this step.
b) If $K < K_i$, or if $K = K_i$ and the information is not reflected on tax form R_i, signal an error.

Try to do all this processing without wasting the taxpayers' money.

10. One way is to attach the key (j, i) to the entry $a_{i,j}$ and to sort using lexicographic order, then omit the keys. (A similar idea can be used to obtain any desired reordering of information, when a simple formula for the reordering can be given.)

In the special case considered in this problem, the method of "balanced two-way merge sorting" treats the keys in such a simple manner that it is unnecessary to actually write them explicitly on the tapes. Given an $n \times n$ matrix, we may proceed as follows: First put odd-numbered rows on tape 1, even-numbered rows on tape 2, etc., obtaining

Tape 1: $a_{11}\ a_{12}\ \ldots\ a_{1n}\ a_{31}\ a_{32}\ \ldots\ a_{3n}\ a_{51}\ a_{52}\ \ldots\ a_{5n}\ \ldots$
Tape 2: $a_{21}\ a_{22}\ \ldots\ a_{2n}\ a_{41}\ a_{42}\ \ldots\ a_{4n}\ a_{61}\ a_{62}\ \ldots\ a_{6n}\ \ldots$

Then rewind these tapes, and process them synchronously, to obtain

Tape 3: $a_{11}\ a_{21}\ a_{12}\ a_{22}\ \ldots\ a_{1n}\ a_{2n}\ a_{51}\ a_{61}\ a_{52}\ a_{62}\ \ldots\ a_{5n}\ a_{6n}\ \ldots$
Tape 4: $a_{31}\ a_{41}\ a_{32}\ a_{42}\ \ldots\ a_{3n}\ a_{4n}\ a_{71}\ a_{81}\ a_{72}\ a_{82}\ \ldots\ a_{7n}\ a_{8n}\ \ldots$

Rewind these tapes, and process them synchronously, to obtain

Tape 1: $a_{11}\ a_{21}\ a_{31}\ a_{41}\ a_{12}\ \ldots\ a_{42}\ \ldots\ a_{4n}\ a_{9,1}\ \ldots$
Tape 2: $a_{51}\ a_{61}\ a_{71}\ a_{81}\ a_{52}\ \ldots\ a_{82}\ \ldots\ a_{8n}\ a_{13,1}\ \ldots$

And so on, until the desired transpose is obtained after $\lceil \log_2 n \rceil$ passes.

11. One way is to attach random distinct key values, sort on these keys, then discard the keys. (Cf. exercise 10; a similar method for obtaining a random *sample* was discussed in Section 3.4.2.) Another technique, involving about the same amount of work but apparently not straining the accuracy of the random number generator as much, is to attach a random integer in the range $0 \leq K_i \leq N - i$ to R_i, then rearrange using the technique of exercise 5.1.1–5.

12. For example, prepare 84-character records $a_1\ a_2 \ldots a_{84}$ as follows. For each committee card, $c_1 \ldots c_{80}$, set $a_1a_2a_3 \leftarrow c_{78}c_{79}c_{80}$, $a_4 \leftarrow$ blank, $a_5 \ldots a_{84} \leftarrow c_1 \ldots c_{80}$. For each faculty card $f_1 \ldots f_{80}$, and for each nonblank field $f_{21+3k}f_{22+3k}f_{23+3k}$ on this card for $0 \leq k < 20$, prepare a record with $a_1a_2a_3 \leftarrow f_{21+3k}f_{22+3k}f_{23+3k}$, $a_4 \ldots a_{22} \leftarrow f_2 \ldots f_{20}$, $a_{23} \ldots a_{21+j} \leftarrow f_1 \ldots f_j$, $a_{22+j} \leftarrow$ ",", $a_{24+j} \leftarrow f_{19}$, $a_{25+j} \leftarrow$ ".", $a_{27+j} \leftarrow f_{20}$, and (if f_{20} is nonblank) $a_{28+j} \leftarrow$ "."; other positions blank. Here j is the largest integer ≤ 18 with f_j nonblank. (If blanks are not lowest in the collating sequence, a_4 on the committee records and all blank characters among $a_4 \ldots a_{22}$ on the faculty records should be changed to the character lowest in the collating sequence.)

Now sort these 84-character records alphabetically. After sorting, process each 84-character record in turn as follows: If a_4 is blank, start a new page and print $a_4 \ldots a_{84}$. If a_4 is nonblank, print $a_{23} \ldots a_{84}$ preceded by 19 blanks. (There are obvious refinements to check for committee numbers without names, and faculty members not on enough committees. This exercise illustrates a fairly general method for creating listings, by sorting on a key which is not printed as part of the listing itself. It would be possible to keep the committee records separate from the faculty records, sorting the two files separately and listing them by processing them in a synchronous manner; but the separation probably doesn't save enough time to be worth the extra effort.)

13. With a character-conversion table, you can design a lexicographic comparison routine which simulates the order used on the other machine. Alternatively, you could create artificial keys, different from the actual characters but giving the desired ordering. The latter method has the advantage that it needs to be done only once; but it takes more space and requires conversion of the entire key. The former method can often determine the result of a comparison by converting only one or two letters of the keys; during later stages of sorting, the comparison will be between nearly equal keys, and it will perhaps be advantageous in the former method to check for equality of letters before converting them.

14. For this problem, just run through the file once keeping 50 or so individual counts. But if "city" were substituted for "state," and if the total number of cities were quite large, it would be a good idea to sort on the city name.

15. As in exercise 14, it depends on the size of the problem. If the total number of cross-reference entries fits into high-speed memory, the best approach is probably to use a symbol table algorithm (Chapter 6) with each identifier associated with the head of a list of references. For larger problems, create a file of records, one record for each cross-reference citation to be put in the index, and sort it.

16. Carry along with each card a key which, sorted lexicographically in the usual simple way, will define the desired ordering. This key is to be supplied by library personnel and attached to the card data when it first enters the system. A possible

key, using MIX character code to define the collating sequence, uses the following two-letter codes to separate words from each other:

␣␣	end of key
␣.	end of cross-reference
␣,	end of surname
␣(	hyphen of multiple surname
␣)	end of author name
␣+	end of place name
␣–	end of subject heading
␣*	end of book title
␣/	space between words.

The given example would then come out as follows (showing only the first 25 characters):

This auxiliary key should be followed by the card data, so that unequal cards having the same auxiliary key (e.g., Sir John = John) are distinguished properly.

17. Prepare two files, one containing $a^{m^n} \bmod p$ and the other containing $(ba^{-n}) \bmod p$ for $0 \leq n < m$. Sort these files and look for a common entry.

Note: This reduces the work from $O(p)$ to $O(\sqrt{p} \log p)$. Is a further reduction possible? It is not difficult to determine if n is even or odd, in $\log p$ steps, by testing

whether $b^{(p-1)/2} \bmod p = 1$ or $(p-1)$. So we may reduce the problem to the case n even; and $a^{2n} \equiv b$ is equivalent to $a^n \equiv \pm\sqrt{b}$. Unfortunately, there is no apparent way to select the appropriate $\sqrt{b}$ which has $n \leq (p-1)/2$.

18. For example, we can make two files containing values of $(u^6 + v^6 + w^6) \bmod W$ and $(z^6 - x^6 - y^6) \bmod W$ for $u \leq v \leq w$, $x \leq y \leq z$, where W is the word size of our computer. Sort these and look for duplicates, then subject the duplicates to further tests. (Some congruences modulo small primes might also be used to place further restrictions on u, v, w, x, y, z.)

19. In general, to find all pairs of numbers (x_i, x_j) with $x_i + x_j = c$, where c is given: Sort the file so that $x_1 < x_2 < \cdots < x_N$. Set $i \leftarrow 1$, $j \leftarrow N$, and then repeat the following operation until $j \leq i$:

If $x_i + x_j = c$, output (x_i, x_j) and (x_j, x_i), set $i \leftarrow i + 1$, $j \leftarrow j - 1$;

If $x_i + x_j < c$, set $i \leftarrow i + 1$;

If $x_i + x_j > c$, set $j \leftarrow j - 1$.

Finally if $j = i$ and $2x_i = c$, output (x_i, x_i). This process is like those of exercises 16 and 17: We are essentially making two sorted files, one containing $x_1, \ldots, x_N$ and the other containing $c - x_N, \ldots, c - x_1$, and checking for duplicates. But the second file doesn't need to be explicitly formed in this case. Another approach when c is odd is to sort on a key such as (x odd $\Rightarrow x$, x even $\Rightarrow c - x$).

20. Some of the alternatives are: (a) For each of the 499,500 pairs i, j with $1 \leq i < j \leq 1000$, set $y_1 \leftarrow x_i \oplus x_j$, $y_2 \leftarrow y_1 \wedge (y_1 - 1)$, $y_3 \leftarrow y_2 \wedge (y_2 - 1)$; then print (x_i, x_j) if and only if $y_3 = 0$. Here $\oplus$ denotes "exclusive or" and $\wedge$ denotes "and". (b) Create a file with 31000 entries, forming 31 entries from each original word x_i by including x_i and the 30 words that differ from x_i in one position. Sort this file and look for duplicates. (c) Do a test analogous to (a) on

i) all pairs of words which agree in their first 10 bits;

ii) all pairs of words which agree in their middle 10 bits (but not the first 10);

iii) all pairs of words which agree in their last 10 bits (but neither the first nor middle 10).

This involves three sorts of the data, using a specified 10-bit key each time. The expected number of pairs in each of the three cases is less than 500, if the original words are randomly distributed.

21. First prepare a file containing all five-letter English words. (Be sure to consider adding suffixes such as -ED, -ER, -ERS, -S to shorter words.) Now take each five-letter word α and sort its letters into ascending order, obtaining the sorted five-letter sequence α'. Finally sort all pairs (α', α) to bring all anagrams together.

Experiments by Kim D. Gibson in 1967 indicate that the second longest set of anagrams is LEAST, SLATE, STALE, STEAL, TAELS, TALES, TEALS. [The use of a larger dictionary would have enlarged this set by adding ASTEL, a splinter; LEATS, water junctions; TESLA, a unit of magnetic induction. And we might also count Madame de Staël! Cf. H. E. Dudeney, *300 Best Word Puzzles*, ed. by Martin Gardner (N. Y.: Chas. Scribner's Sons, 1968), puzzle 194.]

The first and last sets found were ALBAS, BALAS, BALSA, BASAL and STRUT, STURT, TRUST, respectively. The unexpected sets ADDER, DARED, DREAD and ALGOR, ARGOL, GORAL, LARGO are of possible interest to computer scientists.

A faster way to proceed is to compute $f(\alpha) = (x + a_1)(x + a_2)(x + a_3)(x + a_4)(x + a_5) \bmod m$, where $a_1, \ldots, a_5$ are numerical codes for the individual letters in α, and where m is the computer word size. Here x is any fixed value which may be chosen "at random" before starting the computation. Sorting the file $(f(\alpha), \alpha)$ will bring anagrams together; afterwards when $f(\alpha) = f(\beta)$ we must make sure that we have a true anagram with $\alpha' = \beta'$. The value $f(\alpha)$ can be calculated more rapidly than α', and this method avoids the determination of α' for most of the words α in the file.

Note: A similar technique can be used when we want to bring together all sets of records which have equal n-word keys $(a_1, \ldots, a_n)$. Suppose that we don't care about the order of the file, except that records with equal keys are to be brought together; it is sometimes faster to sort on the one-word key $(a_1 x^{n-1} + a_2 x^{n-2} + \cdots + x_n) \bmod m$ instead of the original n-word key.

22. Find isomorphic invariants of the graphs (i.e., functions which take equal values on isomorphic directed graphs) and sort on these, to separate "obviously nonisomorphic" graphs from each other. Examples of isomorphic invariants: (a) Represent vertex v_i by (a_i, b_i), where a_i is its in-degree and b_i is its out-degree; then sort the pairs (a_i, b_i) into lexicographic order. The resulting file is an isomorphic invariant. (b) Represent an arc from v_i to v_j by (a_i, b_i, a_j, b_j), and sort these quadruples into lexicographic order. (c) Separate the directed graph into connected components (cf. Algorithm 2.3.3E), determine invariants of each component, and sort the components into order of their invariants in some way. See also the discussion in exercise 21.

After sorting the directed graphs on their invariants, it will still in general be necessary to make secondary tests to see whether directed graphs with identical invariants are in fact isomorphic. The invariants are helpful for these tests too. In the case of trees it is possible to find "characteristic" or "canonical" invariants which completely characterize the tree, so that secondary testing is unnecessary [see H. I. Scoins, *Machine Intelligence* **3** (1969), 43–60].

23. One way is to form a file containing all three-person cliques, then transform it into a file containing all four-person cliques, etc.; if there are no large cliques this method will be quite satisfactory. (On the other hand, if there is a clique of size n, there are at least $\binom{n}{k}$ cliques of size k, so this method can blow up even when n is only 20 or so.)

Given a file which lists all $(k - 1)$-person cliques, in the form $(a_1, \ldots, a_{k-1})$ where $a_1 < \cdots < a_{k-1}$, we can find the k-person cliques by (i) creating a new file containing the entries $(b, c, a_1, \ldots, a_{k-2})$ for each pair of $(k - 1)$-person cliques of the respective forms $(a_1, \ldots, a_{k-2}, b)$, $(a_1, \ldots, a_{k-2}, c)$ with $b < c$; (ii) sorting this file on its first two components; (iii) for each entry $(b, c, a_1, \ldots, a_{k-2})$ in this new file which matches a pair (b, c) of acquaintances in the originally given file, output the k-person clique $(a_1, \ldots, a_{k-2}, b, c)$.

24. Make another copy of the input file; sort one copy on the first components and the other on the second. Passing over these files in sequence now allows us to create a new file containing all pairs (x_i, x_{i+2}) for $1 \le i \le N - 2$, and to identify (x_{N-1}, x_N). The pairs $(N - 1, x_{N-1})$ and (N, x_N) should be written on still another file.

The process continues inductively. Assume that file F contains all pairs (x_i, x_{i+t}) for $1 \le i \le N - t$, in random order, and that file G contains all pairs (i, x_i) for $N - t < i \le N$ in order of the second components. Let H be a copy of file F, and sort H by first components, F by second. Now go through F, G, and H, creating two

new files F' and G', as follows. If the current records of files F, G, H are, respectively, (x, x'), (y, y'), (z, z'), then:

i) If $x' = z$, output (x, z') to F' and advance files F and H.

ii) If $x' = y'$, output $(y - t, x)$ to G' and advance files F and G.

iii) If $x' > y'$, advance file G.

iv) If $x' > z$, advance file H.

When file F is exhausted, sort G' by second components and merge G with it; then replace t by $2t$, F by F', G by G'.

Thus t takes the values 2, 4, 8, . . . ; for fixed t we do $O(\log n)$ passes over the data to sort it; hence the total number of passes is $O((\log n)^2)$. Eventually $t \geq N$, so F is empty; then we simply sort G on its *first* components.

This ingenious solution is due to Norman Hardy. One phase could be saved at the expense of some complication, by recognizing x_{N+1-i} on the same pass as x_i is presently identified.

SECTION 5.1.1

1. 2 0 5 2 2 3 0 0 0; 2 7 3 5 4 1 8 6.

2. $b_1 = (m - 1) \bmod n$; $b_{j+1} = (b_j + m - 1) \bmod (n - j)$.

3. $\bar{a}_j = a_{n+1-j}$ (the "reflected" permutation). This idea was used by O. Terquem [*Journ. de Math.* (1) **3** (1838), 559–560] to prove that the average number of inversions in a random permutation is $\frac{1}{2}\binom{n}{2}$.

4. **C1.** Set $x_0 \leftarrow 0$. (It is possible to let x_j share memory with b_j in what follows, for $1 \le j \le n$.)

C2. For $k = n, n - 1, \ldots, 1$ (in this order) do the following: Set $j \leftarrow 0$; then set $j \leftarrow x_j$ exactly b_k times; then set $x_k \leftarrow x_j$ and $x_j \leftarrow k$.

C3. Set $j \leftarrow 0$.

C4. For $k = 1, 2, \ldots, n$ (in this order), do the following: Set $a_k \leftarrow x_j$; then set $j \leftarrow x_j$. ∎

To save memory space, see exercise 5.2–12.

5. Let α be a string $[m_1, n_1] \cdots [m_k, n_k]$ of ordered pairs of nonnegative integers; we write $|\alpha| = k$, the length of α. Let ϵ denote the empty (length 0) string. Consider the binary operation defined recursively on pairs of such strings as follows:

$$\epsilon \circ \alpha = \alpha \circ \epsilon = \alpha;$$

$$([m, n]\alpha) \circ ([m', n']\beta) = \begin{cases} [m, n](\alpha \circ ([m' - m, n']\beta)), & \text{if } m \le m', \\ [m', n'](([m - m' - 1, n]\alpha) \circ \beta), & \text{if } m > m'. \end{cases}$$

It follows that the computation time required to evaluate $\alpha \circ \beta$ is proportional to $|\alpha \circ \beta| = |\alpha| + |\beta|$. Furthermore, we can prove that $\circ$ is associative and that $[b_1, 1] \circ [b_2, 2] \circ \cdots \circ [b_n, n] = [0, a_1][0, a_2] \ldots [0, a_n]$. The expression on the left can be evaluated in $\lceil \log_2 n \rceil$ passes, each pass combining pairs of strings, for a total of $O(n \log n)$ steps.

Example: Starting from (2), we want to evaluate $[2, 1] \circ [3, 2] \circ [6, 3] \circ [4, 4] \circ [0, 5] \circ [2, 6] \circ [2, 7] \circ [1, 8] \circ [0, 9]$. The first pass reduces this to $[2, 1][1, 2] \circ [4, 4][1, 3] \circ [0, 5][2, 6] \circ [1, 8][0, 7] \circ [0, 9]$. The second pass reduces it to $[2, 1][1, 2][1, 4][1, 3] \circ [0, 5][1, 8][0, 6][0, 7] \circ [0, 9]$. The third pass yields

$$[0, 5][1, 1][0, 8][0, 2][0, 6][0, 4][0, 7][0, 3] \circ [0, 9].$$

The fourth pass yields (1).

Motivation: A string such as $[4, 4][1, 3]$ stands for "␣␣␣␣4␣3", where "␣" denotes a large number to be filled in later. Note that, together with exercise 2, we obtain an algorithm for the Josephus problem which is $O(n \log n)$ instead of $O(mn)$, partially answering a question raised in exercise 1.3.2–22.

Another $O(n \log n)$ solution to this problem, using a random-access memory, follows from the use of balanced trees in a straightforward manner.

6. Start with $b_1 = b_2 = \cdots = b_n = 0$. For $k = \lfloor \log_2 n \rfloor, \lfloor \log_2 n \rfloor - 1, \ldots, 0$ do the following: Set $x_s \leftarrow 0$ for $0 \le s \le n/2^{k+1}$; then for $j = 1, 2, \ldots, n$ do the following: Set $r \leftarrow \lfloor a_j/2^k \rfloor \bmod 2$, $s \leftarrow \lfloor a_j/2^{k+1} \rfloor$ (these are essentially bit extractions); if $r = 0$, set $b_{a_j} \leftarrow b_{a_j} + x_s$, and if $r = 1$ set $x_s \leftarrow x_s + 1$.

Another solution appears in exercise 5.2.4–21.

7. $B_j < j$ and $C_j \le n - j$ since a_j has less than j elements to its left and $n - j$ elements to its right. To reconstruct $a_1\, a_2 \ldots a_n$ from $B_1\, B_2 \ldots B_n$, start with the element 1; then for $k = 2, \ldots, n$ add one to each element $> B_k$ and append $(B_k + 1)$ at the right. (Cf. Method 2 in Section 1.2.5.) A similar procedure works for the C's. Alternatively, we could use the result of the following exercise.

8. $b' = C$, $c' = B$, $B' = c$, $C' = b$, since each inversion (a_i, a_j) of $a_1 \ldots a_n$ corresponds to the inversion (j, i) of $a'_j \ldots a'_n$. Some further relations: (a) $c_j = j - 1$ iff $(b_i > b_j$ for all $i < j)$; (b) $b_j = n - j$ iff $(c_i > c_j$ for all $i > j)$; (c) $b_j = 0$ iff $(c_i - i < c_j - j$ for all $i > j)$; (d) $c_j = 0$ iff $(b_i + i < b_j + j$ for all $i < j)$; (e) $b_i \le b_{i+1}$ iff $c_i \ge c_{i+1}$; (f) $a_j = j + C_j - B_j$; $a'_j = j + b_j - c_j$.

9. $b = C = b'$ is equivalent to $a = a'$.

10. $\sqrt{10}$. (One way to coordinatize the truncated octahedron lets the respective vectors $(1, 0, 0)$, $(0, 1, 0)$, $\frac{1}{2}(1, 1, \sqrt{2})$, $\frac{1}{2}(1, -1, \sqrt{2})$, $\frac{1}{2}(-1, 1, \sqrt{2})$, $\frac{1}{2}(-1, -1, \sqrt{2})$ stand for adjacent interchanges of the respective pairs 21, 43, 41, 31, 42, 32. The sum of these vectors gives $(1, 1, 2\sqrt{2})$ as the difference between vertices 4321 and 1234.)

A more symmetric solution is to represent vertex π in *four* dimensions by

$$\sum \{\mathbf{e}_u - \mathbf{e}_v \mid (u, v) \text{ is an inversion of } \pi\},$$

where $\mathbf{e}_1 = (1, 0, 0, 0)$, $\mathbf{e}_2 = (0, 1, 0, 0)$, $\mathbf{e}_3 = (0, 0, 1, 0)$, $\mathbf{e}_4 = (0, 0, 0, 1)$. Thus, $1\ 2\ 3\ 4 \leftrightarrow (0, 0, 0, 0)$; $1\ 2\ 4\ 3 \leftrightarrow (0, 0, -1, 1)$; $\ldots$; $4\ 3\ 2\ 1 \leftrightarrow (-3, -1, 1, 3)$. All points lie on the three-dimensional subspace $\{(w, x, y, z) \mid w + x + y + z = 0\}$; the distance between adjacent vertices is $\sqrt{2}$. Equivalently (cf. exercise 8(f)) we may represent $\pi = a_1 a_2 a_3 a_4$ by the vector (a'_1, a'_2, a'_3, a'_4), where $a'_1 a'_2 a'_3 a'_4$ is the inverse permutation. (This 4-D representation of the truncated octahedron with permutations as coordinates, and the n-dimensional generalization, was discussed by C. Howard Hinton in *The Fourth Dimension* (London, 1904), Chapter 10.)

Replicas of the truncated octahedron will fill three-dimensional space in the "simplest" possible way [see H. Steinhaus, *Mathematical Snapshots* (Oxford, 1960),

200–203; C. S. Smith, *Scientific American* 190 (January, 1954), 58–64]. For illustrations of the 14 "Archimedean" solids (i.e., nonprism polyhedra whose faces are regular polygons), see W. W. Rouse Ball, *Mathematical Recreations and Essays*, rev. by H. S. M. Coxeter (Macmillan, 1939), 129–140; H. Martyn Cundy and A. P. Rollett, *Mathematical Models* (Oxford, 1952), 94–109.

11. (a) Obvious. (b) Construct a directed graph with vertices $(1, 2, \ldots, n)$, arcs from $x \longrightarrow y$ if $x > y$ and $(x, y) \in E$ or $x < y$ and $(y, x) \in \overline{E}$. If there are no oriented cycles, this directed graph can be topologically sorted, and the resulting linear order is the desired permutation. If there is an oriented cycle, the shortest has length three, since there are none of length 1 or 2 and since a longer cycle $a_1 \longrightarrow a_2 \longrightarrow a_3 \longrightarrow a_4 \longrightarrow \cdots \longrightarrow a_1$ can be shortened (either $a_1 \longrightarrow a_3$ or $a_3 \longrightarrow a_1$). But an oriented cycle of length 3 contains two arcs of either E or $\overline{E}$, and proves that E or $\overline{E}$ is not transitive after all.

12. [C. Berge, *Principes de Combinatoire* (Paris, 1968), 114–117.] Suppose that $(a, b) \in \overline{E}$, $(b, c) \in \overline{E}$, $(a, c) \notin \overline{E}$. Then for some $k \geq 1$ we have $a = x_0 > x_1 > \cdots > x_k = c$, where $(x_i, x_{i+1}) \in E(\pi_1) \cup E(\pi_2)$ for $0 \leq i < k$. Consider a counterexample of this type where k is minimal. Since $(a, b) \notin E(\pi_1)$ and $(b, c) \notin E(\pi_1)$, we have $(a, c) \notin E(\pi_1)$, and similarly $(a, c) \notin E(\pi_2)$; hence $k > 1$. But if $x_1 > b$, then $(x_1, b) \in \overline{E}$ contradicts the minimality of k, while $(x_1, b) \in E$ implies that $(a, b) \in E$. Similarly if $x_1 < b$ we find that both $(b, x_1) \in \overline{E}$ and $(b, x_1) \in E$ are impossible.

13. For $0 \leq t < m$, the quantity $\sum_{k \bmod m = t} I_n(k)$ is the coefficient of z^{mN+t} in $G_n(z)/(1 - z^m)$ for all large N. The latter function is $1/(1 - z)$ times the polynomial

$$(1 + z) \ldots (1 + z + \cdots + z^{n-1})/(1 + z + \cdots + z^{m-1}),$$

and the desired quantity is the sum of the coefficients of the latter polynomial.

14. The hinted construction takes pairs of distinct-part partitions into each other, except in the two cases $j = k = p_k$ and $j = k = p_k - 1$. In the exceptional cases, n is $(2j - 1) + \cdots + j = (3j^2 - j)/2$ and $(2j) + \cdots + (j + 1) = (3j^2 + j)/2$, respectively, and there is a unique unpaired partition with j parts. [Euler's original proof, in *Novi Comment. acad. sc. Pet.* **5** (1754), 75–83, was also very interesting. He showed by simple manipulations that the infinite product equals s_1, where $s_n = 1 - z^{2n-1} - z^{3n-1}s_{n+1}$ for $n \geq 1$.]

15. Transpose the dot diagram, to go from the p's to the P's. The generating function for the P's is easily obtained, since we first choose any number of 1's (generating function $1/(1 - z)$), then independently choose any number of 2's (generating function $(1 - z^2)$), . . . , finally any number of n's.

16. The coefficient of $z^n q^m$ in the first identity is the number of partitions of m into at most n parts. In the second identity it is the number of partitions of m into n distinct nonnegative parts, i.e., $m = p_1 + p_2 + \cdots + p_n$, where $p_1 > p_2 > \cdots > p_n \geq 0$. This is the same as $m - \binom{n}{2} = q_1 + q_2 + \cdots + q_n$, where $q_1 \geq q_2 \geq \cdots \geq q_n \geq 0$, under the correspondence $q_i = p_i - n + i$. [*Commentarii academiæ scientiarum Petropolitanæ* **13** (1741), 64–93.]

17.

0 0 0 0	0 0 1 0	0 1 0 0	0 0 0 1
1 0 1 1	1 0 2 1	1 2 0 1	2 1 0 1
0 1 0 1	0 1 1 0	0 2 1 0	2 0 1 0
1 1 0 1	1 1 1 0	1 2 1 0	2 1 1 0
1 0 0 1	1 0 1 0	1 1 0 0	2 1 0 0
2 1 0 2	2 1 2 0	2 2 1 0	3 2 1 0

18. Let $q = 1 - p$. The sum $\sum \Pr(\alpha)$ over all instances α of inversions may be evaluated by summing on k, where $0 \le k < n$ is the exact number of leftmost bit positions in which there is equality between i and j as well as between X_i and X_j, in an inversion $X_i \oplus i > X_j \oplus j$ for $i < j$. In this way we obtain the formula $\sum_{0 \le k < n} 2^k (p^2 + q^2)^k (p^2 2^{n-k-1} 2^{n-k-1} + 2pq 2^{n-k-1}(2^{n-k-1} - 1))$; summing and simplifying yields $2^{n-1}(p(2-p)(2^n - (p^2+q^2)^n)/(2 - p^2 - q^2) + (p^2+q^2)^n - 1)$.

19. [*Proc. Amer. Math. Soc.* **19** (1968), 236–240.] Assume that $n > 1$, and that a permutation $a_1 \ldots a_n$ is given. By induction we may assume that $a_1 \ldots a_{n-1}$ corresponds to $b_1 \ldots b_{n-1}$, where index $(a_1 \ldots a_{n-1})$ = inversions $(b_1 \ldots b_{n-1})$ and $a_{n-1} = b_{n-1}$. *Case 1*, $a_{n-1} < a_n$. Let $b_1 \ldots b_{n-1} = \alpha_1 x_1 \ldots \alpha_r x_r$, where $\alpha_1, \ldots, \alpha_r$ are (possibly empty) strings of elements $> a_n$, and where $x_1, \ldots, x_r$ are the elements $< a_n$. Then we take $a_1 \ldots a_n$ into $x_1 \alpha_1 \ldots x_r \alpha_r a_n$. *Case 2*, $a_{n-1} > a_n$. Same as Case 1, with "$<$" and "$>$" interchanged. This transformation is clearly reversible, since we can distinguish Case 1 from Case 2 by comparing the first and last elements. *Example:* 2 7 1 8 3 6 4 is taken into 7 2 8 1 6 3 4; hence 2 7 1 8 3 6 4 5 is left unchanged.

20. See E. M. Wright, *J. London Math. Soc.* **40** (1965), 55–57; and J. Zolnowsky (to appear).

SECTION 5.1.2

1. False (because of a reasonably important technicality). If you said "true," you probably didn't know the definition of $M_1 \cup M_2$ given in Section 4.6.3, which has the property that $M_1 \cup M_2$ is a set whenever M_1 and M_2 are sets. Actually, $\alpha \intercal \beta$ is a permutation of $M_1 \uplus M_2$.

2. $b\ c\ a\ d\ d\ a\ d\ a\ d\ b$.

3. Certainly not, since we may have $\alpha = \beta$. (The unique factorization theorem shows that there aren't too many possibilities, however.)

4. $(d) \intercal (b\ c\ d) \intercal (b\ b\ c\ a\ d) \intercal (b\ a\ b\ c\ d) \intercal (d)$.

5. The number of occurrences of the pair $\ldots xx \ldots$ is always either equal to or one less than the number of $\frac{x}{x}$ columns. When x is the smallest element, the numbers of occurrences are equal iff x is not first in the permutation.

6. Counting the associated number of two-line arrays is easy: $\binom{m}{k}\binom{n}{k}$.

7. Using part (a) of Theorem B, a derivation like that of (20) gives

$$\binom{A-1}{A-k-m-1}\binom{B}{m}\binom{C}{k}\binom{B+k}{B-l}\binom{C-k}{l};$$

$$\binom{A-1}{A-k-m}\binom{B}{m}\binom{C}{k}\binom{B+k-1}{B-l-1}\binom{C-k}{l};$$

$$\binom{A-1}{A-k-m}\binom{B}{m}\binom{C}{k}\binom{B+k-1}{B-l}\binom{C-k}{l}.$$

8. The complete factorization into primes is $(d) \intercal (b\ c\ d) \intercal (b) \intercal (a\ d\ b\ c) \intercal (a\ b) \intercal (b\ c\ d) \intercal (d)$, which is unique since no adjacent pairs commute. So there are eight solutions, with $\alpha = \epsilon$, (d), $(d) \intercal (b\ c\ d)$, $\ldots$.

10. False, but true in interesting cases. Given any linear ordering of the primes, there is at least one factorization of the stated form, since whenever the condition is

violated we can make an interchange which reduces the number of "inversions" in the factorization. So the condition fails only because some permutations have more than one such factorization.

Let $\rho \sim \sigma$ mean that ρ commutes with σ. The following condition is necessary and sufficient for the uniqueness of the factorization as stated:

$$\rho \sim \sigma \sim \tau \qquad \text{and} \qquad \rho \prec \sigma \prec \tau \qquad \text{implies} \qquad \rho \sim \tau.$$

Proof. If $\rho \sim \sigma \sim \tau$ and $\rho \prec \sigma \prec \tau$ and $\rho \not\sim \tau$, we would have two factorizations $\sigma \mathbin{⟙} \tau \mathbin{⟙} \rho = \tau \mathbin{⟙} \rho \mathbin{⟙} \sigma$; hence the condition is necessary. Conversely, to show that it is sufficient for uniqueness, let $\rho_1 \mathbin{⟙} \cdots \mathbin{⟙} \rho_n = \sigma_1 \mathbin{⟙} \cdots \mathbin{⟙} \sigma_n$ be two distinct factorizations satisfying the condition. We may assume that $\sigma_1 \prec \rho_1$, and hence $\sigma_1 = \rho_k$ for some $k > 1$; furthermore $\sigma_1 \sim \rho_j$ for $1 \leq j < k$. Since $\rho_{k-1} \sim \sigma_1 = \rho_k$, we have $\rho_{k-1} \prec \sigma_1$; hence $k > 2$. Let j be such that $\sigma_1 \prec \rho_j$ and $\rho_i \prec \sigma_1$ for $j < i < k$. Then $\rho_{j+1} \sim \sigma_1 \sim \rho_j$ and $\rho_{j+1} \prec \sigma_1 \prec \rho_j$ implies that $\rho_{j+1} \sim \rho_j$; hence $\rho_j \prec \rho_{j+1}$, a contradiction.

Therefore if we are given an ordering relation on a set S of primes, satisfying the above condition, and if we know that all prime factors of a permutation π belong to S, we can conclude that π has a unique factorization of the stated type. Such a condition holds, for example, when S is the set of cycles in (29).

But the set of *all* primes cannot be so ordered; for if we have, say, $(a\ b) \prec (d\ e)$, then we are forced to define

$$(a\ b) \prec (d\ e) \succ (b\ c) \prec (e\ a) \succ (c\ d) \prec (a\ b) \succ (d\ e),$$

a contradiction. (See also the following exercise.)

11. We wish to show that, if $p(1) \ldots p(t)$ is a permutation of $(1, \ldots, t)$, the permutation $x_{p(1)} \ldots x_{p(t)}$ is topologically sorted iff $\sigma_{p(1)} \mathbin{⟙} \cdots \mathbin{⟙} \sigma_{p(t)} = \sigma_1 \mathbin{⟙} \cdots \mathbin{⟙} \sigma_t$; and that if $x_{p(1)} \ldots x_{p(t)}$ and $x_{q(1)} \ldots x_{q(t)}$ are distinct topological sortings, we have $\sigma_{p(j)} \neq \sigma_{q(j)}$ for some j. The first property follows by observing that $x_{p(1)}$ can be first in a topological sort iff $\sigma_{p(1)}$ commutes with (yet is distinct from) $\sigma_{p(1)-1}, \ldots, \sigma_1$; and this condition implies that $\sigma_{p(2)} \mathbin{⟙} \cdots \mathbin{⟙} \sigma_{p(t)} = \sigma_1 \mathbin{⟙} \cdots \mathbin{⟙} \sigma_{p(1)-1} \mathbin{⟙} \sigma_{p(1)+1} \mathbin{⟙} \cdots \mathbin{⟙} \sigma_t$, so induction can be used. The second property follows because if j is minimal with $p(j) \neq q(j)$, we have, say, $p(j) < q(j)$ and $x_{p(j)} \not\prec x_{q(j)}$ by definition of topological sorting; hence $\sigma_{p(j)}$ has no letters in common with $\sigma_{q(j)}$.

To get an arbitrary partial ordering, let the cycle σ_k consist of all ordered pairs (i, j) such that $x_i \prec x_j$ and either $i = k$ or $j = k$; these ordered pairs are to appear in some arbitrary order as individual elements of the cycle. Thus the cycles for the partial ordering $x_1 \prec x_3$, $x_2 \prec x_4$, $x_1 \prec x_4$ would be $\sigma_1 = \big((1, 3)(1, 4)\big)$, $\sigma_2 = \big((2, 4)\big)$, $\sigma_3 = \big((1, 3)\big)$, $\sigma_4 = \big((2, 4)(1, 4)\big)$.

12. No other cycles can be formed, since, for example, the original permutation contains no $\binom{a}{c}$ columns. If $(a\ b\ c\ d)$ occurs s times, then $(a\ b)$ must occur $A - r - s$ times, since there are $A - r$ columns $\binom{a}{b}$, and only two kinds of cycles contribute to such columns.

13. In the two-line notation, first place $A - t$ columns of the form $\binom{d}{a}$, then put the other t a's in the second line, then place the b's, and finally the remaining letters.

14. Since the elements below any given letter in the two-line notation for π^{-1} are

in nondecreasing order, we do not always have $(\pi^{-1})^{-1} = \pi$; but it is true that $((\pi^{-1})^{-1})^{-1} = \pi^{-1}$. In fact, the identity

$$(\alpha \intercal \beta)^{-1} = ((\alpha^{-1} \intercal \beta^{-1})^{-1})^{-1}$$

holds for all α, β.

Given a multiset whose distinct letters are $x_1 < \cdots < x_m$, we can characterize its self-inverse permutations by observing that they each have a unique prime factorization of the form $\beta_1 \intercal \cdots \intercal \beta_m$, where β_j has zero or more prime factors $(x_j) \intercal \cdots \intercal (x_j) \intercal (x_j x_{k_1}) \intercal \cdots \intercal (x_j x_{k_t})$, $j < k_1 \le \cdots \le k_t$. For example, $(a) \intercal (a\ b) \intercal (a\ b) \intercal (b\ c) \intercal (c)$ is a self-inverse permutation. The number of self-inverse permutations of $(m \cdot a, n \cdot b)$ is therefore $\min(m, n) + 1$; of $(\ell \cdot a, m \cdot b, n \cdot c)$ it is the number of solutions of the inequalities $x + y \le \ell$, $y + z \le m$, $z + x \le n$ in nonnegative integers x, y, z. The number of self-inverse permutations of a *set* is considered in Section 5.1.4.

The number of permutations of $(n_1 \cdot x_1, \ldots, n_m \cdot x_m)$ having n_{ij} occurrences of x_i *over* x_j in their two-line notation is $\prod_i n_i! / \prod_{i,j} n_{ij}!$, the same as the number having n_{ij} occurrences of x_i *under* x_j in the two-line notation. Hence there ought to be another way to define the inverse of a multiset permutation, by giving an appropriate one-to-one correspondence.

15. See Theorem 2.3.4.2D. Removing one arc of the directed graph must leave an oriented tree.

16. If the multiset is $(n_1 \cdot x_1, n_2 \cdot x_2, \ldots)$, with $x_1 < x_2 < \cdots$, the inversion table entries for the x_j's must have the form $b_{j1} \le \cdots \le b_{jn_j}$ where b_{jn_j} (the number of inversions of the rightmost x_j) is at most $n_{j+1} + n_{j+2} + \cdots$. So the generating function for the jth part of the inversion table is the generating function for partitions into at most n_j parts, no part exceeding $n_{j+1} + n_{j+2} + \cdots$. The generating function for partitions into at most m parts, no part exceeding n, is the z-binomial coefficient $\binom{m+n}{m}_z$; this is readily proved by induction, and it can also be proved by means of an ingenious construction due to Sylvester [*Amer. J. Math.* **5** (1882), 268–269], or another ingenious construction due to Pólya [*Elemente der Mathematik* **26** (1971), 102–109]. Multiplying the generating functions for $j = 1, 2, \ldots$ gives the desired result.

17. Let $h_n(z) = (n!_z)/n!(1 - z)^n$; the desired generating function is $g(z) = h_n(z)/h_{n_1}(z)h_{n_2}(z)\cdots$. The mean of $h_n(z)$ is $\frac{1}{2}\binom{n}{2}$, by Eq. 5.1.1–12, so the mean of g is

$$\frac{1}{2}\left(\binom{n}{2} - \binom{n_1}{2} - \binom{n_2}{2} - \cdots\right) = \frac{1}{4}\left(n^2 - n_1^2 - n_2^2 - \cdots\right) = \frac{1}{2}\sum_{i<j} n_i n_j.$$

The variance is, similarly,

$$\tfrac{1}{72}(n(n-1)(2n+5) - n_1(n_1-1)(2n_1+5) - \cdots) \\ = \tfrac{1}{36}(n^3 - n_1^3 - n_2^3 - \cdots) + \tfrac{1}{24}(n^2 - n_1^2 - n_2^2 - \cdots).$$

18. Yes. The construction of exercise 5.1.1–17 can be extended in a straightforward way. Alternatively we can generalize the proof given in Section 5.2.1, constructing a one-to-one correspondence between m-tuples $(q_1, \ldots, q_m)$ where q_j is a multiset containing n_j nonnegative integers, on the one hand, and ordered pairs of n-tuples $((a_1, \ldots, a_n), (p_1, \ldots, p_n))$ on the other hand, where $a_1 \ldots a_n$ is a permutation of

$(n_1 \cdot 1, \ldots, n_m \cdot m)$, and $p_1 \geq \cdots \geq p_n \geq 0$. This correspondence is defined as before, inserting the elements of q_j in nonincreasing order; it satisfies the condition

$$\left(\sum q_1\right) + \cdots + \left(\sum q_m\right) = J(a_1 \ldots a_n) + (p_1 + \cdots + p_n)$$

where $\sum q_j$ is the sum of the elements of q_j. [For a further generalization of the technique used in this proof (and in the derivation of Eq. (8) in Section 5.1.3) see D. E. Knuth, *Math. Comp.* **24** (1970), 955–961. See also the comprehensive treatment by Richard P. Stanley, *Memoirs Amer. Math. Soc.* **119** (1972), 104 pp.]

19. (a) Let $S = \{\sigma | \sigma \text{ is prime, } \sigma \text{ is a left factor of } \pi\}$. If S has k elements, the left factors λ of π such that $\mu(\lambda) \neq 0$ are precisely the 2^k intercalations of the subsets of S (see the proof of Theorem C); hence $\sum \mu(\lambda) = \prod_{\sigma \in S} (1 + \mu(\sigma)) = 0$, since $\mu(\sigma) = -1$ and S is nonempty. (b) Clearly $\epsilon(i_1 \ldots i_n) = \mu(\pi) = 0$ if $i_j = i_k$ for some $j \neq k$. Otherwise $\epsilon(i_1 \ldots i_n) = (-1)^r$ where $i_1 \ldots i_n$ has r inversions; this is $(-1)^s$, where $i_1 \cdots i_n$ has s even cycles; and this is $(-1)^{n+t}$ where $i_1 \ldots i_n$ has t cycles.

20. (a) Obvious, by definition of intercalation. (b) By definition,

$$\det (b_{ij}) = \sum_{1 \leq i_1, \ldots, i_m \leq m} \epsilon(i_1 \ldots i_m) b_{1 i_1} \ldots b_{m i_m}.$$

Setting $b_{ij} = \delta_{ij} - a_{ij} x_j$, this becomes

$$\sum_{n \geq 0} \sum_{1 \leq i_1, \ldots, i_n < m} (-1)^n x_{i_1} \ldots x_{i_n} \mu(x_{i_1} \ldots x_{i_n}) \nu(x_{i_1} \ldots x_{i_n}),$$

since $\mu(\pi)$ is usually zero.

(c) Use exercise 19(a) to show that $D \intercal G = 1$ when we regard the products of x's as permutations of noncommutative variables, using the natural algebraic convention $(\alpha + \beta) \intercal \pi = \alpha \intercal \pi + \beta \intercal \pi$.

SECTION 5.1.3

1. We must only show that this value makes (11) valid for $x = k$, when $k \geq 1$. The formula becomes

$$k^n = \sum_{0\leq j\leq r\leq k} (-1)^j (r-j)^n \binom{n+1}{j}\binom{n+k-r}{n}$$

$$= \sum_{0\leq s\leq k} s^n \sum_{0\leq j\leq k-s} (-1)^j \binom{n+1}{j}\binom{n+k-s-j}{n}.$$

For $s < k$, the sum on j can be extended to the range $0 \leq j \leq n+1$, and it is zero (the $(n+1)$st difference of an nth degree polynomial in j).

2. (a) The number of sequences $a_1\, a_2 \ldots a_n$ containing each of the elements $(1, 2, \ldots, q)$ at least once is $\left\{{n \atop q}\right\} q!$ (cf. exercise 1.2.6–64); the number of such sequences satisfying the analog of (10), for $m = q$, is $\binom{n-k}{n-q}$, since we must choose $n - q$ of the possible $=$ signs. (b) Add the results of (a) for $m = n - q$ and $n - q - 1$.

3. By (20),

$$\sum \frac{x^n}{n!} \sum \left\langle {n \atop k} \right\rangle (-1)^k = \sum g_n(-1)x^n = -2/(e^{-2x}+1)$$
$$= -\frac{1}{x}\left(\frac{(-2x)}{e^{-2x}-1} - \frac{(-4x)}{e^{-4x}-1}\right)$$
$$= -\frac{1}{x}\sum_{n\geq 0} \frac{B_n x^n}{n!}\left((-2)^n - (-4)^n\right);$$

hence the result is $(-1)^n B_{n+1} 2^{n+1}(2^{n+1}-1)/(n+1)$. Alternatively, since $-2/(e^{-2x}+1) = -(1+\tanh x)$, we can express the answer as $(-1)^{(n+1)/2} T_n$, when n is odd, where T_n denotes the tangent number defined by the formula

$$\tan z = T_1 z + T_3 z^3/3! + T_5 z^5/5! + \cdots.$$

When $n > 0$ is even, the sum obviously vanishes, by (7).

Note that, by (18), we get the curious identity

$$\sum_k \left\{ {n \atop k} \right\} k!(-\tfrac{1}{2})^k = 2B_{n+1}(1-2^{n+1})/(n+1).$$

4. $(-1)^{n+m}\left\langle {n \atop m+1} \right\rangle$. (Consider the coefficient of z^{m+1} in (18).)

5. First we find that $\left\langle {p-1 \atop k} \right\rangle \bmod p = 1$, for $1 \leq k < p$, by formula (13). Hence by the defining recurrence (2), $\left\langle {p \atop k} \right\rangle \bmod p = 1$ for $1 \leq k \leq p$.

6. Summing first on k is not allowed, because the terms are nonzero for arbitrarily large j and k, and the sum of the absolute values is infinite.

For a simpler example of the fallacy, let $a_{jk} = 0$ when $|j-k| \neq 1$, and let $a_{j(j+1)} = +1$, $a_{(j+1)j} = -1$. Then $\sum_{j\geq 0}(\sum_{k\geq 0} a_{jk}) = \sum_{j\geq 0}(\delta_{j0}) = +1$, while $\sum_{k\geq 0}(\sum_{j\geq 0} a_{jk}) = \sum_{k\geq 0}(-\delta_{k0}) = -1$.

7. Yes. [David and Barton, *Combinatorial Chance* (1962), 150–154.]

8. [*Combinatory Analysis* **1** (1915), 190.] By inclusion and exclusion. For example, $1/(l_1+l_2)!l_3!(l_4+l_5+l_6)!$ is the probability that $x_1 < \cdots < x_{l_1+l_2}$, $x_{l_1+l_2+1} < \cdots < x_{l_1+l_2+l_3}$, and $x_{l_1+l_2+l_3+1} < \cdots < x_{\Sigma l}$.

9. $p_{km} = q_{km} - q_{k(m+1)}$ in (23). Since $\sum_{k,m} q_{km} z^m x^k = g(x,z)/(1-x)$, we have $h(z,x) = \sum h_k(z)x^k = g(x,z)/(1-x) - \big(g(x,z) - g(x,0)\big)/z(1-x) = (z-1)x/(ze^{(x-1)z} - x) + x/z(1-x)$. Thus $h_1(z) = e^z - (e^z-1)/z$; $h_2(z) = (e^{2z} - ze^z) + e^z - (e^{2z}-1)/z$.

10. Let $M_n = L_1 + \cdots + L_n$ be the mean; then $\sum M_n x^n = h'(1,x)$, where the derivative is taken with respect to z, and this is $x/(e^{x-1} - x) - x/(1-x) = M(x)$, say. By the residue theorem,

$$\frac{1}{2\pi i}\oint M(z) z^{-n-1}\,dz = M_n - 2(n+\tfrac{1}{3}) + 1 + \frac{z_1^{-n}}{z_1 - 1} + \frac{\bar{z}_1^{-n}}{\bar{z}_1 - 1},$$

if we integrate around a circle of radius r where $|z_1| < r < |z_2|$. (Note the double pole at $z = 1$.) Furthermore, the absolute value of this integral is $< \oint |M(z)| r^{-n-1}\,dz = O(r^{-n})$. Integrating over larger and larger circles gives the convergent series $M_n = 2n - \frac{1}{3} + \sum_{k\geq 1} 2\,\Re\,(1/z_k^n(1-z_k))$.

To determine the variance, we have $h''(1, x) = -2h'(1, x) + 2x(x-1)e^{x-1}/(e^{x-1} - x)^2$. An argument similar to that used for the mean, this time with a triple pole, shows that the coefficients of $h''(1, x)$ are asymptotically $4n^2 + \frac{4}{3}n - 2M_n$ plus smaller terms; this leads to the asymptotic formula $\frac{2}{3}n + \frac{2}{9}$ (plus exponentially smaller terms) for the variance.

11. $P_{kn} = \sum_{t_1 \geq 1, \ldots, t_k \geq 1} D(t_1, \ldots, t_{k-1}, n, 1)$, where $D(l_1, l_2, \ldots, l_k)$ is MacMahon's determinant of exercise 8. Evaluating this determinant by its first row, we find $P_{kn} = c_0 P_{(k-1)n} + c_1 P_{(k-2)n} + \cdots + c_{k-2} P_{1n} - E_k(n)$, where c_j and E_k are defined as follows:

$$c_j = (-1)^j \sum_{t_1, \ldots, t_{j+1} \geq 1} \frac{1}{(t_1 + \cdots + t_{j+1})!} = (-1)^j \sum_{m \geq 0} \binom{m}{j} \frac{1}{(m+1)!}$$

$$= (-1)^j \sum_{r, m \geq 0} \binom{-1}{j-r} \binom{m+1}{r} \frac{1}{(m+1)!} = -1 + e\left(\frac{1}{0!} - \frac{1}{1!} + \cdots + (-1)^k \frac{1}{k!}\right).$$

$$E_1(n) = -1/n! + 1/(n+1)!; \qquad E_2(n) = 1/(n+1)!;$$

$$E_k(n) = (-1)^k \sum_{m \geq 0} \binom{m}{k-3} \frac{1}{(n+2+m)!}, \qquad k \geq 3.$$

Let $P_{0n} = 0$, $C(z) = \sum c_j z^j = (e^{1-z} - 1)/(1-z)$, and let

$$E(z, x) = \sum_{n,k} E_{k+1}(n) z^n x^k$$

$$= 1 - e^z + \frac{(e^{1-x} - 1)x^2}{(1-x)^2} - \frac{x^2(e^{1-x} - e^z)}{(1-x)(1-x-z)} + \frac{e^z - 1 - z}{z(1-x)}.$$

The recurrence relation we have derived is equivalent to the formula $C(x)H(z, x) = H(z, x)/x + E(z, x)$; hence $H(z, x) = E(z, x)x(1-x)/(xe^{1-x} - 1)$. Expanding this power series gives $H_1(z) = h_1(z)$ (see exercise 9); $H_2(z) = eh_1(z) + 1 - e^z$.

[*Note:* The generating functions for the first three runs were derived by Knuth, *CACM* **6** (1963), 685–688. Barton and Mallows, *Ann. Math. Statistics* **36** (1965), 249, stated the formula $1 - H_{n+1}(z) = (1 - H_n(z))/(1-z) - L_n h_1(z)$, together with (25). Another way to attack this problem is illustrated in exercise 23. Because adjacent runs are not independent, there is no simple relation between the problem solved here and the simpler (probably more useful) result of exercise 9.]

12. [*Combinatory Analysis* **1** (1915), 209–211.] The number of ways to put the multiset into t distinguishable boxes is

$$N_t = \binom{t + n_1 - 1}{n_1} \binom{t + n_2 - 1}{n_2} \cdots \binom{t + n_m - 1}{n_m},$$

since there are $\binom{t+n_1-1}{n_1}$ ways to place the 1's, etc. If we require that no box be empty, the method of inclusion and exclusion tells us that the number of ways is

$$M_t = N_t - \binom{t}{1} N_{t-1} + \binom{t}{2} N_{t-2} - \cdots.$$

Let P_k be the number of permutations having k runs; if we put $k-1$ vertical lines between the runs, and $t-k$ additional vertical lines in any of the $n-k$ remaining places, we get one of the M_t ways to divide the multiset into t nonempty distinguishable parts. Hence

$$M_t = P_t + \binom{n-t+1}{1} P_{t-1} + \binom{n-t+2}{2} P_{t-2} + \cdots .$$

Equating the two values of M_t allows us to determine $P_1, P_2, \ldots$ successively in terms of $N_1, N_2, \ldots$. (A more direct proof would be desirable.)

13. $1 + \frac{1}{2}13 \times 3 = 20.5$.

14. By Foata's correspondence the given permutation corresponds to

$$\begin{pmatrix} 1 & 1 & 1 & 1 & 2 & 2 & 2 & 2 & 3 & 3 & 3 & 3 & 4 & 4 & 4 & 4 \\ 3 & 1 & 1 & 2 & 3 & 4 & 3 & 2 & 1 & 1 & 3 & 4 & 2 & 2 & 4 & 4 \end{pmatrix};$$

by (33) this corresponds to

$$\begin{pmatrix} 1 & 1 & 1 & 1 & 2 & 2 & 2 & 2 & 3 & 3 & 3 & 3 & 4 & 4 & 4 & 4 \\ 2 & 4 & 4 & 3 & 3 & 3 & 1 & 1 & 4 & 4 & 2 & 1 & 2 & 1 & 2 & 3 \end{pmatrix};$$

and this corresponds to 2 3 4 2 3 4 1 4 2 1 4 3 2 1 3 1 with 9 runs.

15. The number of alternating runs is the number of j such that $1 < j < n$ and either $a_{j-1} < a_j > a_{j+1}$ or $a_{j-1} > a_j < a_{j+1}$. For fixed j, the probability is $\frac{2}{3}$; hence the average, for $n \geq 2$, is $1 + \frac{2}{3}(n-2)$.

16. Each permutation on $\{1, 2, \ldots, n-1\}$, having k alternating runs, yields k permutations with k such runs, 2 with $k+1$, and $n-k-2$ with $k+2$, when the new element n is inserted in all possible places. Hence

$$\left\langle\!\left\langle {n \atop k} \right\rangle\!\right\rangle = k \left\langle\!\left\langle {n-1 \atop k} \right\rangle\!\right\rangle + 2 \left\langle\!\left\langle {n-1 \atop k-1} \right\rangle\!\right\rangle + (n-k) \left\langle\!\left\langle {n-1 \atop k-2} \right\rangle\!\right\rangle .$$

It is convenient to let $\langle\langle {1 \atop k} \rangle\rangle = \delta_{k0}$, $G_1(z) = 1$. Then

$$G_n(z) = \frac{z}{n}\left((1-z^2)G'_{n-1}(z) + (2+(n-2)z)G_{n-1}(z)\right).$$

Differentiation leads to the recurrence

$$x_n = \frac{1}{n}\left(x_{n-1}(n-2) + 2n - 2\right)$$

for $x_n = G'_n(1)$, and this has the solution $x_n = \frac{2}{3}n - \frac{1}{3}$ for $n \geq 2$. Another differentiation leads to the recurrence

$$y_n = \frac{1}{n}\left(y_{n-1}(n-4) + \tfrac{8}{3}n^2 - \tfrac{26}{3}n + 6\right)$$

for $y_n = G''_n(1)$. Set $y_n = \alpha n^2 + \beta n + \gamma$ and solve for α, β, γ to get $y_n = \frac{4}{9}n^2 - \frac{14}{15}n + \frac{11}{90}$ for $n \geq 4$. Hence var $(g_n) = \frac{1}{90}(16n - 29)$, $n \geq 4$.

These formulas for the mean and variance are due to J. Bienaymé, who stated them without proof [*Bull. Soc. Math. de France* **2** (1874), 153–154; *Comptes Rendus* **81** (Acad. Sciences, Paris, 1875), 417–423, see also Bertrand's remarks on p. 458]. The recurrence relation for $\langle\langle {n \atop k} \rangle\rangle$ is due to D. André [*Comptes Rendus* **97** (Acad. Sciences, Paris, 1883), 1356–1358; *Annales scientifiques de l'Ecole normale supérieure* (3) **1** (Paris, 1884), 121–134]. André noted that $g_n(-1) = 0$ for $n \geq 4$; i.e., the number of permutations with an even number of alternating runs is $n!/2$. He also proved the formula for the mean, and determined the number of permutations which have the maximum number of alternating runs (see exercise 5.1.4–22). It can be shown that

$$G_n(z) = \left(\frac{1+z}{2}\right)^{n-1} (1+w)^{n+1} g_n\left(\frac{1-w}{1+w}\right), \qquad w = \sqrt{\frac{1-z}{1+z}}, \qquad n \geq 2,$$

where $g_n(z)$ is the generating function (18) for ascending runs. [See David and Barton, *Combinatorial Chance* (London: Griffin, 1962), 157–162.]

17. $({n+1 \atop 2k-1})$; $({n \atop 2k-2})$ end with 0, $({n \atop 2k-1})$ end with 1.

18. Let the given sequence be $C_1\ C_2\ \ldots\ C_n$, an inversion table such as we have considered in exercise 5.1.1–7. If there are k runs in this sequence, there are k in the corresponding permutation; hence the answer is $\langle {n \atop k} \rangle$.

19. (a) $\langle {n \atop k+1} \rangle$, by the correspondence of Theorem 5.1.2B. (b) There are $(n-k)!$ ways to put $n-k$ further nonattacking rooks on the entire board; hence the answer is $1/(n-k)!$ times $\sum_{j \geq 0} a_{nj} {j \atop k}$, where $a_{nj} = \langle {n \atop j+1} \rangle$ is the solution for part (a) with $j = k$. This comes to $\{ {n \atop n-k} \}$, by exercise 2.

A direct proof of this result, due to E. A. Bender, associates each partition of $\{1, 2, \ldots, n\}$ into k nonempty disjoint subsets with an arrangement of $(n-k)$ rooks: Let the partition be

$$\{1, 2, \ldots, n\} = \{a_{11}, a_{12}, \ldots, a_{1n_1}\} \cup \cdots \cup \{a_{k1}, \ldots, a_{kn_k}\},$$

where $a_{ij} < a_{i(j+1)}$ for $1 \leq j < n_i$, $1 \leq i \leq k$. The corresponding arrangement puts rooks in column a_{ij} of row $a_{i(j+1)}$, for $1 \leq j < n_i$, $1 \leq i \leq k$. For example, the configuration illustrated in Fig. 4 corresponds to the partition $\{1, 3, 8\} \cup \{2\} \cup \{4, 6\} \cup \{5\} \cup \{7\}$.

20. The number of readings is the number of runs in the inverse permutation. The first run corresponds to the first reading, etc.

21. It has $n+1-k$ runs and requires $n+1-j$ readings.

22. [*J. Combinatorial Theory* **1** (1966), 350–374.] If $rs < n$, some reading will pick up $t > r$ elements, $a_{i_1} = j+1, \ldots, a_{i_t} = j+t$, where $i_1 < \cdots < i_t$. We cannot have $a_m > a_{m+1}$ for all m in the range $i_k \leq m < i_{k+1}$, so the permutation contains at least $t-1$ places with $a_m < a_{m+1}$; it therefore has at most $n-t+1$ runs.

But if $rs \geq n$, consider the permutation

$$(tr) \ldots (2r)\ (r) \ldots (3)\ ((t-1)r+2) \ldots (r+2)\ (2)\ ((t-1)r+1) \ldots (r+1)\ (1)$$

where $\lceil n/r \rceil = t \leq s$, and where elements $> n$ are to be omitted. It has $n+1-r$ runs and it requires $n+1-r$ readings. By rearranging the groups $\{kr+r, \ldots, kr+1\}$ independently among themselves, it is possible to adjust the number of readings to any desired lesser value $s \geq t$.

23. [*SIAM Review* **3** (1967), 121–122.] Assume that the infinite permutation consists of independent samples from the uniform distribution. Let $f_k(x)\,dx$ be the probability that the kth long run begins with x; and let $g(u, x)\,dx$ be the probability that a long run begins with x, when the preceding long run begins with u. Then $f_1(x) = 1$, $f_{k+1}(x) = \int_0^1 f_k(u)g(u, x)\,du$. We have $g(u, x) = \sum_{m\geq 1} g_m(u, x)$, where $g_m(u, x) = \Pr(u < X_1 < \cdots < X_m > x \text{ or } u > X_1 > \cdots > X_m < x) = \Pr(u < X_1 < \cdots < X_m) + \Pr(u > X_1 > \cdots > X_m) - \Pr(u < X_1 < \cdots < X_m < x) - \Pr(u > X_1 > \cdots > X_m > x) = (u^m + (1-u)^m + |u-x|^m)/m!$; hence $g(u, x) = e^u + e^{1-u} - 1 - e^{|u-x|}$. Consequently, $f_2(x) = 2e - 1 - e^x - e^{1-x}$. It can be shown that $f_k(x)$ approaches the limiting value $(2\cos(x-\frac{1}{2}) - \sin\frac{1}{2} - \cos\frac{1}{2})/(3\sin\frac{1}{2} - \cos\frac{1}{2})$. The average length of a run starting with x is $e^x + e^{1-x} - 1$ hence the length LL_k of the kth long run is $\int_0^1 f_k(x)(e^x + e^{1-x} - 1)\,dx$; $LL_1 = 2e - 3 \approx 2.4365$; $LL_2 = 3e^2 - 8e + 2 \approx 2.4209$. See Section 5.4.1 for similar results.

24. Arguing as before, the result is

$$1 + \sum_{0\leq k<n} 2^k(p^2+q^2)^k\big(p^2 + 2pq(2^{n-k-1} - 1 + q^2((2pq)^{n-k-1} - 1)/(2pq-1))\big);$$

carrying out the sum and simplifying yields

$$2^n(p^2+q^2)^n(p(p-q)/(p^2+q^2-pq) - \tfrac{1}{2}) + (2pq)^n pq^3/(p^2+q^2)(p^2+q^2-pq) + q^2/(p^2+q^2) + 2^{n-1}.$$

SECTION 5.1.4

1.

1	2	3	8
4	5	7	
6	9		

1	3	5	8
2	4	9	
6	7		

; $\begin{pmatrix} 1 & 3 & 4 & 5 & 7 & 8 & 9 \\ 5 & 9 & 2 & 4 & 8 & 1 & 7 \end{pmatrix}$.

2. When p_i is inserted into column t, let the element in column $t-1$ be p_j. Then (q_j, p_j) is in class $t-1$, $q_j < q_i$, and $p_j < p_i$; so, by induction, indices $i_1, \ldots, i_t$ exist with the property. Conversely, if $q_j < q_i$ and $p_j < p_i$ and if (q_j, p_j) is in class $(t-1)$, then column $t-1$ contains an element $< p_i$ when p_i is inserted, so (q_i, p_i) is in class t.

3. The columns are the "bumping sequences" (9) when p_i is inserted. Lines 1 and 2 reflect the operations on row 1, cf. (14). If we remove columns in which line 2 has ∞ entries, lines 0 and 2 constitute the "bumped" array, as in (15). The stated method for going from line k to line $k+1$ is just the class-determination algorithm of the text.

4. Let there be t classes in all; exactly k of these have an odd number of elements, since the elements of a class have the form

$$(p_{i_k}, p_{i_1}), \qquad (p_{i_{k-1}}, p_{i_2}), \qquad \ldots, \qquad (p_{i_1}, p_{i_k}).$$

(See (18) and (22).) The "bumped" two-line array has exactly $t-k$ fixed points, because of the way it is constructed; hence by induction the tableau minus its first

row has $t - k$ columns of odd length. So the t elements in the first row lead to k odd-length columns in the whole tableau.

5. (a) Use a case analysis, by induction on the size of the tableau, considering first the effect on row 1 and then the effect on the sequence of elements bumped from row 1. (b) Admissible interchanges can simulate the operations of Algorithm I, with the tableau represented as a canonical permutation before and after the algorithm. For example, we can transform

$$17\ 11\ 4\ 13\ 14\ 2\ 6\ 10\ 15\ 1\ 3\ 5\ 9\ 12\ 16\ 8$$

into

$$17\ 11\ 13\ 4\ 10\ 14\ 2\ 6\ 9\ 15\ 1\ 3\ 5\ 8\ 12\ 16$$

by a sequence of admissible interchanges (cf. (4) and (5)).

6. Admissible interchanges are symmetrical between left and right, and the canonical permutation for P obviously goes into P^T when the insertion order is reversed.

7. The number of columns, namely the length of row 1, is the number of classes (exercise 2). The number of rows is the number of columns of P^T, so exercise 6 (or Theorem D) completes the proof.

8. With more than n^2 elements, the corresponding P tableau must either have more than n rows or more than n columns. But there are $n \times n$ tableaux. [This result was originally proved in *Compositio Math.* **2** (1935), 463–470.]

9. Such permutations are in 1–1 correspondence with pairs of tableaux of shape $(n, n, \ldots, n)$; so by (34) the answer is

$$\left(\frac{n^2!\,\Delta(2n-1, 2n-2, \ldots, n)}{(2n-1)!(2n-2)!\ldots n!}\right)^2 = \left(\frac{n^2!}{(2n-1)(2n-2)^2\ldots n^n(n-1)^{n-1}\ldots 1^1}\right)^2$$

The existence of such a simple formula for this problem is truly amazing. We can also count the number of permutations of $\{1, 2, \ldots, mn\}$ with no increasing subsequences longer than m, no decreasing subsequences longer than n.

10. We prove inductively that, at step S3, $P_{(r-1)s}$ and $P_{r(s-1)}$ are both less than $P_{(r+1)s}$ and $P_{r(s+1)}$.

11. We also need to know, of course, the element which was originally P_{11}. Then it is possible to restore things using an algorithm remarkably similar to Algorithm S.

12. $\binom{n_1+1}{2} + \binom{n_2+2}{2} + \cdots + \binom{n_m+m}{2} - \binom{m+1}{3}$.

The minimum is the sum of the first n terms of the sequence 1, 2, 2, 3, 3, 3, 4, 4, 4, 4, ... of exercise 1.2.4–41; this sum is approximately $\sqrt{8/9}\, n^{3/2}$. (Since the majority of tableaux on n elements come reasonably near this lower bound, according to the tables cited in exercise 28, the average number of times is almost surely $O(n^{3/2})$, but this has not been proved.)

13. Assume that the elements permuted are $\{1, 2, \ldots, n\}$ so that $a_i = 1$; and assume that $a_j = 2$. *Case 1*, $j < i$. Then 1 bumps 2, so row 1 of the tableau corresponding to $a_1 \ldots a_{i-1}\ a_{i+1} \ldots a_n$ is row 1 of P^S; and the "bumped" permutation is the former bumped permutation except for its smallest element, 2, so we may use

induction on n. *Case 2*, $j > i$. Apply Case 1 to P^T, in view of exercise 6 and the fact $(P^T)^S = (P^S)^T$.

15. As in (37), the example permutation corresponds to the tableau

1	2	5	9	11
3	6	7		
4	8	10		

;

hence the number is $f(l, m, n) = (l+m+n)!(l-m+1)(l-n+2)(m-n+1)/(l+2)!(m+1)!(n)!$, provided, of course, that $l \geq m \geq n$.

16. By Theorem H, 80080.

17. Since g is antisymmetric in the x's, it is zero when $x_i = x_j$, so it is divisible by $x_i - x_j$ for all $i < j$. Hence $g(x_1, \ldots, x_n; y) = h(x_1, \ldots, x_n; y)\Delta(x_1, \ldots, x_n)$. Here h must be homogeneous in $x_1, \ldots, x_n, y$, of total degree 1, and symmetric in $x_1, \ldots, x_n$; so $h(x_1, \ldots, x_n; y) = a(x_1 + \cdots + x_n) + by$ for some a, b depending only on n. We can evaluate a by setting $y = 0$; we can evaluate b by taking the partial derivative with respect to y and then setting $y = 0$. We have

$$\frac{\partial}{\partial y}\Delta(x_1, \ldots, x_i + y, \ldots, x_n)|_{y=0} = \frac{\partial}{\partial x_i}\Delta(x_1, \ldots, x_n)$$

$$= \Delta(x_1, \ldots, x_n)\sum_{j\neq i}\frac{1}{x_i - x_j}.$$

Finally,

$$\sum_i\sum_{j\neq i}(x_i/(x_i - x_j)) = \sum_i\sum_{j<i}(x_i/(x_i - x_j) + x_j/(x_j - x_i)) = \binom{n}{2}.$$

18. It must be $\Delta(x_1, \ldots, x_n)\cdot(b_0 + b_1y + \cdots + b_my^m)$, where each b_k is a homogeneous symmetric polynomial of degree $m - k$ in the x's. We have

$$\frac{\partial^k}{k!\partial y^k}\Delta(x_1, \ldots, x_i + y, \ldots, x_n)|_{y=0} = \Delta(x_1, \ldots, x_n)\sum 1/\prod_l(x_i - x_{j_l})$$

summed over all $\binom{n-1}{k}$ choices of distinct indices $j_1, \ldots, j_k \neq i$. Now in $b_k = \sum x_i^m/\prod_l(x_i - x_j)$ we may combine those groups of $k+1$ terms having a given set of indices $\{i, j_1, \ldots, j_k\}$; for example, when $k = 2$, we group sets of three terms of the form $a^m/(a-b)(a-c) + b^m/(b-a)(b-c) + c^m/(c-a)(c-b)$. The sum of each such group is evaluated as in exercise 1.2.3–33; it is the coefficient of z^{m-k} in $1/(1 - x_iz)(1 - x_{j_1}z)\cdots(1 - x_{j_k}z)$. We find therefore that

$$b_k = \sum_j\binom{n-j}{k+1-j}\sum s(p_1, \ldots, p_j),$$

where $s(p_1, \ldots, p_j)$ is the monomial symmetric function consisting of all distinct terms having the form $x_{i_1}^{p_1}\ldots x_{i_j}^{p_j}$, for distinct indices $i_1, \ldots, i_j \in \{1, \ldots, n\}$; and the second sum is over all partitions of $m - k$ into exactly j parts, namely $p_1 \geq \cdots \geq p_j \geq 1, p_1 + \cdots + p_j = m - k$. (This result was obtained jointly with E. A. Bender.)

When $m = 2$ the answer is $(s(2) + (n-1)s(1)y + \binom{n}{3}y^2)\,\Delta(x_1, \ldots, x_n)$; for $m = 3$ we get $(s(3) + ((n-1)s(2) + s(1,1))y + \binom{n-1}{2}s(1)y^2 + \binom{n}{4}y^3)\,\Delta(x_1, \ldots, x_n)$; etc.

Another expression gives b_k as the coefficient of z^m in

$$\left(\binom{n}{k+1}z^k - \binom{n-1}{k+1}a_1 z^{k+1} + \binom{n-2}{k+1}a_2 z^{k+2} - \cdots\right) \Big/ (1 - a_1 z + a_2 z^2 - \cdots),$$

where $a_l = \sum_{1 \le i_1 < \cdots < i_l \le n} x_{i_1} \ldots x_{i_l}$ is an "elementary symmetric function." Multiplying by y^k and summing on k gives the answer as the coefficient of z^m in

$$\frac{1}{yz}\left(\frac{(1 + z(y - x_1)) \cdots (1 + z(y - x_n))}{(1 - zx_1) \cdots (1 - zx_n)} - 1\right)\Delta(x_1, \ldots, x_n).$$

19. Let the shape of the transposed tableau be $(n_1', n_2', \ldots, n_r')$; the answer is $\frac{1}{2}f(n_1, n_2, \ldots, n_m)$ times $(\sum(n_i^2) - \sum(n_j'^2))/n(n-1) + 1$, where $n = \sum n_i = \sum n_j'$. (This formula was obtained after a rather elaborate computation, using the sum

$$\sum_{i<j} x_i x_j \Delta(x_1, \ldots, x_i + y, \ldots, x_j + y, \ldots, x_n)$$
$$= \left(s(1,1) + s(1)\binom{n-1}{2}y + \left\{\begin{matrix} n \\ n-2 \end{matrix}\right\}y^2\right)\Delta(x_1, \ldots, x_n)$$

at one point; cf. exercise 18, and note that

$$\left\{\begin{matrix} n \\ n-2 \end{matrix}\right\} = \binom{n}{3} + 3\binom{n}{4}.$$

The answer can be expressed in a less symmetrical form using the relation $\sum i n_i = n + \frac{1}{2}\sum n_j'^2$.)

20. The fallacious argument in the discussion following Theorem H is actually valid for this case (the corresponding probabilities *are* independent).

21. [*Michigan Math. J.* 1 (1952), 81–88.] Let $g(n_1, \ldots, n_m) = (n_1 + \cdots + n_m)!\,\Delta(n_1, \ldots, n_m)/n_1! \ldots n_m!\sigma(n_1, \ldots, n_m)$, where $\sigma(x_1, \ldots, x_m) = \prod_{1 \le i < j \le m}(x_i + x_j)$. To prove that $g(n_1, \ldots, n_m)$ is the number of ways to fill the shifting tableau, we must prove that $g(n_1, \ldots, n_m) = g(n_1 - 1, \ldots, n_m) + \cdots + g(n_1, \ldots, n_m - 1)$. The identity corresponding to exercise 17 is $x_1\Delta(x_1 + y, \ldots, x_n)/\sigma(x_1 + y, \ldots, x_n) + \cdots + x_n\Delta(x_1, \ldots, x_n + y)/\sigma(x_1, \ldots, x_n + y) = (x_1 + \cdots + x_n)\Delta(x_1, \ldots, x_n)/\sigma(x_1, \ldots, x_n)$, independent of y; for if we calculate the derivative as in exercise 17, we find that $2x_i x_j/(x_j^2 - x_i^2) + 2x_j x_i/(x_i^2 - x_j^2) = 0$.

22. [*Journ. de Math.* (3) 7 (1881), 167–184.] (This is a special case of exercise 5.1.3–8, with all runs, except perhaps the last, of length 2.) When $n > 0$, element n must appear in one of the rightmost positions of a row; once it has been placed in the rightmost box on row k, we have $\binom{n-1}{2k-1}A_{2k-1}A_{n-2k}$ ways to complete the job. Let

$$h(z) = \sum_{n \ge 1} A_{2n-1}z^{2n-1}/(2n-1)! = \tfrac{1}{2}(g(z) - g(-z));$$

then

$$h(z)g(z) = \sum_{k,n \ge 1}\binom{n}{2k-1}A_{2k-1}A_{n-2k+1}z^n/n! = \left(\sum_{n \ge 1} A_{n+1}z^n/n!\right) - 1 = g'(z) - 1.$$

Replace z by $-z$ and add, obtaining $h(z)^2 = h'(z) - 1$; hence $h(z) = \tan z$. Setting $k(z) = g(z) - h(z)$, we have $h(z)k(z) = k'(z)$; hence $k(z) = \sec(z)$ and $g(z) = \sec z + \tan z = \tan(\frac{1}{2}z + \frac{1}{4}\pi)$. The coefficients A_{2n} are therefore the Euler numbers E_{2n}; the coefficients A_{2n+1} are the tangent numbers T_{2n+1}. Tables of these numbers appear in *Math. Comp.* **21** (1967), 663–688.

23. Assume that $m = N$, by adding 0's to the shape if necessary; if $m > N$ and $n_m > 0$, the number of ways is clearly zero. When $m = N$ the answer is

$$\det \begin{pmatrix} \binom{n_1+m-1}{m-1} & \binom{n_2+m-2}{m-1} & \cdots & \binom{n_m}{m-1} \\ \vdots & & & \vdots \\ \binom{n_1+m-1}{0} & \binom{n_2+m-1}{0} & \cdots & \binom{n_m}{0} \end{pmatrix}.$$

Proof: We may assume that $n_m = 0$, for if $n_m > 0$, the first n_m columns of the array must be filled with i in row i, and we may consider the remaining shape $(n_1 - n_m, \ldots, n_m - n_m)$. By induction on m, the number of ways is

$$\sum_{\substack{n_2 \le k_1 \le n_1 \\ \vdots \\ n_m \le k_{m-1} \le n_{m-1}}} \det \begin{pmatrix} \binom{k_1+m-2}{m-2} & \binom{k_2+m-2}{m-2} & \cdots & \binom{k_m}{m-2} \\ \vdots & & & \vdots \\ \binom{k_1+m-2}{0} & \binom{k_2+m-2}{0} & \cdots & \binom{k_m}{0} \end{pmatrix},$$

where $n_j - k_j$ represents the number of m's in row j. The sum on each k_j may be carried out independently, giving

$$\det \begin{pmatrix} \binom{n_1+m-1}{m-1} - \binom{n_2+m-2}{m-1} & \binom{n_2+m-2}{m-1} - \binom{n_3+m-3}{m-1} & \cdots & \binom{n_{m-1}+1}{m-1} - \binom{n_m}{m-1} \\ \vdots & & & \vdots \\ \binom{n_1+m-1}{1} - \binom{n_2+m-2}{1} & \binom{n_2+m-2}{1} - \binom{n_3+m-3}{1} & \cdots & \binom{n_{m-1}+1}{1} - \binom{n_m}{1} \end{pmatrix}.$$

which is the desired answer since $n_m = 0$. The answer can be converted into a Vandermonde determinant by row operations, giving the formula $\Delta(n_1 + m - 1, n_2 + m - 2, \ldots, n_m)/(m-1)!(m-2)!\ldots 0!$. [The answer to this exercise, in connection with an equivalent problem in group theory, appears in D. E. Littlewood's *Theory of Group Characters* (Oxford, 1940), 189.]

25. In general, if u_{nk} is the number of permutations on $\{1, 2, \ldots, n\}$, having no cycles of length $> k$, $\sum u_{nk} z^n/n! = \exp(z + z^2/2 + \cdots + z^k/k)$; this is proved by multiplying $\exp(z) \times \cdots \times \exp(z^k/k)$, obtaining

$$\sum_n z^n/n! \left(\sum_{j_1+2j_2+\cdots+kj_k=n} 1/1^{j_1} j_1! 2^{j_2} j_2! \ldots \right);$$

cf. exercise 1.3.3–21. Similarly, $\exp(\sum_{s \in S} z^s/s)$ is the corresponding generating function for permutations whose cycle lengths are all members of a given set S.

26. The integral from 0 to ∞ is $n^{(t+1)/4}\Gamma((t+1)/2)/2^{(t+3)/2}$, by the gamma function integral (exercise 1.2.5–20, $t = 2x^2/\sqrt{n}$). So, from $-\infty$ to ∞, we get 0 when t is odd, otherwise $n^{(t+1)/4}\sqrt{\pi}\, t!/2^{(3t+1)/2}(t/2)!$.

27. (a) If $r_i < r_{i+1}$ and $c_i < c_{i+1}$, $i < Q_{r_i c_{i+1}} < i+1$ is impossible. If $r_i \geq r_{i+1}$ and $c_i < c_{i+1}$, clearly $r_i \neq r_{i+1}$ so a similar contradiction is obtained. (b) Prove, by induction on the number of rows in the tableau for $a_1 \ldots a_i$, that $a_i < a_{i+1}$ implies $c_i < c_{i+1}$, and $a_i > a_{i+1}$ implies $c_i \geq c_{i+1}$. (Consider row 1 and the "bumped" sequences.) (c) This follows from Theorem D(c).

30. [*Discrete Math.* **2** (1972), 73–94.]

31. $x_n = a_{\lfloor n/2 \rfloor}$ where $a_0 = 1$, $a_1 = 2$, $a_n = 2a_{n-1} + (2n-2)a_{n-2}$; $\sum a_n z^n/n! = \exp(2z + z^2) = (\sum t_n z^n/n!)^2$; $x_n \sim \exp(\frac{1}{4}n \ln n - \frac{1}{4}n + \sqrt{n} - \frac{1}{2} - \frac{1}{2}\ln 2)$.

SECTION 5.2

1. Yes, i and j may run through the set of values $1 \le j < i \le N$ in any order. This shows that counting can take place simultaneously as records are being read in.

2. The sorting is "stable" as defined at the beginning of the chapter; for the algorithm is essentially sorting by lexicographic order on the *distinct* key-pairs $(K_1, 1)$, $(K_2, 2)$, . . . , (K_N, N). (If we think of each key as extended on the right by its location in the file, no equal keys are present, and the sorting is stable.)

3. It would sort, but not in a "stable" manner; if $K_j = K_i$ and $j < i$, R_j will come *after* R_i in the final ordering. This change would also make Program C run more slowly.

4.
```
ENT1    N               1
LD2     COUNT,1         N
LDA     INPUT,1         N
STA     OUTPUT+1,2      N
DEC1    1               N
J1P     *-4             N
```
∎

5. The running time is changed by $N - 1 - A + B$ units, and this is almost always an improvement.

6. $u = 0, v = 9$.

After D1,	COUNT =	0	0	0	0	0	0	0	0	0	0
After D2,	COUNT =	2	2	1	0	1	3	3	2	1	1
After D4,	COUNT =	2	4	5	5	6	9	12	14	15	16
During D5,	COUNT =	2	3	5	5	5	8	9	12	15	16 $j = 8$
	OUTPUT =	—	—	—	1G	—	4A	—	—	5L	6A 6T 6I 7O 7N — —
After D5,	OUTPUT =	0C	0O	1N	1G	2R	4A	5T	5U	5L	6A 6T 6I 7O 7N 8S 9.

7. Yes (note that COUNT[K_j] is decreased in step D6, and j decreases).

8. It would sort, but not in a "stable" manner (cf. exercise 7).

9. Let $M = v - u$; LOC(R_j) ≡ INPUT + j; LOC(COUNT[j]) ≡ COUNT + j; LOC(S_j) ≡ OUTPUT + j; rI1 ≡ i; rI2 ≡ j; rI3 ≡ $i - v$, K_j. Assume that $|u|$, $|v|$ fit in two bytes.

```
 M      EQU     V-U
KEY     EQU     0:2             (Satellite information in bytes 3:5.)

    J2P   6B             N    N ≥ j > 0.  ∎
```

The running time is $(10M + 22N + 10)u$.

10. In order to avoid using N extra "tag" bits [see Section 1.3.3 and *Cybernetics* **1** (1965), 95], yet keep the running time essentially proportional to N, we may use the following algorithm based on the cycle structure of the permutation:

P1. [Loop on i.] Do step P2 for $1 \le i \le N$; then terminate the algorithm.
P2. [Is $p(i) = i$?] Do steps P3 through P5, if $p(i) \neq i$.
P3. [Begin cycle.] Set $t \leftarrow R_i$, $j \leftarrow i$.
P4. [Fix R_j.] Set $k \leftarrow p(j)$, $R_j \leftarrow R_k$, $p(j) \leftarrow j$, $j \leftarrow k$. If $p(j) \neq i$, repeat this step.
P5. [End cycle.] Set $R_j \leftarrow t$, $p(j) \leftarrow j$. ∎

This algorithm changes $p(i)$, since the sorting application lets us assume that $p(i)$ is stored in memory. On the other hand, there are applications such as matrix transposition where $p(i)$ is a function of i which is to be computed (not tabulated) in order to save memory space. In such a case we can use the following method, performing steps B1 through B3 for $1 \le i \le N$:

B1. Set $k \leftarrow p(i)$.
B2. If $k > i$, set $k \leftarrow p(k)$ and repeat this step.
B3. If $k < i$, do nothing; but if $k = i$ (this means that i is smallest in its cycle), we permute the cycle containing i as follows: Set $t \leftarrow R_i$; then while $p(k) \neq i$ repeatedly set $R_k \leftarrow R_{p(k)}$ and $k \leftarrow p(k)$; finally set $R_k \leftarrow t$. ∎

This algorithm is similar to the procedure of J. Boothroyd [*Comp. J.* **10** (1967), 310], but requires less data movement; some refinements have been suggested by I. D. G. MacLeod [*Australian Comp. J.* **2** (1970), 16–19]. For random permutations the analysis in exercise 1.3.3–14 shows that step B2 is performed $(N + 1)H_N - N$ steps on the average. Cf. D. E. Knuth [*Proc. IFIP Congress* 1971, **1**, 19–27]. Similar algorithms

can be designed to replace $(R_{p(1)}, \ldots, R_{p(N)})$ by $(R_1, \ldots, R_N)$, e.g. if the rearrangement in exercise 4 were to be done with OUTPUT = INPUT.

11. Let rI1 $\equiv i$; rI2 $\equiv j$; rI3 $\equiv k$; rX $\equiv t$.

```
1H    ENT1   N            1          P1. Loop on i.
2H    CMP1   P,1          N          P2. Is p(i) = i?
      JE     8F           N          Jump if p(i) = i.
3H    LDX    INPUT,1      A — B      P3. Begin cycle.  t ← R_i.
      ENT2   0,1          A — B      j ← i.
4H    LD3    P,2          N — A      P4. Fix R_j.  k ← p(j).
      LDA    INPUT,3      N — A
      STA    INPUT,2      N — A      R_j ← R_k.
      ST2    P,2          N — A      p(j) ← j.
      ENT2   0,3          N — A      j ← k.
      CMP1   P,2          N — A
      JNE    4B           N — A      Repeat if p(j) ≠ i.
5H    STX    INPUT,2      A — B      P5. End cycle.  R_j ← t.
      ST2    P,2          A — B      p(j) ← j.
8H    DEC1   1            N
      J1P    2B           N          N ≥ i ≥ 1.  ∎
```

The running time is $(17N - 5A - 7B + 1)u$, where A is the number of cycles in the permutation $p(1) \ldots p(N)$, and B is the number of fixed points (1-cycles). By Eqs. 1.3.3–21 and 28, A = (min 1, ave H_N, max N, dev $\sqrt{H_N - H_N^{(2)}}$); B = (min 0, ave 1, max N, dev 1), for $N \geq 2$.

12. The following "direct" method is due to M. D. MacLaren. (Assume for convenience that $0 \leq$ LINK(P) $\leq N$, for $1 \leq$ P $\leq N$, where $\Lambda \equiv 0$.)

M1. [Initialize.] Set P $\leftarrow$ HEAD, $k \leftarrow 1$.

M2. [Done?] If P $= \Lambda$ (or equivalently if $k = N + 1$), the algorithm terminates.

M3. [Ensure P $\geq k$.] If P $< k$, set P $\leftarrow$ LINK(P) and repeat this step.

M4. [Exchange.] Interchange R_k and R[P]. (Assume that LINK(k) and LINK(P) are also interchanged in this process.) Then set Q $\leftarrow$ LINK(k), LINK(k) $\leftarrow$ P, P $\leftarrow$ Q, $k \leftarrow k + 1$, and return to step M2. ∎

A proof that MacLaren's method is valid can be based on an inductive verification of the following property which holds at the beginning of step M2: The entries which are $\geq k$ in the sequence P, LINK(P), LINK(LINK(P)), ..., Λ are $a_1, a_2, \ldots, a_{N+1-k}$, where $R_1 \leq \cdots \leq R_{k-1} \leq R_{a_1} \leq \cdots \leq R_{a_{N+1-k}}$ is the desired final order of the records. Furthermore LINK(j) $\geq j$ for $1 \leq j < k$, so that LINK(j) $= \Lambda$ implies $j \geq k$.

It is quite interesting to analyze the above algorithm; one of its remarkable properties is that it can be run backwards, reconstructing the original set of links from the final values of LINK(1) ... LINK(N). Each of the $N!$ possible output configurations with $j \leq$ LINK(j) $\leq N$ corresponds to exactly one of the $N!$ possible input configurations. If A is the number of times P $\leftarrow$ LINK(P) in step M3, then $N - A$ is the number of j such that LINK(j) $= j$ at the conclusion of the algorithm; this occurs if and only if j was largest in its cycle; hence $N - A$ is the number of cycles in the permutation, and A = (min 0, ave $N - H_N$, max $N - 1$).

13. D5′. Set $r \leftarrow N$.

D6′. If $r = 0$, stop. Otherwise if $\texttt{COUNT}[K_r] < r$ set $r \leftarrow r - 1$ and repeat this step; if $\texttt{COUNT}[K_r] = r$, decrease both $\texttt{COUNT}[K_r]$ and r by 1 and repeat this step. Otherwise set $R \leftarrow R_r$, $j \leftarrow \texttt{COUNT}[K_r]$, $\texttt{COUNT}[K_r] \leftarrow j - 1$.

D7′. Set $S \leftarrow R_j$, $k \leftarrow \texttt{COUNT}[K_j]$, $\texttt{COUNT}[K_j] \leftarrow k - 1$, $R_j \leftarrow R$, $R \leftarrow S$, $j \leftarrow k$. Then if $j \neq r$ repeat this step; if $j = r$ set $R_j \leftarrow R$, $r \leftarrow r - 1$, and go back to D6′. ∎

To prove that this is valid, observe that at the beginning of step D6′ all records R_j such that $j > r$ which are not in their final resting place must move to the left; when $r = 0$ there can't be any such records since *somebody* must move right. The algorithm is elegant but not "stable" for equal keys; it is intimately related to Foata's construction in Theorem 5.1.2B.

1. Yes, equal elements are never moved across each other.

2. Yes, but the running time would be slower when equal elements are present and the sorting would be just the opposite of stable.

3. The following eight-liner is conjectured to be the shortest MIX sorting routine, although it is not recommended for speed. We assume that the numbers appear in locations $1, \ldots, N$ (i.e. `INPUT EQU 0`; otherwise another line of code is necessary).

```
2H      LDA   0,1      B
        CMPA  1,1      B
        JLE   1F       B
        MOVE  1,1      A
        STA   0,1      A
START   ENT1  N        A + 1
1H      DEC1  1        B + 1
        J1P   2B       B + 1
```

Note: To estimate the running time of this program, note that A is the number of inversions. B is a reasonably simple function of the inversion table, and (assuming distinct inputs in random order) it has the generating function

$$z^{N-1}(1+z)(1+z^2+z^{2+1})(1+z^3+z^{3+2}+z^{3+2+1})\cdots\Big(1+z^{N-1}+z^{2N-3}+\cdots+z^{\binom{N}{2}}\Big)\Big/N!.$$

The mean value of B is $N-1+\sum_{1\le k\le N}(k-1)(2k-1)/6 = (N-1)(4N^2+N+36)/36$; hence the average running time of this program is roughly $\frac{7}{9}N^3u$.

4. Consider the inversion table $B_1 \ldots B_N$ of the given input permutation, in the sense of exercise 5.1.1–7. A is one less than the number of B_j's which are equal to $j-1$, and B is the sum of the B_j's. Hence both $B-A$ and B are maximized when the input permutation is $N \ldots 2\ 1$; they both are minimized when the input is $1\ 2 \ldots N$. Hence the minimum achievable time occurs for $A=0$, $B=0$, namely $(10N-9)u$; the maximum occurs for $A=N-1$, $B=\binom{N}{2}$, namely $4.5N^2+2.5N-6$.

5. The generating function is z^{10N-9} times the generating function for $9B-3A$. By considering the inversion table as in the previous exercise, remembering that individual entries of the inversion table are independent of each other, the desired

generating function is $z^{10N-9}\prod_{1<j\le N}((1+z^9+\cdots+z^{9j-18}+z^{9j-12})/j)$. The variance comes to $2.25N^3+3.375N^2-32.625N+36H_N-9H_N^{(2)}$.

6. Treat the input area as a circular list, with position N adjacent to position 1. Take new elements to be inserted from either the left or the right of the current segment of unsorted elements, according as the previously inserted element fell to the right or left of the center of the sorted elements, respectively. Afterwards it will usually be necessary to "rotate" the area, moving each record k places around the circle for some fixed k; this can be done in gcd (N, k) passes (cyclically permute R_i, R_{i+k}, ..., R_{N+i-k} for $1 \le i \le$ gcd (N, k); cf. W. Fletcher and R. Silver, *CACM* **9** (1966), 326).

7. The average value of $|a_j - j|$ is

$$\frac{1}{n}(|1-j|+|2-j|+\cdots+|n-j|) = \frac{1}{n}\left(\binom{j}{2}+\binom{n-j+1}{2}\right);$$

summing on j gives

$$\frac{1}{n}\left(\binom{n+1}{3}+\binom{n+1}{3}\right) = \frac{1}{3}(n^2-1).$$

8. No; for example, consider the keys 2 1 1 1 1 1 1 1 1 1 1.

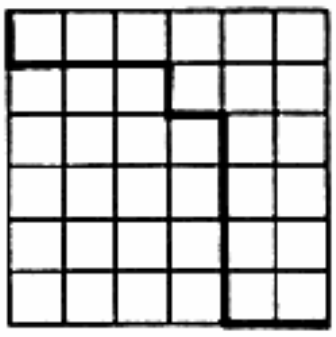
9. For Table 3, $A = 3+0+2+1 = 6$, $B = 3+1+4+21 = 29$; in Table 4, $A = 4+2+2+0 = 8$, $B = 4+3+8+10 = 25$; hence the running time of Program D comes to $786u$ and $734u$, respectively. Although the number of moves has been cut from 41 to 25, the running time is not competitive with Program S since the bookkeeping time for four passes is wasted when $N = 16$. When sorting 16 items we will be better off using only two passes; a two-pass Program D begins to beat Program S at about $N = 13$, although they are fairly equal for awhile (and for such small N the length of the program is perhaps significant).

10. Insert "`INC1 INPUT; ST1 3F(0:2)`" between lines 07 and 08, and change lines 10–17 to:

```
3H   CMPA   INPUT+N-H,1        NT - S
     JGE    8F                 NT - S
4H   ENT2   N-H,1              NT - S - C
5H   LDX    INPUT,2            B
6H   STX    INPUT+H,2          B
     DEC2   0,4                B
     J2NP   7F                 B
     CMPA   INPUT,2            B - A
     JL     5B                 B - A
7H   STA    INPUT+H,2          NT - S - C
```

For a net increase of four instructions, this saves $3(C-T)$ units of time, where C is the number of times $K_j \ge K_{j-h}$. In Tables 3 and 4 the time savings is approximately 87 and 88, respectively; empirically the value of $C/(NT-S)$ seems to be about 0.4 when $h_{s+1}/h_s \approx 2$ and about 0.3 when $h_{s+1}/h_s \approx 3$, so the improvement is worth while. (On the other hand, the analogous change to Program S is not desirable, since the savings in that case is only proportional to $\log N$ unless the input is known to be pretty well ordered.)

11.



12. When the path includes the line segment from (i, j) to $(i+1, j)$, we have $a_{2i+1} = i+j+1$ in the corresponding permutation $a_1 \ldots a_n$. If $i \le j$, there are $j-i$ elements to the right of a_{2i+1} which are less than it, but all elements to its left are less; a similar argument for the case $i \ge j$ shows that a_{2i+1} contributes to exactly $|i-j|$ inversions. This completes the proof, since each inversion involves one element with an odd subscript.

13. Put the weight $|i-j|$ on the segment from $(i, j-1)$ to (i, j). A path using this segment has $a_{2j} = i+j$, so we may argue as in exercise 12.

14. (a) Interchange i, j in the sum for A_{2n} and add these two sums. (b) Taking half of this result, we see that

$$A_{2n} = \sum_{0 \le i \le j} (j-i) \binom{i+j}{i} \binom{2n-i-j}{n-j};$$

hence $\sum A_{2n} z^n = z/(1-4z)^2$ by two applications of the stated identity.

The above proof was suggested to the author by Leonard Carlitz. Another proof can be based on interplay between horizontal and vertical weights (cf. exercise 13); but no simple combinatorial derivation of the formula $A_n = \lfloor n/2 \rfloor 2^{n-2}$ is apparent.

15. For $n > 0$,

$$\bar{g}_n(z) = z^{n-1} g_{n-1}(z); \; \bar{h}_n(z) = \bar{g}_n(z) + z^{-n} \bar{g}_n(z);$$
$$g_n(z) = \sum_{1 \le k \le n} \bar{g}_k(z) g_{n-k}(z); \; h_n(z) = \sum_{1 \le k \le n} \bar{h}_k(z) h_{n-k}(z).$$

Letting $G(w, z) = \sum_n g_n(z) w^n$, we find that $wzG(w, z)G(wz, z) = G(w, z) - 1$. From this representation we can deduce that, if $t = \sqrt{1-4w} = 1 - 2w - 2w^2 - 4w^3 - \cdots$, we have $G(w, 1) = (1-t)/(2w)$; $G_{,}(w, 1) = 1/(wt) - (1-t)/(2w^2)$; $G'(w, 1) = 1/(2t^2) - 1/(2t)$; $G_{,,}(w, 1) = 2/(wt^3) - 2/(w^2 t) + (1-t)/w^3$; $G'_{,}(w, 1) = 2/t^4 - 1/t^3$; and $G''(w, 1) = 1/t^3 - (1-2w)/t^4 + 10w^2/t^5$. Here lower primes denote differentiation with respect to the first parameter, and upper primes denote differentiation with respect to the second parameter. Similarly from the formula

$$w(zG(wz, z) + G(w, z))H(w, z) = H(w, z) - 1$$

we deduce that

$$H'(w, 1) = w/t^4, \qquad H''(w, 1) = -w/t^3 - w/t^4 + 2w/t^5 + (2w^2 + 20w^3)/t^7.$$

The formula manipulation summarized here was done by hand, but it should have been done by computer. In principle all moments of the distribution are obtainable in this way.

16. For $h = 2$ the maximum clearly occurs for the path that goes through the upper right corner of the lattice diagram, namely

$$\binom{\lfloor n/2 \rfloor + 1}{2}.$$

For general h the corresponding number is

$$\bar{f}(n, h) = \binom{h}{2}\binom{q+1}{2} + \binom{r}{2}(q+1),$$

where q and r are defined in Theorem H; for the permutation with $a_{i+jh} = (n+1 - i(q+1) + j$, if $1 \le i \le r$; $n+1-r-iq+j$, if $r < i \le h)$ maximizes the number of inversions between each of the $\binom{h}{2}$ pairs of sorted subsequences. The maximum number of moves is obtained if we replace f by $\bar{f}$ in (6).

17. The only two-ordered permutation of $\{1, 2, \ldots, 2n\}$ which has as many as $\binom{n+1}{2}$ inversions is $(n+1)\ 1\ (n+2)\ 2\ \ldots\ (2n)\ n$. Using this idea recursively, we obtain the permutation defined by adding unity to each element of the sequence $(2^t - 1)^R \ldots 1^R 0^R$, where R denotes the operation of writing an integer as a t-bit binary number, then reversing the left-to-right order of the digits!

18. Take out a common factor and let $h_{t+1} = 4N/\pi$; we want to minimize $\sum_{t \ge s \ge 1} h_{s+1}^{1/2}/h_s$, when $h_1 = 1$. Differentiation yields $h_s^3 = 4h_{s+1}^2 h_{s-1}$, which has the solution $h_s = 2^{s-2+s/(2^s-1)} h_{s+1}^{(2^{s-1}-1)/(2^s-1)}$. The minimum value of the originally-given estimate comes to $(1 - 2^{-t})\pi^{(2^{t-1}-1)/(2^t-1)} N^{1+(2^{t-1}+1)/(2^t-1)}/2^{1+(t-1)/(2^t-1)}$ which rapidly approaches $N\sqrt{\pi N}/2$ as $t \to \infty$.

Typical examples of "optimum" h's when $N = 1000$ (see also Table 6):

$$h_3 = 57.64, \quad h_2 = 6.13, \quad h_1 = 1;$$

$$h_5 = 284.5, \quad h_4 = 67.23, \quad h_3 = 16.34, \quad h_2 = 4.028, \quad h_1 = 1;$$

$$h_{10} = 9165, \quad h_9 = 12294, \quad h_8 = 7120, \quad h_7 = 2709, \quad h_6 = 835.5, \quad \ldots, \quad h_2 = 3.97, \quad h_1 = 1.$$

19. Let $g(n, h) = H_r - 1 + \sum_{r < j \le h} q/(qj + r)$, where q and r are defined in Theorem H; then replace f by g in (6).

20. (This is much harder to write down than to understand.) Assume that a k-ordered file $R_1, \ldots, R_N$ has been h-sorted, and let $1 \le i \le N - k$; we want to show that $K_i \le K_{i+k}$. Find u, v such that $1 \le u, v \le h$; $i \equiv u$ and $i + k \equiv v$ (modulo h); and apply Lemma L with $m = (u - v + k)/h$, $r = \lfloor (N - k + h - u)/h \rfloor$, $n + r = \lfloor (N + h - u)/h \rfloor$, $x_j = K_{v+(j-1)h}$, $y_j = K_{u+(j-1)h}$.

21. If $ah + bk = hk - h - k$, then $a \bmod k = k - 1$ and $b \bmod h = h - 1$; hence $ah + bk \ge (k-1)h + (h-1)k > hk - h - k$, a contradiction. Conversely, if $n \ge (h-1)(k-1)$, choose a so that $0 \le a < k$ and $ah \equiv n$ (modulo k). Then $(n - ah)/k$ is a nonnegative integer, b; hence n is representable.

A slight strengthening of this argument shows that exactly $\frac{1}{2}(h-1)(k-1)$ positive integers are unrepresentable in the stated form. (See R. Z. Norman, *AMM* **67** (1960), 594.)

22. To avoid cumbersome notation, consider $h = 4$, which is representative of the general case. Let n_k be the smallest number representable in the form $15a_0 + 31a_1 + \cdots$ which is congruent to k (modulo 15); then we find easily that

$k =$	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14
$n_k =$	15	31	62	63	94	125	126	127	158	189	190	221	252	253	254.

Hence $239 = 2^4(2^4 - 1) - 1$ is the largest unrepresentable number, and the total number of unrepresentables is

$$\begin{aligned} x_4 &= (n_1 - 1 + n_2 - 2 + \cdots + n_{14} - 14)/15 \\ &= (2+4+4+6+8+8) + 8 + (10+12+12+14+16+16) + 16 \\ &= 2x_3 + 8 \cdot 9; \end{aligned}$$

in general, $x_h = 2x_{h-1} + 2^{h-1}(2^{h-1} + 1)$.

For the other problem the answers are $2^{2h} + 2^h + 2$ and $2^{h-1}(2^h + h - 1) + 2$, respectively.

23. Each of the N numbers has at most $\lceil (h_{s+2} - 1)(h_{s+1} - 1)/h_s \rceil$ inversions in its subfile.

24. (Solution obtained jointly with V. Pratt.) Construct the "h-recidivous permutation" of $\{1, 2, \ldots, N\}$ as follows. Start with $a_1 \ldots a_N$ blank; then for $j = 2, 3, 4, \ldots$ do Step j: Fill in all blank positions a_i from left to right, using the smallest number that has not yet appeared in the permutation, whenever $(2^h - 1)j - i$ is a positive integer representable as in exercise 22. Continue until all positions are filled. Thus the 2-recidivous permutation for $N = 20$ is

6 2 1 9 4 3 12 7 5 15 10 8 17 13 11 19 16 14 20 18.

The h-recidivous permutation is $(2^k - 1)$-ordered for all $k \geq h$. When $2^h < j \leq N/(2^h - 1)$, exactly $2^h - 1$ positions are filled during step j; the $(k+1)$st of these adds at least $2^{h-1} - 2k$ to the number of moves required to $(2^{h-1} - 1)$-sort the permutation. Hence the number of moves to sort the h-recidivous permutation with increments $h_s = 2^s - 1$ when $N = 2^{h+1}(2^h - 1)$ is $> 2^{3h-4} > \frac{1}{128}N^{3/2}$. Pratt has generalized this construction to a large family of similar sequences, including (8), in his Ph.D. thesis (Stanford University, 1972).

25. F_{n+1} [this result is due to H. B. Mann, *Econometrica* **13** (1945), 256]; for the permutation must begin either 1 . . . or 2 1 . . . . There are at most $\lfloor n/2 \rfloor$ inversions; and the total number of inversions is

$$\frac{n-1}{5} F_n + \frac{2n}{5} F_{n-1}.$$

(See exercise 1.2.8–12.) Note that the F_{n+1} permutations can conveniently be represented by "Morse code" sequences of dots and dashes, where a dash corresponds to an inversion; thus when $n = 4$ the permutations

1 2 3 4, 1 2 4 3, 1 3 2 4, 2 1 3 4, 2 1 4 3

correspond respectively to the Morse code sequences

••••, ••—, •—•, —••, ——

of length 4. Hence we have found the total number of dashes among all Morse code sequences of length n.

Since 3-sorting followed by 2-sorting doesn't leave a "random" 3- and 2-ordered permutation, the total number of inversions does not tell us anything precise about the average number obtained in Algorithm D.

26. Yes; a shortest example is 4 1 3 7 2 6 8 5, which has nine inversions. In general, the construction $a_{3k+s} = 3k + 4s$ for $-1 \le s \le 1$ yields files which are 3-, 5-, and 7-ordered, having approximately $\frac{4}{3}N$ inversions. When $N \bmod 3 = 2$ this construction is best possible.

28. 255 63 15 7 3 1. But better sequences are possible, see exercise 29.

29. Experiments by C. Tribolet in 1971 resulted in the choices 373 137 53 19 7 3 1 ($B_{\text{ave}} \approx 7100$) and 317 101 31 11 3 1 ($B_{\text{ave}} \approx 8300$). [The first of these resulted in a sorting time of $126457u$, compared to $131002u$ when the same data were sorted using increments (8).] In general, Tribolet suggests letting h_s be the nearest prime number to $N^{(s-1)/t}$. Experiments by Shelby Siegel in 1972 indicate that the best number of increments in such a method, for $N \le 10000$, is $t \approx \frac{4}{3} \ln (N/5.75)$.

Another good sequence, found by Robert L. Tomlinson, Jr., is 199 79 31 11 5 1 ($B_{\text{ave}} \approx 7600$).

The best three-increment sequence, according to extensive tests by Carole M. McNamee, appears to be 45 7 1 ($B_{\text{ave}} \approx 17600$). For four increments, 91 23 7 1 was the winner in her tests ($B_{\text{ave}} \approx 11500$), but a rather broad range of increments gave roughly the same performance.

30. The number of integer points in the triangular region

$$\{x \ln 2 + y \ln 3 < \ln N,\ x \ge 0,\ y \ge 0\} \qquad \text{is} \qquad \tfrac{1}{2}(\log_2 N)(\log_3 N) + O(\log N).$$

While we are h-sorting, the file is already $2h$-ordered and $3h$-ordered, by Theorem K; hence exercise 25 applies.

31.

```
01    START  ENT3   T                    1

```

Here A is the number of right-to-left maxima, in the sense that A in Program D is the number of left-to-right minima; both quantities have the same statistical behavior.

The simplifications in the inner loop have cut the running time to $7NT + 7A - 2S + 1 + 15T$ units, curiously independent of B!

When $N = 8$ the increments are 6, 4, 3, 2, 1, and we have $A_{\text{ave}} = 3.892$, $B_{\text{ave}} = 6.762$; the average total running time is $276.24u$. (Cf. Table 5.) Both A and B are maximized in the permutation 7 3 8 4 5 1 6 2. When $N = 1000$ there are 40 increments, 972, 864, 768, 729, . . . , 8, 6, 4, 3, 2, 1; empirical tests like those in Table 6 give $A \approx 875$, $B \approx 4250$, and a total time of about $268000u$ (about twice as long as Program D with the increments of exercise 28).

Instead of storing the increments in an auxiliary table, it is convenient to generate them as follows on a binary machine:

P1. Set $m \leftarrow 2^{\lceil \log_2 N \rceil - 1}$, the largest power of 2 less than N.

P2. Set $h \leftarrow m$.

P3. Use h as the increment for one sorting pass.

P4. If h is even, set $h \leftarrow h + h/2$; then if $h < N$, return to P3.

P5. Set $m \leftarrow \lfloor m/2 \rfloor$ and if $m \geq 1$ return to P2.

Although the increments are not being generated in descending order, the order specified here is sufficient to make the sorting algorithm valid.

32. 4 12 11 13 2 0 8 5 10 14 1 6 3 9 16 7 15.

33. Two separate types of improvements can be made. First, by assuming that the artificial key K_0 is ∞, we can omit testing whether or not $p > 0$. (This idea has been used, for example, in Algorithm 2.2.4A.) Secondly, a standard "optimization" technique: We can make two copies of the inner loop with the register assignments for p and q interchanged; this avoids the assignment $q \leftarrow p$. (This idea has been used in exercise 1.1–3.)

Thus we assume that location INPUT contains the largest possible value in its (0:3) field, and we replace lines 07 and following of Program L by:

```
07   8H   LD3    INPUT,2(LINK)    B'     p ← L_q.  (Here p ≡ rI2, q ≡ rI3.)
08        CMPA   INPUT,3(KEY)     B'
09        JG     4F               B'     To L4 if K > K_p.
10   7H   ST1    INPUT,2(LINK)    N'     L_q ← j.
11        ST3    INPUT,1(LINK)    N'     L_j ← p.
12        JMP    6F               N'     Go to decrease j.
13   4H   LD2    INPUT,3(LINK)    B''    p ← L_q.  (Here p ≡ rI2, q ≡ rI3.)
14        CMPA   INPUT,2(KEY)     B''
15        JG     8B               B''    To L4 if K > K_p.
16   5H   ST1    INPUT,3(LINK)    N''    L_q ← j.
17        ST2    INPUT,1(LINK)    N''    L_j ← p.
18   6H   DEC1   1                N      j ← j − 1.
19        ENT3   0                N      q ← 0.
20        LDA    INPUT,1          N      K ← K_j.
21        J1P    4B               N      N > j ≥ 1.  ∎
```

Here $B' + B'' = B + N - 1$, $N' + N'' = N - 1$, so the total running time is $5B + 14N + N' - 3$ units. (N' is the number of elements with an odd number of

lesser elements to their right; so it has the statistics (min 0, ave $\frac{1}{2}N + \frac{1}{4}H_{\lfloor N/2 \rfloor} - \frac{1}{2}H_N$, max $N - 1$).)

The trick of setting $K_0 \leftarrow -\infty$ makes a similar saving in the running time of Program S, reducing it to $(8B + 11N - 10)u$.

34. There are $\binom{N}{n}$ sequences of N choices in which the given list is chosen n times; each such sequence has probability $(1/M)^n(1 - 1/M)^{N-n}$ of occurring, since the given list is chosen with probability $1/M$.

35. Program L: $A = 3$, $B = 41$, $N = 16$, time $= 496u$. Program M: $A = 2 + 1 + 1 + 3 = 7$, $B = 2 + 0 + 3 + 3 = 8$, $N = 16$, time $= 549u$. (Because of the 16 multiplications. But the improved Program L in exercise 33 takes only $358u$.)

36. To minimize $AC/M + BM$ we need $M = \sqrt{AC/B}$, so M is one of the integers just above or below this quantity. (In the case of Program M we would choose M proportional to N.)

37. The stated identity is equivalent to

$$g_{NM}(z) = M^{-N} \sum_{n_1+\cdots+n_M=N} \left(\frac{N!}{n_1! \ldots n_M!}\right) g_{n_1}(z) \ldots g_{n_M}(z),$$

which is proved as in exercise 34. It may be of interest to tabulate some of these generating functions, to indicate the trend for increasing M:

$$\begin{aligned}
g_{41}(z) &= (216 + 648z + 1080z^2 + 1296z^3 + 1080z^4 + 648z^5 + 216z^6)/5184,\\
g_{42}(z) &= (945 + 1917z + 1485z^2 + 594z^3 + 135z^4 + 81z^5 + 27z^6)/5184,\\
g_{43}(z) &= (1704 + 2264z + 840z^2 + 304z^3 + 40z^4 + 24z^5 + 8z^6)/5184.
\end{aligned}$$

Differentiating the stated identity twice with respect to z and then setting $z = 1$ yields

$$G''_{NM}(1) = M^{-N}\left(M(M-1)\sum_{m,n}\binom{N}{m,\,n,\,N-m-n}\right.$$
$$\left.\times (M-2)^{N-m-n} g'_m(1) g'_n(1) + M\sum_n \binom{N}{n}(M-1)^{N-n} g''_n(1)\right).$$

Using the formula

$$g''_n(1) = \frac{3}{2}\binom{n}{4} + \frac{5}{3}\binom{n}{3},$$

these sums present no special difficulty, and we find that

$$G''_{NM}(1) = \left(\frac{3}{2}\binom{N}{4} + \frac{5}{3}\binom{N}{3}\right) \Big/ M^2.$$

Finally since

$$G'_{NM}(1) = \frac{1}{2}\binom{N}{2} \Big/ M, \qquad G'_{NM}(1)^2 = \left(\frac{3}{2}\binom{N}{4} + \frac{3}{2}\binom{N}{3} + \frac{1}{4}\binom{N}{2}\right) \Big/ M^2,$$

the variance is

$$\left(\frac{1}{6}\binom{N}{3}+\frac{(2M-1)}{4}\binom{N}{2}\right)\Big/ M^2.$$

38. $\sum_{j,n}\binom{N}{n}p_j^n(1-p_j)^{N-n}\binom{n}{2} = \binom{N}{2}\sum_j p_j^2$; setting $p_j = F(j/M) - F((j-1)/M)$, and $F'(x) = f(x)$, this converges to $\binom{N}{2}/M$ times $\int_0^1 f(x)^2\,dx$ when F is reasonably well behaved.

39. (Solution by R. W. Floyd.) A deletion-insertion operation essentially moves only a_i. In a sequence of such operations, unmoved elements retain their relative order. Therefore if π can be sorted with k deletion-insertions, it has an increasing subsequence of length $n - k$; and conversely. Hence dis $(\pi) = n -$ (length of longest increasing subsequence of π). (A longest increasing subsequence can be found in $O(n \log n)$ steps; cf. Section 5.1.4.)

SECTION 5.2.2

1. No, it has $2m + 1$ *less* inversions, where $m \geq 0$ is the number of elements a_k such that $i < k < j$ and $a_i > a_k > a_j$. (Hence *all* exchange-sorting methods will eventually converge to a sorted permutation.)

2. (a) 6. (b) [A. Cayley, *Philos. Mag.* **34** (1849), 527–529.] Consider the cycle representation of π: Any exchange of elements in the *same* cycle increases the number of cycles by 1; any exchange of elements in *different* cycles decreases the number by 1. (This is essentially the content of exercise 2.2.4–3.) A completely sorted permutation is characterized by having n cycles. Hence xch (π) is n minus the number of cycles in π.

3. Yes, equal elements are never moved across each other.

4. The probability that $b_1 > b_2, \ldots, b_n$ in the inversion table, namely

$$\left(\sum_{1\leq k<n} k! \cdot k^{n-k-1}\right) \Big/ n! = \sqrt{\pi/2n} + O(n^{-1}) = \text{negligible.}$$

5. We may assume that $r > 0$. Let $b'_i = (b_i \geq r \Rightarrow b_i - r + 1; 0)$ be the inversion table after $r - 1$ passes. If $b'_i > 0$, element i is preceded by b'_i larger elements, the largest of which will bubble up at least to position $b'_i + i$ (in view of the i elements $\leq i$). Furthermore if element j is the rightmost to be exchanged, we have $b'_j > 0$ and BOUND $= b'_j + j - 1$ after the rth pass.

6. Solution 1: An element displaced farthest to the right of its final position moves one step left on each pass except the last. Solution 2 (higher level): By exercise 5.1.1–8, answer (f), $a'_i - i = b_i - c_i$, for $1 \leq i \leq n$, where $c_1\, c_2 \ldots c_n$ is the dual inversion table. If $b_j = \max(b_1, \ldots, b_n)$ then $c_j = 0$.

7. $(2(n+1)(1 + P(n) - P(n+1)) - P(n) - P(n)^2)^{1/2} = \sqrt{(2 - \pi/2)n} + O(1)$.

8. For $i < k + 2$ there are $j + k - i + 1$ choices for b_i; for $k + 2 \leq i < n - j + 2$ there are $j - 1$ choices; and for $i \geq n - j + 2$ there are $n - i + 1$.

10. (a) If $i = 2k - 1$, from $(k - 1, a_i - k)$ to $(k, a_i - k)$. If $i = 2k$, from $(a_i - k, k - 1)$ to $(a_i - k, k)$. (b) Step a_{2k-1} is above the diagonal iff $k \leq a_{2k-1} - k$ iff $a_{2k-1} \geq 2k$ iff $a_{2k-1} > a_{2k}$ iff $a_{2k} \leq 2k - 1$ iff $a_{2k} - k \leq k - 1$ iff step a_{2k} is above the diagonal. Exchanging them interchanges horizontal and vertical steps. (c) Step a_{2k+d} is at least m below the diagonal iff $k + m - 1 \geq a_{2k+d} - (k + m) + m$ iff

$a_{2k+d} < 2k + m$ iff $a_{2k} \geq 2k + m$ iff $a_{2k} - k \geq k + m$ iff step a_{2k} is at least m below the diagonal. (If $a_{2k+d} < 2k + m$ and $a_{2k} < 2k + m$, there are at least $(k + m) + k$ elements less than $2k + m$; that's impossible. If $a_{2k+d} \geq 2k + m$ and $a_{2k} \geq 2k + m$, one of the $\geq$ must be $>$; but we can't fit all of the elements $\leq 2k + m$ into less than $(k + m) + k$ positions. Hence $a_{2k+d} < a_{2k}$ iff $a_{2k+d} < 2k + m$ iff $2k + m \leq a_{2k}$. A rather unexpected result!)

11. 16 10 13 5 14 6 9 2 15 8 11 3 12 4 7 1 (61 exchanges), by considering the lattice diagram. In general, when $N = 2^t$ the set $\{K_2, K_4, \ldots\}$ should be $\{1, 2, \ldots, \lfloor N/3 \rfloor + 1, \lfloor N/3 \rfloor + 3, \lfloor N/3 \rfloor + 5, \ldots\}$, permuted so as to maximize the exchanges for $N/2$ elements.

12. In this program, TT $\equiv 2^{t-1}$, $p \equiv$ rI1, $r \equiv$ rI2, $i \equiv$ rI3, $i + d - N \equiv$ rI4; assume that $N \geq 2$.

```
01       START   ENT1    TT              1       M1. Initialize p. p ← 2^(t-1).
02               ST1     P               1

```

The running time depends on six quantities, only one of which depends on the input data (the remaining five are functions of N alone): $T = t$, the number of "major cycles"; $A = t(t+1)/2$, the number of passes or "minor cycles"; B = the (variable) number of exchanges; C = the number of comparisons; D = the number of times $i \wedge p \neq r$ in step M2; and E = the number of times $i \wedge p \neq r$ and $i + p + d \geq N$ in step M2. When $N = 2^t$, it can be shown that $D = 2^t(t-2) + 2 + E$, and $E = \binom{t}{2}$. For Table 1, $T = 4$, $A = 10$, $B = 3+0+1+4+0+0+8+0+4+5 = 25$, $C = 63$, $D = 40$, $E = 6$, so the total running time is $11A + 6B + 13C + 3D + 5E + 13T + 3 = 1284u$.

13. No, nor are Algorithms Q, R.

14. (a) When $p = 1$ we do $(2^{t-1} - 0) + (2^{t-1} - 1) + (2^{t-1} - 2) + (2^{t-1} - 4) + \cdots + (2^{t-1} - 2^{t-2}) = (t-1)2^{t-1} + 1$ comparisons for the final merge. (b) $x_t = x_{t-1} + \frac{1}{2}(t-1) + 2^{-t} = \cdots = x_0 + \sum_{0 \leq k < t} (\frac{1}{2}k + 2^{-k-1}) = \frac{1}{2}\binom{t}{2} + 1 - 2^{-t}$. Hence $c(2^t) = 2^{t-2}(t^2 - t + 4) - 1$.

15. (a) Consider the number of comparisons such that $i + d = N$; then use induction on r. (b) If $b(n) = c(n+1)$, we have $b(2n) = a(1) + \cdots + a(2n) = a(0) + a(1) + a(1) + \cdots + a(n-1) + a(n) + x(1) + x(2) + \cdots + x(2n) = 2b(n) + y(2n) - a(n)$; similarly $b(2n+1) = 2b(n) + y(2n+1)$. (c) Cf. exercise 1.2.4–42. (d) A rather laborious calculation of $(z(N) + 2z(\lfloor N/2 \rfloor) + \cdots) - a(N)$, using formulas such as

$$\sum_{0 \leq k \leq n} 2^k(n-k) = 2^{n+1} - n - 2, \qquad \sum_{0 \leq k \leq n} 2^k \binom{n-k}{2} = 2^{n+1} - \binom{n+2}{2} - 1,$$

leads to the result

$$c(N) = N\left(\frac{1}{2}\binom{e_1}{2} + 2e_1 - 1\right) - 2^{e_1}(e_1 - 1) - 1 + \sum_{1 \leq j \leq r} 2^{e_j}\left(e_1 + \cdots + e_{j-1} - j(e_1 - 1) + \frac{1}{2}\binom{e_1 - e_j}{2}\right).$$

16. Consider the $\binom{2n}{n}$ lattice paths from $(0, 0)$ to (n, n). For $k \geq 0$, the number of times a line $(i, i+k) - (i, i+k+1)$ is traversed for some i, summed over all paths, is

$$\sum_i \binom{k+2i}{i}\binom{2n-1-k-2i}{n-i},$$

the coefficient of x^{2n} in $x^{k+1}y^{2k+1}/(1-4x)$, where $y = (1 - \sqrt{1-4x})/2x$. (Cf. exercise 5.2.1–14.) It can now be shown that the number of exchanges during the final merge when $N = 2n$, summed over all paths, is the coefficient of x^N in

$$\frac{x}{(1-4x)^{3/2}} \frac{1}{1-z}\left(1 + \frac{2z}{1+z^2} + \frac{2z^2}{1+z^4} + \frac{2z^4}{1+z^8} + \cdots\right), \qquad z = xy^2 = y - 1.$$

The asymptotic value of this coefficient is desired.

17. K_{N+1} is inspected when we are sorting a subfile with $r = N$ and K_l the largest key. K_0 is inspected during a straight-insertion sorting phase with $l = 1$, when left-to-right minima sink to position R_1.

18. Each comparison is followed by a transfer; the partitioning process for $R_l \ldots R_r$ ends with $i = \lceil (l+r)/2 \rceil$ in step Q7, bisecting the subfile as perfectly as possible. (Quantitatively speaking, we replace Eqs. (17) by $A = 1$, $B = \lfloor (N-1)/2 \rfloor$, $C = N$, $X = 1 - (N \bmod 2)$; this puts us essentially in the *best* case of the algorithm, as in exercise 27 below, except that $B \approx \frac{1}{2}C$.) If the "$<$" signs in steps Q3 and Q5 are changed, we need "$<$" signs in (13); and the algorithm behaves terribly, letting j run from N down to 0 each time and making the slowest conceivable progress. Thus the extra transfers are well worth making. [Another way to handle equal keys is suggested in exercise 30.]

19. Yes, the other subfiles may be processed in any order (without increasing the size of the storage area); but a stack is easiest to work with.

20. $\lfloor \log_2 (N+1)/(M+2) \rfloor$. (The worst case occurs when $N = 2^k(M+1) - 1$ and all subfiles are perfectly bisected when they are partitioned.)

21. If $s > 1$, the first occurrence of step Q4 removes s from the keys in memory, and no comparison in steps Q3 and Q5 will come out $=$. Exactly t records are transferred from the area $R_2 \ldots R_s$ to $R_{s+1} \ldots R_N$; and $t + h$ are transferred from $R_s \ldots R_N$ to $R_1 \ldots R_{s-1}$. If $h = 1$, the last comparison is $K_i{:}K$ with $i = s+1$ and $j = s$; if $h = 0$ it is $K{:}K_j$ with $j = s - 1$ and $i = s$. So we obtain (17); in fact, $C' = N + 2 - s - h - \delta_{s1}$ and $C'' = s - 1 + h$.

22. The stated relations for $A_N(z)$ follow easily because $A_{s-1}(z)\,A_{N-s}(z)$ is the generating function for the value of A after independently sorting randomly ordered files of sizes $s - 1$ and $N - s$. Similarly, we obtain the relations

$$B_N(z) = \sum_{1 \le s \le N} \sum_{0 \le k \le s} b_{stN}\, z^t\, B_{s-1}(z) B_{N-s}(z),$$

$$C_N(z) = \frac{1}{N} \sum_{1 \le s \le N} z^{N+1-\delta_{s1}} C_{s-1}(z) C_{N-s}(z),$$

$$D_N(z) = \frac{1}{N} \sum_{1 \le s \le N} D_{s-1}(z) D_{N-s}(z),$$

$$E_N(z) = \frac{1}{N} \sum_{1 \le s \le N} E_{s-1}(z) E_{N-s}(z),$$

$$L_N(z) = \frac{1}{N} \sum_{1 \le s \le N} L_{s-1}(z) L_{N-s}(z),$$

$$X_N(z) = \frac{1}{N} \sum_{1 \le s \le N} (1 + (z-1)h_{sN}) X_{s-1}(z) X_{N-s}(z),$$

for $N > M$. Here b_{stN} is the probability that s and t have given values in a file of length N, namely

$$\binom{s-1}{t}\binom{N-s}{t} \Big/ N\binom{N-1}{s-1},$$

which is $(1/N!)$ times the $(s-1)!$ ways to permute $\{1, \ldots, s-1\}$ times the $(N-s)!$

ways to permute $\{s+1, \ldots, N\}$ times the $\binom{s-1}{t}\binom{N-s}{t}$ patterns with t displaced elements on each side; and h_{sN} is the probability that $h = 1$ when N and s are given, namely $(s-1)/(N-1)$. For $0 \le N \le M$, we have $B_N(z) = C_N(z) = X_N(z) = 1$; $L_N(z) = 1$, except $L_0(z) = L_1(z) = z$; $D_N(z) = z^{N-1}$, except $D_0(z) = 1$; and $E_N(z)$ is $\prod_{1\le k\le N} ((1+z+\cdots+z^{k-1})/k)$.

23. When $N > M$, $A_N = 1 + (2/N)\sum_{0\le k<N} A_k$; $B_N = \sum_{0\le t<s\le N} b_{stN}(t + B_{s-1} + B_{N-s}) = (1/N)\sum_{1\le s\le N} ((s-1)(N-s)/(N-1) + B_{s-1} + B_{N-s}) = (N-2)/6 + (2/N)\sum_{0\le k<N} B_k$ [cf. exercise 22]; $D_N = (2/N)\sum_{0\le k<N} D_k$; E_N and L_N are similar; $X_N = (1/N)\sum_{1\le s\le N} (h_{sN} + X_{s-1} + X_{N-s}) = \frac{1}{2} + (2/N)\sum_{0\le k<N} X_k = \frac{1}{2}A_N$. Each of these recurrences has the form (20) for some function f_n.

24. The recurrence $C_N = N - 1 + (2/N)\sum_{0\le k<N} C_k$, $N > M$, has the solution $(N+1)\big(2H_{N+1} - 2H_{M+2} + 1 - 4/(M+2) + 2/(N+1)\big)$, $N > M$. (So we save about $4N/M$ comparisons, but each comparison takes longer.)

25. (Use (17) repeatedly with $s = 1$.) $A = N - M$, $B = 0$, $C = \binom{N+1}{2} - \binom{M+1}{2}$, $D = M - 1$, $E = 0$, $L = N - M + \delta_{M1}$, $X = 0$.

26. $N\ M\ (M-1) \ldots 1\ (M+1)\ (M+2) \ldots (N-1)$. Using (17) repeatedly with $s = N$, we have $A = N - M$, $B = 0$, $C = \binom{N+2}{2} - \binom{M+2}{2}$, $D = M - 1$, $E = \binom{M}{2}$, $L = N - M + \delta_{M1}$, $X = N - M$. (Since $B = 0$ this may not be the worst possible case.)

27. Eq. (17) with $A = 1$, $B = 0$, $C = N + 1$, $X = 1$, and $s = \lfloor (N+1)/2 \rfloor$ is best for the partitioning; and $E = 0$ is best for straight insertion. When $N = (M+1)2^k - 1$, the totals are $A = X = 2^k - 1$, $B = E = 0$, $C = k(M+1)2^k$, $D = 2^k(M-1)$; when $N = (M+2)2^k - 1$, $A = X = 2^{k+1} - 1$, $C = (k+1)(M+2)2^k$, $D = 2^{k+1}\lfloor (M-1)/2 \rfloor$. In general, the approximate values are $A = X \approx$ between N/M and $2N/M$; $B = E = 0$; $C \approx N \log_2 (N/M)$; $D \approx N$.

28. The recurrence

$$C_n = n + 1 + \frac{2}{\binom{n}{3}} \sum_{1\le k\le n} (k-1)(n-k)C_{k-1}$$

can be transformed into

$$\binom{n}{3}C_n - 2\binom{n-1}{3}C_{n-1} + \binom{n-2}{3}C_{n-2} = 2(n-1)(n-2) + 2(n-2)C_{n-2}.$$

29. In general, consider the recurrence

$$C_n = n + 1 + \frac{2}{\binom{n}{2t+1}} \sum_{1\le k\le n} \binom{k-1}{t}\binom{n-k}{t} C_{k-1},$$

which arises when the median of $2t+1$ elements governs the partitioning. Letting $C(z) = \sum_n C_n z^n$, the recurrence can be transformed to $(1-z)^{t+1}C^{(2t+1)}(z)/(2t+2)! = 1/(1-z)^{t+2} + C^{(t)}(z)/(t+1)!$. Let $f(x) = C^{(t)}(1-x)$; then $p_t(\vartheta)f(x) = (2t+2)!/(x)^{\underline{t+2}}$, where ϑ denotes the operator $x(d/dx)$, and $p_t(x) = (t-x)^{\underline{t+1}} - (2t+2)^{\underline{t+1}}$. The general solution to $(\vartheta - \alpha)g(x) = x^\beta$ is $g(x) = x^\beta/(\beta-\alpha) + Cx^\alpha$, for $\alpha \ne \beta$; $g(x) = x^\beta(\ln x + C)$ for $\alpha = \beta$. We have $p_t(-t-2) = 0$; so the general solution to our differential equation is

$$C^{(t)}(z) = (2t+2)!\ln(1-z)/p_t'(-t-2)(1-z)^{t+2} + \sum_{0\le j\le t} c_j(1-z)^{\alpha_j}$$

where $\alpha_0, \ldots, \alpha_t$ are the roots of $p_t(x) = 0$, and the constants c_i depend on the initial values $C_t, \ldots, C_{2t}$. The handy identity

$$\frac{1}{(1-z)^{m+1}} \ln\left(\frac{1}{1-z}\right) = \sum_{n\ge 0} (H_{n+m} - H_m)\binom{n+m}{m} z^n, \qquad m \ge 0,$$

now leads to the surprisingly simple *closed form solution*

$$C_n = (H_{n+1} - H_{t+1})(n+1)/(H_{2t+2} - H_{t+1}) + \left(\sum_{0\le j\le t} c_j(-\alpha_j)^{\overline{n-t}}\right)/n!,$$

from which the asymptotic formula is easily deduced. (The leading term $n \ln n/(H_{2t+2} - H_{t+1})$ was discovered by M. H. van Emden [*CACM* **13** (1970), 563–567] using an information-theoretic approach. In fact, suppose we wish to analyze any partitioning process such that the left subfile contains at most xN elements with asymptotic probability $\int_0^x f(x)\,dx$, as $N \to \infty$, for $0 \le x \le 1$; van Emden has proved that the average number of comparisons required to sort the file completely is $\sim n \ln n/\alpha$, where $\alpha = -1/\int_0^1 \big(f(x) + f(1-x)\big)x \ln x\,dx$. This formula applies to radix exchange as well as quicksort and various other methods. See also H. Hurwitz, *CACM* **14** (1971), 99–102.)

30. Each subfile may be identified by four quantities (l, r, k, X), where l and r are the boundaries (as presently), k indicates the number of words of the keys which are known to be equal throughout the subfile, and X is a lower bound for the $(k+1)$st words of the keys. Assuming nonnegative keys, we have $(l, r, k, X) = (1, N, 0, 0)$ initially. When partitioning a file, we let K be the $(k+1)$st word of the test key K_q. If $K > X$, partitioning takes place with all keys $\ge K$ at the right and all keys $< K$ at the left (looking only at the $(k+1)$st word of the key each time; the partitioned subfiles get the respective identifications $(l, i-1, k, X)$ and (i, r, k, K). But if $K = X$, partitioning takes place with all keys $> K$ at the right and all keys $\le K$ [actually $= K$] at the left; the partitioned subfiles get the respective identifications $(l, i, k+1, 0)$ and $(i+1, r, k, K)$. In both cases we are unsure that R_i is in its final position since we haven't looked at the $(k+2)$nd words. Obvious further changes are made to handle boundary conditions properly. By adding a fifth "upper bound" component, the method could be made symmetrical between left and right.

31. Go through a normal partitioning process, with R_1 finally falling into position R_k. If $k = m$, stop; if $k > m$, use the same technique to find the $(m-k)$th smallest element of the right-hand subfile; and if $k < m$ find the mth smallest element of the left-hand subfile. [*CACM* **4** (1961), 321–322.]

32. The recurrence is $C_{nm} = n - 1 + (A_{nm} + B_{nm})/n$, where

$$A_{nm} = \sum_{1\le k<m} C_{n-k,m-k} \qquad \text{and} \qquad B_{nm} = \sum_{m\le k<n} C_{km},$$

for $1 \le m \le n$. Since $A_{n+1,m+1} = A_{nm} + C_{nm}$ and $B_{n+1,m} = B_{nm} + C_{nm}$, we can first find a formula for $(n+1)C_{n+1,m+1} - nC_{nm}$, then sum this to obtain the answer $2\big((n+1)H_n - (n+3-m)H_{n+1-m} - (m+2)H_m + n + 3\big)$. When $n = 2m-1$,

it becomes $4m(H_{2m-1} - H_m) + 4m - 8H_m + 4 = (4 + 4\ln 2)m - 8\ln m - 8\gamma + 1 + O(m^{-1}) \approx 3.39n$.

33. Proceed as in the first stage of radix exchange, using the sign instead of bit 1.

34. We can avoid testing whether or not $i \le j$, as soon as we have found at least one 0 bit and at least one 1 bit in each stage, i.e., after making the first exchange in each stage. This saves approximately $2C$ units of time in Program R.

35. $A = N - 1$, $B = (\min 0,\ \text{ave}\ \frac{1}{4}N\log_2 N,\ \max \frac{1}{2}N\log_2 N)$, $C = N\log_2 N$, $G = \frac{1}{2}N$, $K = L = R = 0$, $S = \frac{1}{2}N - 1$, $X = (\min 0, \text{ave}\ \frac{1}{2}(N-1), \max N - 1)$. [It is interesting to note that, in general, the quantities A, C, G, K, L, R, and S depend only on the set of keys in the file, not on their initial order; only B and X are influenced by the initial order of the keys.]

36. (a) $\sum\binom{n}{k}\binom{k}{j}(-1)^{k+j}a_j = \sum\binom{n}{j}\binom{n-j}{k-j}(-1)^{k-j}a_j = \sum\binom{n}{j}\delta_{nj}a_j = a_n$. (b) $\langle\delta_{n0}\rangle$; $\langle-\delta_{n1}\rangle$; $\langle(-1)^n\delta_{nm}\rangle$; $\langle(1-a)^n\rangle$; $\langle\binom{n}{m}(-a)^m(1-a)^{n-m}\rangle$. (c) Writing the relations to be proved as $x_n = y_n = a_n + z_n$, we have $y_n = a_n + z_n$ by part (a); also $2^{1-n}\sum_{k\ge 2}\binom{n}{k}y_k = z_n$, so y_n satisfies the same recurrence as x_n. [See exercises 53 and 6.3–17 for some generalizations of this result. It does not appear to be easy to prove *directly* that $\hat{x}_n = \hat{a}_n 2^{n-1}/(2^{n-1} - 1)$.]

37. $\langle\sum_m c_m\binom{n}{2m}2^{-n}\rangle$ for an arbitrary sequence of constants $c_0, c_1, c_2, \ldots$. [This answer, although correct, does not reveal immediately that $\langle 1/(n+1)\rangle$ and $\langle n - \delta_{n1}\rangle$ are such sequences! Sequences having the form $\langle a_n + \hat{a}_n\rangle$ are always self-dual. Note that, in terms of the generating function $A(z) = \sum a_n z^n/n!$, we have $\hat{A}(z) = e^z A(-z)$; hence $A = \hat{A}$ is equivalent to saying that $A(z)e^{-z/2}$ is an even function.

38. A partitioning stage which yields a left subfile of size s and a right subfile of size $N - s$ makes the following contributions to the total running time:

$$A = 1, \quad B = t, \quad C = N, \quad K = \delta_{s1}, \quad L = \delta_{s0}, \quad R = \delta_{sN}, \quad X = h,$$

where t is the number of keys $K_1, \ldots, K_s$ with bit b equal to 1, and h is bit b of K_{s+1}; if $s = N$, then $h = 0$. (Cf. (17).) This leads to recurrence equations such as

$$B_N = 2^{-N}\sum_{0\le t\le s\le N}\binom{s}{t}\binom{N-s}{t}(t + B_s + B_{N-s})$$

$$= \frac{1}{4}(N-1) + 2^{1-N}\sum_{s\ge 2}\binom{N}{s}B_s, \qquad \text{for } N \ge 2;\quad B_0 = B_1 = 0.$$

(Cf. exercise 23.) Solving these recurrences by the method of exercise 36 yields the formulas $A_N = V_N - U_N + 1$, $B_N = \frac{1}{4}(U_N + N - 1)$, $C_N = V_N + N$, $K_N = N/2$, $L_N = R_N = \frac{1}{2}(V_N - U_N - N) + 1$, $X_N = \frac{1}{2}(A_N - L_N)$. Clearly $G_N = 0$.

39. Each stage of quicksort puts at least one element into its final position, but this need not happen during radix exchange (cf. Table 3).

40. If we switch to straight insertion whenever $r - l < M$ in step R2, the problem doesn't arise unless more than M equal elements occur. If the latter is a likely prospect, we can test whether or not $K_l = \cdots = K_r$ whenever $j < l$ or $j = r$ in step R8.

43. As $a \to 0+$, $\int_0^1 y^{a-1}(e^{-y} - 1)\,dy + \int_1^\infty y^{a-1}e^{-y}\,dy = \Gamma(a) - 1/a = \big(\Gamma(a+1) - \Gamma(1)\big)/a \to \Gamma'(1) = -\gamma$, by exercise 1.2.7–24.

44. For $k \geq 0$, we have $r_k(m) \sim \frac{1}{2}(2m)^{(k+1)/2}\Gamma\big((k+1)/2\big) - \sum_{j\geq 0}(-1)^j B_{k+2j+1}/\big((k+2j+1)j!(2m)^j\big)$. When $k = -1$, the contributions from $f_k^{(j-1)}(m)$ in (36) cancel with similar terms in the expansion of H_{m-1}, and we have $r_{-1}(m) = H_{m-1} + (1/\sqrt{2m})\sum_{t\geq 0} f_{-1}(t) \sim \frac{1}{2}\big(\ln(2m) + \gamma\big) - \sum_{j\geq 1}(-1)^j B_{2j}/(2j)j!(2m)^j$. Therefore the contribution to W_{m-1} from the term N^t/t of (33) is obtained from $m\sum_{t\geq 1} t^{-1}\exp(-t^2/2m)(1 - t^3/3m^2 + t^6/18m^4)(1 - t^4/4m^3)(1 - t/2m - t^2/8m^2) + O(m^{-1/2}) = \frac{1}{2}m\ln m + \frac{1}{2}(\ln 2 + \gamma)m - \frac{5}{12}\sqrt{2\pi m} + \frac{4}{9} + O(m^{-1/2})$. The term $-\frac{1}{2}N^{t-1}$ contributes $-\frac{1}{2}\sum_{t\geq 1}\exp(-t^2/2m)(1 - t^3/3m^2)(1 - t/2m)(1 + t/m) + O(m^{-1/2}) = -\frac{1}{4}\sqrt{2\pi m} - \frac{1}{6}$. The term $\frac{1}{2}\delta_{t1}$ yields $\frac{1}{2}$. And finally the term $\frac{1}{2}(t-1)B_2N^{t-2}$ contributes $\frac{1}{12}m^{-1}\sum_{t\geq 1} t\exp(-t^2/2m) + O(m^{-1/2}) = \frac{1}{12} + O(m^{-1/2})$.

45. The argument used to derive (42) is also valid for (43), except that we leave out the residues at $z = -1$ and $z = 0$.

46. Proceeding as we did with (45), we obtain $(s-1)!/\ln 2 + f_s(n)$, where

$$f_s(n) = \frac{2}{\ln 2}\sum_{k\geq 1}\Re\big(\Gamma(s - 2\pi ik/\ln 2)\exp(2\pi ik\log_2 n)\big).$$

[Note that $|\Gamma(s+it)|^2 = \big(\prod_{0\leq k<s}(k^2+t^2)\big)\pi/(t\sinh\pi t)$, for integer $s \geq 0$, so we can bound $f_s(n)$.]

47. In fact, $\sum_{j\geq 1} e^{-n/2^j}(n/2^j)^s$ equals the integral in exercise 46, for all $s > 0$.

48. Making use of the intermediate identity

$$1 - e^{-x} = \frac{-1}{2\pi i}\int_{-1/2-i\infty}^{-1/2+i\infty}\Gamma(z)x^{-z}\,dz,$$

we proceed as in the text, with $1 - e^{-x}$ playing the role of $e^{-x} - 1 + x$; $V_{n+1}/(n+1) = (-1/2\pi i)\int_{-1/2-i\infty}^{-1/2+i\infty}\Gamma(z)n^{-z}\,dz/(2^{-z}-1) + O(n^{-1})$, and the integral equals $\log_2 n + \gamma/(\ln 2) - \frac{1}{2} - f_0(n)$ in the notation of exercise 46. [Thus A_N in exercise 38 is $N\big(1/(\ln 2) - f_0(N-1) - f_{-1}(N)\big) + O(1)$.]

49. The right-hand side of Eq. (40) can be improved to $e^{-x}\big(n/x + \frac{1}{2}x + x^3O(n^{-1})\big)$. The effect is to subtract $\frac{1}{2}$ times the sum in exercise 47, replacing $O(1)$ in (47) by $2 - \frac{1}{2}\big(1/(\ln 2) + f_1(n)\big) + O(n^{-1})$. (The "2" comes from the "$2/n$" in (45).)

50. $U_{mn} = n\log_m n + n\big((\gamma-1)/(\ln m) - \frac{1}{2} + f_{-1}(n)\big) + m/(m-1) - 1/(2\ln m) - \frac{1}{2}f_1(n) + O(n^{-1})$, where $f_s(n)$ is defined as in exercise 46 but with $\ln 2$ and $\log_2$ replaced by $\ln m$ and $\log_m$. [*Note:* For $m = 2, 3, 4, 5, 10, 100, 1000, 10^6$ we have $f_{-1}(n) <$ .0000001725, .00041227, .000296, .00085, .00627, .068, .153, .341, respectively.]

51. Let $N = 2m$. We may extend the sum (35) over all $t \geq 1$, when it equals

$$\sum_{t\geq 1}(1/2\pi i)\int_{a-i\infty}^{a+i\infty}\Gamma(z)(t^2/N)^{-z}t^k\,dz = (1/2\pi i)\int_{a-i\infty}^{a+i\infty}\Gamma(z)N^z\zeta(2z-k)\,dz,$$

provided that $a > (k+1)/2$. So we need to know properties of the zeta function. When $\Re(w) \geq -q$, $\zeta(w) = O(|w|^{q+1})$ as $|w| \to \infty$; hence we can shift the line of integration to the left as far as we please if we only take the residues into account. The factor $\Gamma(z)$ has poles at $0, -1, -2, \ldots$, and $\zeta(2z-k)$ has a pole only at $z = (k+1)/2$. The residue at $z = -j$ is $N^{-j}(-1)^j\zeta(-2j-k)/j!$, and $\zeta(-n) =$

$(-1)^{n+1}B_{n+1}/(n+1)$. The residue at $z = (k+1)/2$ is $\frac{1}{2}\Gamma\big((k+1)/2\big)N^{(k+1)/2}$. But when $k = -1$ there is a double pole at $z = 0$; $\zeta(z) = 1/(z-1) + \gamma + O(|z-1|)$, so the residue at 0 in this case is $\gamma + \frac{1}{2}\ln N - \frac{1}{2}\gamma$. We therefore obtain the asymptotic series mentioned in the answer to exercise 44.

52. Set $x = t/n$; then

$$\binom{2n}{n+t}\Big/\binom{2n}{n} = \exp\big(-2n(x^2/1\cdot 2 + x^4/3\cdot 4 + \cdots) + (x^2/2 + x^4/4 + \cdots) - (1/6n)(x^2 + x^4 + \cdots) + \cdots\big);$$

the desired sum can now be expressed in terms of $\sum_{t\ge 1} t^k\, d(t)e^{-t^2/n}$, for various k. Proceeding as in exercise 51, since $\zeta(z)^2 = \sum_{t\ge 1} d(t)t^{-z}$, we wish to evaluate the residues of $\Gamma(z)n^z\zeta(2z-k)^2$ when $k \ge 0$. At $z = -j$ the residue is $n^{-j}(-1)^j\big(B_{2j+k+1}/(2j+k+1)\big)^2/j!$, and at $z = (k+1)/2$ the residue is $n^{(k+1)/2}\Gamma\big((k+1)/2\big)\big(\gamma + \frac{1}{4}\ln n + \frac{1}{4}\psi\big((k+1)/2\big)\big)$, where $\psi(z) = \Gamma'(z)/\Gamma(z) = H_{z-1} - \gamma$; thus, for example, when $k = 0$, $\sum_{t\ge 1}e^{-t^2/n}\,d(t) = \frac{1}{4}\sqrt{\pi n}\ln n + (\frac{3}{4}\gamma - \frac{1}{2}\ln 2)\sqrt{\pi n} + \frac{1}{4} + O(n^{-M})$ for all M. For $S_n/\binom{2n}{n}$, add $(\frac{1}{32}\ln n + \frac{3}{32}\gamma + \frac{1}{24} - \frac{1}{16}\ln 2)\sqrt{\pi/n} + O(n^{-1})$ to this quantity. (Cf. exercise 1.2.7–23, 1.2.9–19.)

53. Let $q = 1 - p$. Generalizing exercise 36(c), if

$$x_n = a_n + \sum_{k\ge 2}\binom{n}{k}(p^k q^{n-k} + q^k p^{n-k})x_k,$$

then

$$x_n = a_n + \sum_{k\ge 2}\binom{n}{k}(-1)^k \hat{a}_k(p^k + q^k)/(1 - p^k - q^k).$$

We can therefore find B_N and C_N as before (the factor $\frac{1}{4}$ in B_N should be replaced by pq). The asymptotic examination of U_N proceeds essentially as in the text, with

$$\begin{aligned} T_n &= \sum_{r\ge 1,\, s\ge 0}\binom{r}{s}(e^{-np^sq^{r-s}} - 1 + np^sq^{r-s}) \\ &= (1/2\pi i)\int_{-3/2-i\infty}^{-3/2+i\infty}\Gamma(z)n^{-z}(p^{-z} + q^{-z})\,dz/(1 - p^{-z} - q^{-z}) \\ &= (n/h_p)\big(\ln n + \gamma - 1 + h_p^{(2)}/2h_p - h_p + f(n)\big) + O(1), \end{aligned}$$

where

$$h_p = -(p\ln p + q\ln q), \qquad h_p^{(2)} = p(\ln p)^2 + q(\ln q)^2,$$

and

$$f(n) = \sum \Gamma(z)n^{-1-z}/h_p$$

summed over all complex $z \ne -1$ such that $p^{-z} + q^{-z} = 1$. The latter set of points seems to be difficult to analyze in general; but when $p = \phi^{-1}$, $q = \phi^{-2}$, the solutions are $z = (-1)^{k+1} + k\pi i/(\ln\phi)$. The dominant term, $(n\ln n)/h_p$, could also have been obtained from van Emden's general formula quoted in the answer to exercise 29. For $p = \phi^{-1}$ we have $1/h_p = 1.521$, compared to $1/h_{1/2} = 1.4427$.

54. Let C be a circle of radius $(M+\frac{1}{2})b$, so that the integral vanishes on C as $M\to\infty$. (The asymptotic form of U_n can now be derived in a new way, expanding $\Gamma(n+1)/\Gamma(n+ibm)$. The method of this exercise applies to *all* sums of the form $\sum_k\binom{n}{k}(-1)^k f(k)$, when f is reasonably well behaved!)

55. Analysis shows that it is actually a little better to use $\lceil(l+r)/2\rceil$ in place of $\lfloor(l+r)/2\rfloor$, because of the way Program Q is written. Thus, we replace lines 09 and 10 of Program Q by

```
ENTA  0,3                 LDA   INPUT,5               JGE   Line13
INCA  1,4                 LDX   INPUT,3               LDA   INPUT,5
SRB   1                   CMPA  INPUT,4               LDX   INPUT,3
STA   TEMP                JL    5F                    CMPA  INPUT,4
LD5   TEMP                STX   INPUT,5               JG    5F
LDA   INPUT,3             JMP   Line19                STX   INPUT,5
CMPA  INPUT,4        5H   LDA   INPUT,4               JMP   Line13
JL    1F                  STX   INPUT,4          5H   LDA   INPUT,4

JLE   Line19         1H   CMPA  INPUT,5               JMP   Line21
```

The first three of these lines should be replaced by "`ENTX 0,3; INCX 1,4; ENTA 0; DIV =2=`" if binary shifting is not available. In this code, "`Line19`" refers to line 19 of Program Q, etc.

56. We may solve the recurrence $\binom{n}{3}x_n = b_n + 2\sum_{1\le k\le n}(k-1)(n-k)x_{k-1}$, $n>m$, by letting $y_n = nx_n$, $u_n = ny_{n+1} - (n+2)y_n$, $v_n = nu_{n+1} - (n-5)u_n$; it follows that $v_n = 6(b_{n+2} - 2b_{n+1} + b_n)$, for $n>m$. *Example:* Let $x_n = \delta_{n1}$ for $n\le m$, and let $b_n\equiv 0$. Then $v_n = 0$ for all $n>m$, hence $n^{\underline{5}}u_{n+1} = m^{\underline{5}}u_{m+1}$. Since $y_{m+1} = 12/m$, $y_{m+2} = 12/(m+1)$, we ultimately find $x_n = \frac{48}{7}(n+1)/m(m+1)(m+2) + \frac{36}{7}(m-1)^{\underline{4}}/n^{\underline{6}}$ for $n>m$. In general, when b_n is identically zero, let $f_n = \big(12/(n-1)(n-2)\big)\sum_{1\le k\le n}(k-1)(n-k)x_{k-1}$; the solution for $n>m$ is $x_n = (n+1)\big((m+1)f_{m+2} - (m-4)f_{m+1}\big)/7(m+1)(m+2) + \big((m+1)f_{m+2} - (m+3)f_{m+1}\big)m^{\underline{5}}/7n^{\underline{6}}$. When $b_n = \binom{n}{3}/n^{\underline{p}}$ and $x_n = 0$ for $n\le m$, the solution is

$$x_n/(n+1) = (p-3)(p-2)/(p-6)(p+1)(n+1)^{\underline{p+1}} + 12/7(p+1)(m+2)^{\underline{p+1}} - 12(m+1-p)^{\underline{6-p}}/7(p-6)(n+1)^{\underline{7}},$$

for $n>m$; except that when $p=-1$, $x_n/(n+1) = \frac{12}{7}(H_{n+1} - H_{m+2}) + \frac{37}{49} + \frac{12}{49}(m+2)^{\underline{7}}/(n+1)^{\underline{7}}$, and when $p=6$, $x_n/(n+1) = -\frac{12}{7}(H_{n-6} - H_{m-5})/(n+1)^{\underline{7}} + \frac{12}{49}/(m+2)^{\underline{7}} + \frac{37}{49}/(n+1)^{\underline{7}}$.

The above recurrence arises in the following ways in this problem, if we use $\lceil(l+r)/2\rceil$ in place of $\lfloor(l+r)/2\rfloor$ (cf. exercise 55):

Quantity	Value for $n\le m$	$b_n/\binom{n}{3}$ for $n>m$	Solution for $n>m$.
A_n	0	1	$(n+1)\big(\frac{12}{7}/(m+2)\big) - 1$
B_n	0	$\frac{2n-3}{10} + \frac{3}{32}\frac{\pi(\pi-2)}{(\pi-1)(\pi-3)}$	$(n+1)\big(\frac{12}{35}(H_{n+1} - H_{m+2}) + \frac{37}{245} - \frac{24}{56}/(m+2) + \cdots\big)$
C_n	0	$n+1$	$(n+1)\big(\frac{12}{7}(H_{n+1} - H_{m+2}) + \frac{37}{49}\big)$
D_n	$n-1$	0	$(n+1)\big(1 - \frac{24}{7}/(m+2)\big)$
E_n	$n(n-1)/4$	0	$(n+1)\big(\frac{6}{35}m - \frac{17}{35} + \frac{6}{7}/(m+2)\big)$
L_n	δ_{n1}	0	$(n+1)\big(\frac{24}{7}/(m+2)(m+1)m\big)$
X_n	0	$\frac{1}{2} - \frac{3}{4}\frac{n+1-\pi}{(\pi-1)(\pi-3)}$	$(n+1)\big(\frac{6}{7}/(m+2) - \cdots\big) - \frac{1}{2}$

Here $\bar{n} = 2\lceil n/2 \rceil$, and the solutions involve further terms of $O(n^{-6})$. The total average running time of the program in exercise 55 is $52\frac{1}{6}A_N + 14B_N + 4C_N + 12D_N + 8E_N - L_N + 8X_N + 15$; $M = 9$ and $M = 10$ are about equally good. With DIV instead of SRB, add $13A_N$ to the running time and take $M = 10$.

57. The asymptotic series for

$$\sum_{n>N} n^{-1}(1 - \alpha/N)^{n-N} = -N^{-1} + \sum_{k\geq 0} (N+k)^{-1}(1 - \alpha/N)^k$$

can be obtained by restricting k to $O(N^{1+\epsilon})$, expanding $(1 - \alpha/N)^k$ as $e^{-\alpha k/N}$ times $(1 - k\alpha^2/2N^2 + \cdots)$, and using Euler's summation formula; it comes to $e^\alpha E_1(\alpha)(1 + \alpha^2/2N) - (1+\alpha)/2N + O(N^{-2})$. Hence the asymptotic value of 5.2.1–11 is $N(\ln\alpha + \gamma + E_1(\alpha))/\alpha + (1 - e^{-\alpha}(1+\alpha))/2\alpha + O(N^{-1})$. [The coefficient of N is 0.7966, 0.6596, 0.2880, respectively, for $\alpha = 1, 2, 10$.] Note that $\ln\alpha + \gamma + E_1(\alpha) = \int_0^\alpha (1-e^{-t})t^{-1}dt$.

SECTION 5.2.3

1. No; but the method using ∞ (described just before Algorithm S) is stable.

2. Traversing a linear list stored sequentially in memory is often slightly faster if we scan the list from higher indices to lower, since it is usually easier to test if an index is zero than to test if it exceeds N. (For the same reason, the search in step S2 runs from j down to 1; but see exercise 8!)

3. (a) The permutation $a_1 \ldots a_{N-1}\ N$ occurs for inputs $N\ a_2 \ldots a_{N-1}\ a_1$, $a_1\ N\ a_3 \ldots a_{N-1}\ a_2$, $\ldots$, $a_1\ a_2 \ldots a_{N-2}\ N\ a_{N-1}$, $a_1 \ldots a_{N-1}\ N$. (b) The average number of times the maximum is changed during the first iteration of step S2 is $H_N - 1$, as shown in Section 1.2.10. [Hence B_N can be found from Eq. 1.2.7–8.]

4. If the input is a permutation of $\{1, 2, \ldots, N\}$, the number of times $i = j$ in step S3 is exactly one less than the number of cycles in the permutation. (Indeed, it is not hard to show that steps S2 and S3 simply remove element j from its cycle; hence S3 is inactive only when j was the smallest element in its cycle.) By Eq. 1.3.3–21 we could save $H_N - 1$ of the $N - 1$ executions of step S3, on the average.

Thus it is inefficient to insert an extra test "$i = j$?" before step S3. Instead of testing i vs. j, however, we could lengthen the program for S2 slightly, duplicating part of the code, so that S3 never is encountered if the initial guess K_j is not changed during the search for the maximum; this would make Program S a wee bit faster.

5. $(N-1) + (N-3) + \cdots = \lfloor N^2/4 \rfloor$.

6. (a) If $i \neq j$ in step S3, that step decreases the number of inversions by $2m - 1$, where m is one more than the number of keys in $K_{i+1} \ldots K_{j-1}$ lying between K_i and K_j; clearly m is not less than the contribution to B on the previous step S2. Now apply the observation of exercise 4, connecting cycles to the condition $i = j$. (b) Every permutation can be obtained from $N \ldots 2\ 1$ by successive interchanges of adjacent elements that are out of order. (Apply, in reverse sequence, the interchanges that sort the permutation into decreasing order.) Each such operation decreases I by one and changes C by ± 1. Hence no permutation has a value of $I - C$ which exceeds the corresponding value for $N \ldots 2\ 1$. [By exercise 5 the inequality $B \leq \lfloor N^2/4 \rfloor$ is best possible.]

7. [When $N = 5$ the generating function is $\frac{1}{120}(1 + 4z + 15z^2 + 30z^3 + 37z^4 + 26z^5 + 7z^6)$.]

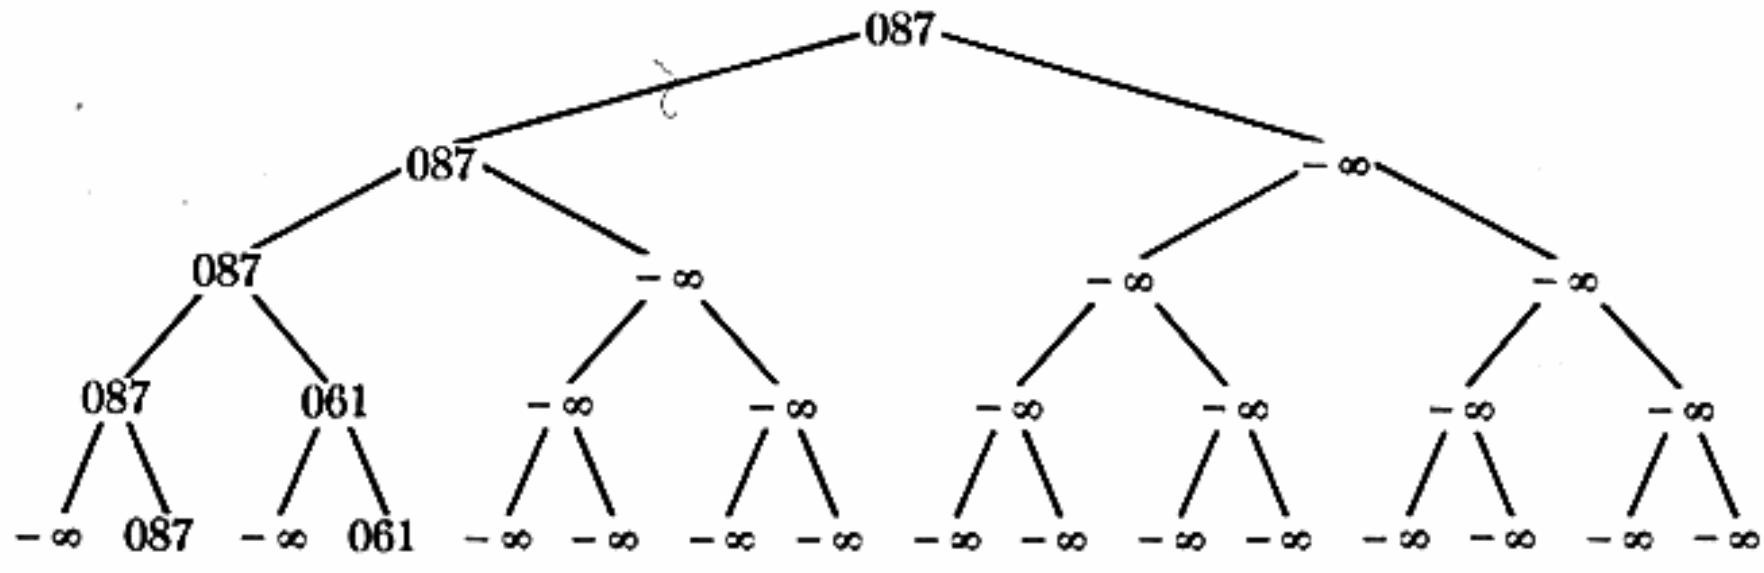
8. We can start the next iteration of step S2 at position K_i, provided that we have remembered max $(K_1, \ldots, K_{i-1})$. One way to keep all of this auxiliary information is to use a link table $L_1 \ldots L_N$ such that K_{L_k} is the previous boldface element whenever K_k is boldface; $L_1 = 0$. [We could also use less auxiliary storage, at the expense of some redundant comparisons.]

The following MIX program uses address modification so that the inner loop is fast. rI1 $\equiv j$, rI2 $\equiv k - j$, rI3 $\equiv i$, rA $\equiv K_i$.

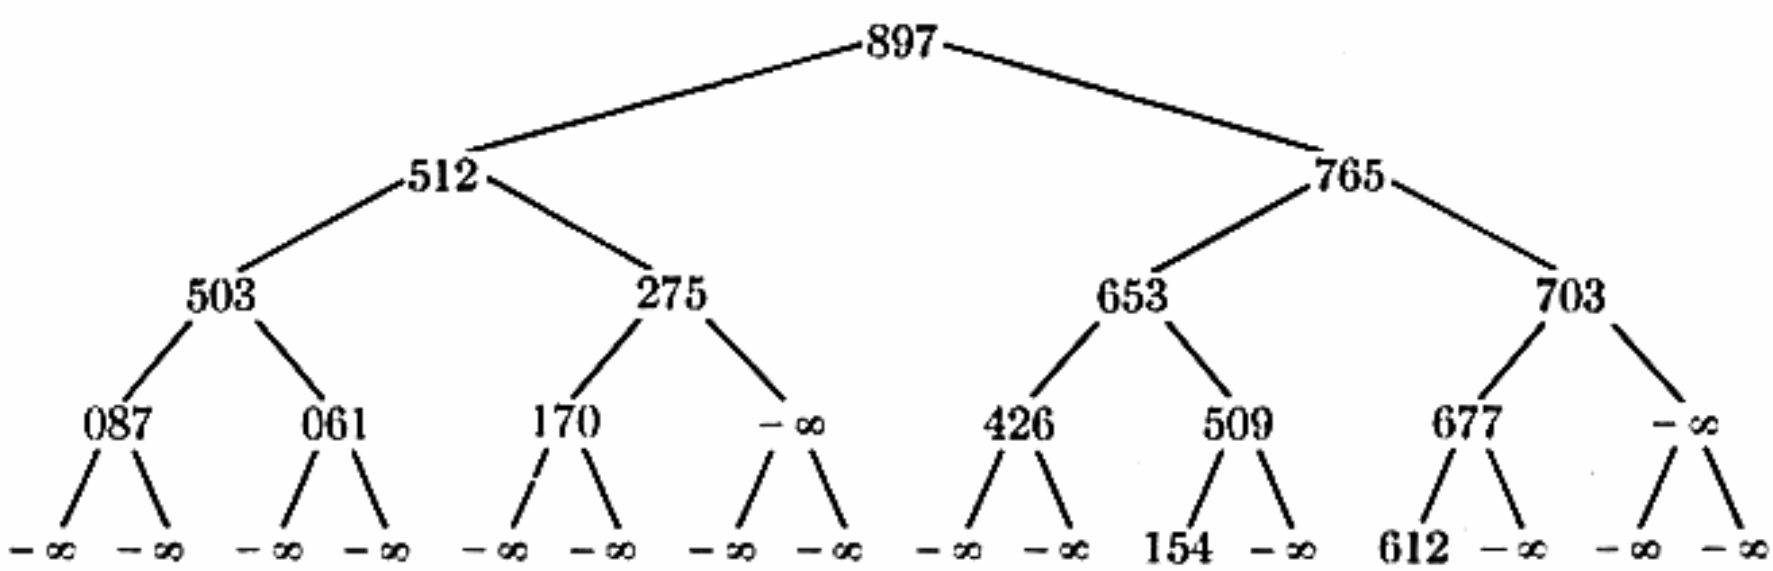
```
01  START  ENT1  N              1          j ← N.
02         STZ   LINK+1         1
03         JMP   9F             1
04  1H     ST1   6F(0:2)        N - D      Modify addresses in loop.
05         ENT4  INPUT,1        N - D
06         ST4   7F(0:2)        N - D
07         ENT4  LINK,1         N - D
08         ST4   8F(0:2)        N - D
09  7H     CMPA  INPUT+J,2      A                          [Address modified]
10         JGE   *+4            A          Jump if K_i ≥ K_k.
11  8H     ST3   LINK+J,2       N + 1 - C  Otherwise L_k ← i, [Address modified]
12  6H     ENT3  J,2            N + 1 - C  i ← k.          [Address modified]
13         LDA   INPUT,3        N + 1 - C
14         INC2  1              A          k ← k + 1
15         J2NP  7B             A          Jump if k ≤ j.
16  4H     LDX   INPUT,1        N
17         STX   INPUT,3        N          R_i ← R_j.
18         STA   INPUT,1        N          R_j ← former R_i.
19         DEC1  1              N          j ← j - 1.
20         ENT2  0,3            N          rI2 ← i.
21         LD3   LINK,3         N          i ← L_i.
22         J3NZ  5F             N          If i > 0, k will start at i.
23  9H     ENT3  1              C          Otherwise i ← 1;
24         ENT2  2              C          k will start at 2.
25  5H     DEC2  0,1            N + 1
26         LDA   INPUT,3        N + 1      rA ← K_i.
27         J2NP  1B             N + 1      Jump if k ≤ j.
28         J1P   4B             D + 1      Jump if j > 0.  ∎
```

9. $N - 1 + \sum_{N \ge k \ge 2} ((k-1)/2 - 1/k) = \frac{1}{2}\binom{N}{2} + N - H_N$. [The average values of C and D are, respectively, $H_N + 1$ and $H_N - \frac{1}{2}$; hence the average running time of the program is $(1.25N^2 + 31.75N - 15H_N + 14.5)u$.] Program H is much better.

10.



11.



12. $2^n - 1$, once for each "$-\infty$" in a branch node.

13. If $K \geq K_{r+1}$, then step H4 may go to step H5 if $j = r$. (Step H5 is inactive unless $K_r < K_{r+1}$, when step H6 will go to H8 anyway.) To ensure that $K \geq K_{r+1}$ throughout the algorithm, we may start with $K_{N+1} \leq \min(K_1, \ldots, K_N)$; instead of setting $R_r \leftarrow R_1$ in step H2, set $R_{r+1} \leftarrow R_{N+1}$ and $R_{N+1} \leftarrow R_1$; also set $R_2 \leftarrow R_{N+1}$ after $r = 1$. (This trick does not speed up the algorithm nor does it make Program H any shorter.)

14. When inserting an element, give it a key which is less (or greater) than all previously assigned keys, to get the effect of a simple queue (or stack, respectively).

15. For efficiency, the following solution is a little bit tricky, avoiding all multiples of 3 [*CACM* **10** (1967), 570].

a) Set $p[1] \leftarrow 2$, $p[2] \leftarrow 3$, $k \leftarrow 2$, $n \leftarrow 5$, $d \leftarrow 2$, $r \leftarrow 1$, $t \leftarrow 25$, and place (25, 10, 30) in the priority queue. (In this algorithm, $p[i] =$ ith prime; $k =$ number of primes found so far; $n =$ prime candidate; $d =$ distance to next candidate; $r =$ number of elements in the queue; $t = p[r+2]^2$, the next n for which we should increase r. The queue entries have the form $(u, v, 6p)$, where p is the smallest prime divisor of u, $v = 2p$ or $4p$, and $u + v$ is not a multiple of 3.)

b) Let (q, q', q'') be the queue element having the smallest first component. If $n \neq q$, set $k \leftarrow k+1$, $p[k] \leftarrow n$, $n \leftarrow n + d$, $d \leftarrow 6 - d$, and repeat this step until either $n > N$ or $n = q$.

c) If $n = t$, set $r \leftarrow r+1$, $u \leftarrow p[r+2]$, $t \leftarrow u^2$ and insert $(t, 2u, 6u)$ or $(t, 4u, 6u)$ into the queue according as $u \bmod 3 = 2$ or $u \bmod 3 = 1$.

d) Replace (q, q', q'') in the queue by $(q + q', q'' - q', q'')$. Set $n \leftarrow n + d$, $d \leftarrow 6 - d$, and return to (b).

Thus the computation begins as follows:

Queue contents	Primes found
(25, 10, 30)	5, 7, 11, 13, 17, 19, 23
(35, 20, 30)(49, 28, 42)	29, 31
(49, 28, 42)(55, 10, 30)	37, 41, 43, 47
(55, 10, 30)(77, 14, 42)(121, 22, 66)	53

Note that the queue entries always have distinct first components. If the queue is maintained as a heap, we can find all primes $\leq N$ in $O(N \log N)$ steps; the length of the heap is at most the number of primes $\leq \sqrt{N}$. The sieve of Eratosthenes (exercise 4.5.4–8) is a $O(N)$ method requiring considerably more random-access storage.

16. *Step 1.* Set $K \leftarrow$ key to be inserted; $j \leftarrow n + 1$.
Step 2. Set $i \leftarrow \lfloor j/2 \rfloor$.
Step 3. If $i = 0$ or $K_i \geq K$, set $K_j \leftarrow K$ and terminate the algorithm.
Step 4. Set $K_j \leftarrow K_i$, $j \leftarrow i$, and return to step 2.

17. The file 1 2 3 goes into the heap 3 2 1 with Algorithm H, but into 3 1 2 with exercise 16. (*Note:* The latter method of heap creation has a worst case of order $N \log N$; but empirical tests have shown that the number of iterations of step 2 during the creation of a heap is only about $2.27N - 32$, for random input.)

18. (For convenience we assume the presence of an artificial key $K_0 \geq \max(K_1, \ldots, K_N)$.) Delete step H6, and replace H8 by:

H8′. [Move back up.] Set $j \leftarrow i$, $i \leftarrow \lfloor j/2 \rfloor$.

H9′. [Does K fit?] If $K \leq K_i$, set $K_j \leftarrow K$ and return to H2. Otherwise set $K_j \leftarrow K_i$ and return to H8′. ∎

The method is essentially the same as in exercise 16, but with a different starting place in the heap. The net change to the file is the same as in Algorithm H. Empirical tests on this method show that the number of times $K_j \leftarrow K_i$ occurs per siftup during the selection phase is (0, 1, 2) with respective probabilities (.848, .135, .016). This method makes Program H somewhat longer but improves its asymptotic speed to $13N \log_2 N + O(N)$. An instruction to halve the value of an index register would be desirable.

19. Proceed as in the revised sift-up algorithm of exercise 18, with $K = K_N$, $l = 1$, $r = N - 1$, starting with a given value of j in step H3.

20. For $0 \leq k \leq n$, the number of positive integers $\leq N$ whose binary representation has the form $(b_n \ldots b_k a_1 \ldots a_q)_2$ for some $q \geq 0$ is clearly $\sum_{0 \leq q < k} 2^q + (b_{k-1} \ldots b_0)_2 + 1 = (1 b_{k-1} \ldots b_0)_2$.

21. Let $j = (c_r \ldots c_0)_2$ be in the range $\lfloor N/2^{k+1} \rfloor = (b_n \ldots b_{k+1})_2 < j < (b_n \ldots b_k)_2 = \lfloor N/2^k \rfloor$. Then s_j is the number of positive integers $\leq N$ whose binary representation has the form $(c_r \ldots c_0 a_1 \ldots a_q)_2$ for some $q \geq 0$, namely $\sum_{0 \leq q < k} 2^q = 2^{k+1} - 1$. Hence the number of nonspecial subtrees of size $2^{k+1} - 1$ is

$$\lfloor N/2^k \rfloor - \lfloor N/2^{k+1} \rfloor - 1 = \lfloor (N - 2^k)/2^{k+1} \rfloor.$$

[For the latter identity, use the replicative law in exercise 1.2.4–38 with $n = 2$ and $x = N/2^{k+1}$.]

22. Before $l = 1$ the five possibilities are 5 3 4 1 2, 3 5 4 1 2, 4 3 5 1 2, 1 5 4 3 2, 2 5 4 1 3. Each of these possibilities $a_1 a_2 a_3 a_4 a_5$ leads to three possible permutations $a_1 a_2 a_3 a_4 a_5$, $a_1 a_4 a_3 a_2 a_5$, $a_1 a_5 a_3 a_4 a_2$ before $l = 2$.

23. (a) After B iterations, $j \geq 2^B l$; hence $2^B l \leq r$. (b) $\sum_{1 \leq l \leq N} \lfloor \log_2 (N/l) \rfloor = (\lfloor N/2 \rfloor - \lfloor N/4 \rfloor) + 2(\lfloor N/4 \rfloor - \lfloor N/8 \rfloor) + 3(\lfloor N/8 \rfloor - \lfloor N/16 \rfloor) + \cdots = \lfloor N/2 \rfloor + \lfloor N/4 \rfloor + \lfloor N/8 \rfloor + \cdots = N - \nu(N)$, where $\nu(N)$ is the number of ones in the binary representation of N. Also by exercise 1.2.4–42 we have $\sum_{1 \leq r < N} \lfloor \log_2 r \rfloor = N \lfloor \log_2 N \rfloor - 2^{\lfloor \log_2 N \rfloor + 1} + 2$. We know by Theorem H that this upper bound on B is best possible during the heap creation phase. Furthermore it is interesting to note that there is a unique heap containing the keys $\{1, 2, \ldots, N\}$ such that K is identically equal to 1 throughout the selection phase of Algorithm H. (For example, when $N = 7$ that heap is 7 5 6 2 4 3 1; it is not difficult to pass from N to $N + 1$.) This heap gives the maximum value of B (as well as the maximum value $\lfloor N/2 \rfloor$ of D) for the selection phase of heapsort, so the best possible upper bound on B for the entire sort is $N - \nu(N) + N \lfloor \log_2 N \rfloor - 2^{\lfloor \log_2 N \rfloor + 1} + 2$.

24. $\sum_{1 \leq k \leq N} \lfloor \log_2 k \rfloor^2 = (N + 1 - 2^n) n^2 + \sum_{0 \leq k < n} k^2 2^k = (N + 1) n^2 - 6 -$

$(2n-3)2^{n+1}$, where $n = \lfloor \log_2 N \rfloor$ (cf. exercise 4.5.2–23); hence the variance of the last sift-up is $\beta_N = \big((N+1)n^2 - (2n-3)2^{n+1} - 6\big)/N - \big((N+1)n + 2 - 2^{n+1}\big)^2/N^2 = O(1)$. The standard deviation of B'_N is $(\sum_{s \in M_N} \beta_s)^{1/2} = O(\sqrt{N})$.

25. The sift-up is "uniform," and each comparison $K_j : K_{j+1}$ has probability $\frac{1}{2}$ of coming out $<$. The average contribution to C in this case is just one-half the sum of the average contributions to A and B, namely $\big((2n-3)2^{n-1} + \frac{1}{2}\big)/(2^{n+1}-1)$.

26. (a) $(\frac{10}{25} + \frac{1}{2} + 1\frac{3}{9} + \frac{1}{2} + 1\frac{1}{2} + 1\frac{2}{5} + 2\frac{1}{2} + \frac{1}{2} + 1\frac{1}{2} + 1\frac{1}{2} + 2\frac{1}{2} + 1\frac{1}{2} + 2 + 2 + 3 + 0 + 1 + 1 + 2 + 1 + 2 + 2 + 3 + 1 + 2 + 2)/26$. (b) $\big(\sum_{1 \le k \le N} \nu(k) - N + \frac{1}{2}\lfloor N/2 \rfloor - \frac{1}{2}n + \sum_{1 \le k < n} \min(\alpha_{k-1}, \alpha_k - \alpha_{k-1} - 1)/(\alpha_k - 1)\big)/N$, where $\nu(k)$ is the number of one bits in the binary representation of k, and $\alpha_k = (1b_k \ldots b_0)_2$. If $N = 2^{e_1} + 2^{e_2} + \cdots + 2^{e_t}$, with $e_1 > e_2 > \cdots > e_t \ge 0$, it can be shown that $\sum_{0 \le k \le N} \nu(k) = \frac{1}{2}\big((e_1+2)2^{e_1} + (e_2+4)2^{e_2} + \cdots + (e_t+2t)2^{e_t}\big) + t - N$.

27. In general, the Lambert series $\sum_{n \ge 1} a_n x^n/(1-x^n) = \sum_{N \ge 1} (\sum_{d \backslash n} a_d) x^N = \sum_{m \ge 1} x^{m^2}(a_m + \sum_{k \ge 1} (a_m + a_{m+k}) x^{km})$.

[Note that when $a_n = n$ and $x = \frac{1}{2}$ we obtain the relation

$$\beta = \sum_{n \ge 1} \frac{1}{2^n - 1} = \sum_{n \ge 1} 2^{-n^2} \left(n \left(\frac{2^n + 1}{2^n - 1} \right) + \frac{2^n}{(2^n-1)^2} \right) = 2.74403\ 38887\ 59488\ldots;$$

this constant arises in (20), where we have $B'_N \sim (\beta - 2)N$ and $C'_N \sim (\frac{1}{2}\beta - \frac{1}{4}\alpha - \frac{1}{2})N$.]

28. The sons of node k are nodes $3k-1$, $3k$, and $3k+1$. A MIX program analogous to Program H will take asymptotically $21\frac{2}{3} N \log_3 N \approx 13.7 N \log_2 N$ units of time. Using the idea of exercise 18 lowers this to $18\frac{2}{3} N \log_3 N \approx 11.8 N \log_2 N$, although the division by 3 will add a large $O(N)$ term.

31. Let A, B be arrays of n elements each such that $A[\lfloor i/2 \rfloor] \le A[i]$ and $B[i] \le B[\lfloor i/2 \rfloor]$ for $1 < i \le n$; furthermore we require that $A[i] \le B[i]$ for $1 \le i \le n$. (The latter condition holds for all i iff it holds for $n/2 < i \le n$, because of the heap structure.) This "twin-heap" contains $2n$ elements; to handle an odd number of elements, we simply keep one element off to the side. Appropriate modifications of the other algorithms in this section can be used to maintain twin heaps, and it is interesting to work out the details.

32. Let P, Q point to the given priority queues; for brevity, the following algorithm uses the convention DIST(Λ) = 0.

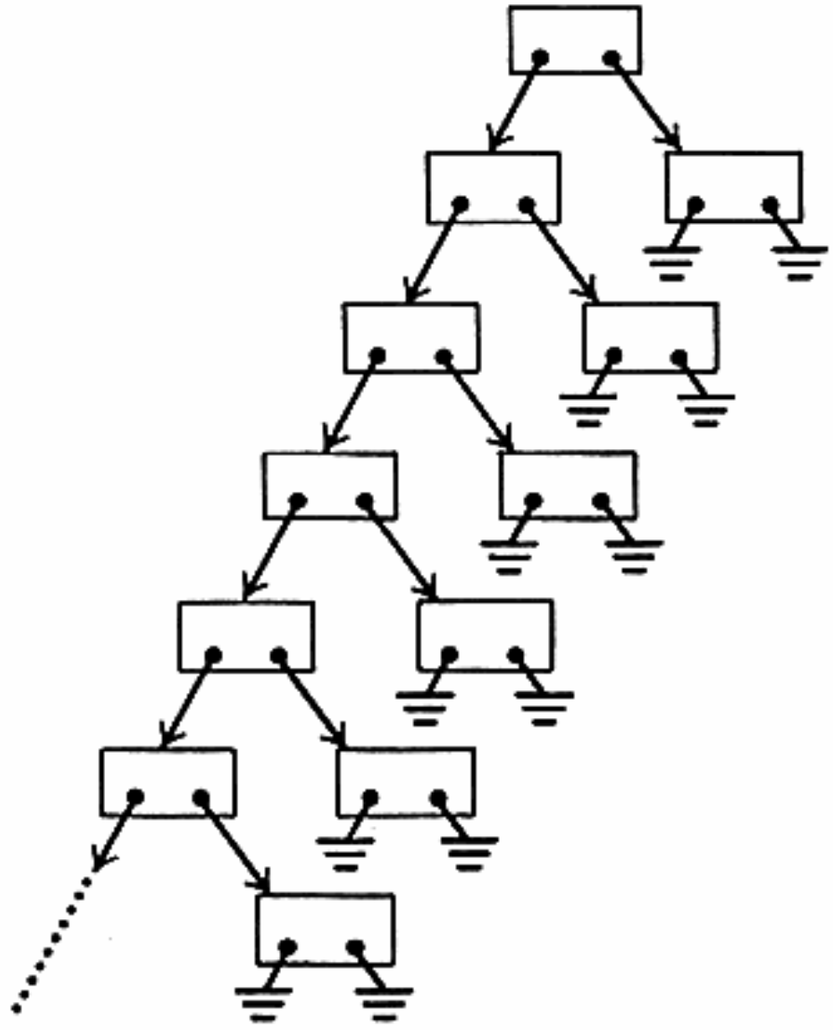
M1. [Initialize.] Set R ← Λ.

M2. [List merge.] If Q = Λ, set D ← DIST(P) and go to M3. If P = Λ, set P ← Q, D ← DIST(P), and go to M3. Otherwise if KEY(P) ≥ KEY(Q), set T ← RIGHT(P), RIGHT(P) ← R, R ← P, P ← T and repeat step M2. If KEY(P) > KEY(Q), set T ← RIGHT(Q), RIGHT(Q) ← R, R ← Q, Q ← T and repeat step M2. (This step essentially merges the two "right lists" of the given trees, temporarily inserting upward pointers into the RIGHT fields.)

M3. [Done?] If R = Λ, terminate the algorithm; P points to the answer.

M4. [Fix DISTs.] Set Q ← RIGHT(R). If DIST(LEFT(R)) < D, then set D ← DIST(LEFT(R)) + 1, RIGHT(R) ← LEFT(R), LEFT(R) ← P; otherwise set D ← D + 1, RIGHT(R) ← P. Finally set DIST(R) ← D, R ← Q, P ← R, and return to M3. ∎

33. We might have to promote about half the nodes in a lop-sided tree such as



34. Let the number be L_{N+1}. It is not difficult to prove that $L_{m+n} \leq L_m L_n$, hence (taking logarithms) $\lim L_n^{1/n}$ exists. (This suggestion is due to D. A. Klarner. Some calculations by E. Logg suggest that $L_{n+1}/L_n \geq L_n/L_{n-1}$ may hold for all n.)

35. Let the DIST field of the deleted node be d_0, and let the DIST field of the merged subtrees be d_1. If $d_0 = d_1$, we need not go up at all. If $d_0 > d_1$, and if we go up n levels, the new DIST fields of the ancestors of P must be, respectively, $d_1 + 1$, $d_1 + 2$, $\ldots$, $d_1 + n$. If $d_0 < d_1$, the upward path must go only leftwards.

36. Instead of a general priority queue, it is simplest to use a doubly-linked list; when "using" a node, move it to one end of the list, and delete nodes from the other end. [See the discussion of "self-organizing files" in Section 6.1.]

SECTION 5.2.4

1. Start with $i_1 = \cdots = i_k = 1$, $j = 1$. Repeatedly find $\min(x_{1i_1}, \ldots, x_{ki_k}) = x_{ri_r}$ and set $z_j \leftarrow x_{ri_r}$, $j \leftarrow j + 1$, $i_r \leftarrow i_r + 1$. (In this case the use of $x_{i(m_i+1)} = \infty$ is a decided convenience.)

When k is moderately large, it is desirable to keep the keys $x_{1i_1}, \ldots, x_{ki_k}$ in a tree structure suited to repeated selection, as discussed in Section 5.2.3, so that only $\lfloor \log_2 k \rfloor$ comparisons are needed to find the new minimum each time after the first. Indeed this is a typical application of the principle of "smallest in, first out" in a priority queue. The keys can be maintained as a heap, and ∞ can be avoided entirely. See the further discussion in Section 5.4.1.

2. Let C be the number of comparisons; we have $C = m + n - S$, where S is the number of elements transmitted in step M4 or M6. The probability that $S \geq s$ is easily seen to be

$$q_s = \left(\binom{m+n-s}{m} + \binom{m+n-s}{n} \right) \Big/ \binom{m+n}{m}$$

for $1 \le s \le m+n$; $q_s = 0$ for $s > m+n$. Hence the mean of S is $\mu_{mn} = q_1 + q_2 + \cdots = m/(n+1) + n/(m+1)$ [cf. exercises 3.4.2–5, 6], and the variance is $\sigma^2_{mn} = (q_1 + 3q_2 + 5q_3 + \cdots) - \mu^2_{mn} = m(2m+n)/(n+1)(n+2) + (m+2n)n/(m+1)(m+2) - \mu^2_{mn}$. Thus

$$C = (\min\ \min(m, n), \quad \text{ave}\ m+n-\mu_{mn}, \quad \max\ m+n-1, \quad \text{dev}\ \sigma_{mn}).$$

When $m = n$ the average was first computed by H. Nagler, *CACM* **3**(1960), 618–620; it is asymptotically $2n - 2 + O(n^{-1})$, with a standard deviation of $\sqrt{2} + O(n^{-1})$. Thus C hovers close to its maximum value.

3. M2′. If $K_i < K'_j$, go to M3′; if $K_i = K'_j$, go to M7′; if $K_i > K'_j$, go to M5′.

M7′. Set $K''_k \leftarrow K'_j$, $k \leftarrow k+1$, $i \leftarrow i+1$, $j \leftarrow j+1$. If $i > M$, go to M4′; otherwise if $j > N$, go to M6′; otherwise return to M2′. ▮

(Appropriate modifications are made to other steps of Algorithm M. Again many special cases disappear if we insert artificial keys $K_{M+1} = K'_{N+1} = \infty$ at the end of the files.)

4. The sequence of elements which appears at a fixed internal node of the selection tree, as time passes, is obtained by merging the sequences of elements which appear at the sons of that node. (The discussion in Section 5.2.3 is based on selecting the *largest* element, but it could equally well have reversed the order.) So the operations involved in tree selection are essentially the same as those involved in merging, but they are performed in a different sequence and using different data structures.

Another relation between merging and tree selection is indicated in exercise 1. Note that an N-way merge of one-element files is a selection sort; compare also four-way merging of (A, B, C, D) to two-way merging of (A, B), (C, D), then (AB, CD).

5. In step N6 we always have $K_i < K_{i-1} \le K_j$; in N10, $K_j < K_{j+1} < K_i$.

6. 2 6 4 10 8 14 12 16 15 11 13 7 9 3 5 1. After one pass we have 1 2 5 6 7 8 13 14 16 15 12 11 10 9 4 3 (two of the expected stepdowns disappear). This possibility was noted by D. A. Bell, *Comp. J.* **1** (1958), 74. Quirks like this make it almost hopeless to carry out a precise analysis of Algorithm N.

7. $\lceil \log_2 N \rceil$, if $N > 1$. (Consider how many times p must be doubled until it is $\ge N$.)

8. If N is not a multiple of $2p$, there is one short run on the pass, and it is always near the middle; letting its length be t, we have $0 \le t < p$, and the situation is essentially $x_1 \le x_2 \le \cdots \le x_p \mid y_t \ge \cdots \ge y_1$. If $x_p \le y_t$, the left-hand run is exhausted first, and step S6 will take us to S13 after x_p has been transmitted. On the other hand, if $t = 0$ or $x_p > y_t$, the right-hand side will be artificially exhausted, but $K_j = x_p$ will never be $< K_i$ in step S3! Thus S6 will eventually take us to S13 in all cases.

10. For example, Algorithm M can merge elements $x_{j+1} \ldots x_{j+m}$ with $x_{j+m+1} \ldots x_{j+m+n}$ into positions $x_1 \ldots x_{m+n}$ of an array without conflict, if $j \ge n$. With care we can exploit this idea so that $N + 2^{\lfloor \log_2 N \rfloor - 1}$ locations are required for an entire sort. But the program seems to be rather complicated compared to Algorithm S. [*Comp. J.* **1** (1958), 75; see also L. S. Lozinskiĭ, *Kibernetika* **1**, 3 (1965), 58–62.]

11. Yes. This can be seen, for example, by considering the relation to tree selection mentioned in exercise 4. But Algorithms N and S are obviously not stable.

12. Set $L_0 \leftarrow 1$, $t \leftarrow N+1$; then for $p = 1, 2, \ldots, N-1$, do the following:

If $K_p \le K_{p+1}$ set $L_p \leftarrow p+1$; otherwise set $L_t \leftarrow -(p+1)$, $t \leftarrow p$.

Finally set $L_t \leftarrow 0$, $L_N \leftarrow 0$, $L_{N+1} \leftarrow |L_{N+1}|$.

(Stability is preserved. The number of passes is $\lceil \log_2 r \rceil$, where r is the number of ascending runs in the input; the exact distribution of r is analyzed in Section 5.1.3. We may conclude that "natural" merging is preferable to "straight" merging when linked allocation is being used, although it was inferior for sequential allocation.)

13. The running time for $N \ge 3$ is $(11A + 6B + 3B' + 9C + 2C'' + 4D + 5N + 9)u$, where A is the number of passes; $B = B' + B''$ is the number of subfile-merge operations performed, where B' is the number of such merges in which the p subfile was exhausted first; $C = C' + C''$ is the number of comparisons performed, where C' is the number of such comparisons with $K_p \le K_q$; $D = D' + D''$ is the number of elements remaining in subfiles when the other subfile has been exhausted, where D' is the number of such elements belonging to the q subfile.

Algorithm L does a sequence of merges on subfiles whose sizes (m, n) can be determined as follows: Let $N - 1 = (b_k \ldots b_1 b_0)_2$ in binary notation. There are $(b_k \ldots b_{j+1})_2$ "ordinary" merges with $(m, n) = (2^j, 2^j)$, for $0 \le j < k$; and there are "special" merges with $(m, n) = (2^j, 1 + (b_{j-1} \ldots b_0)_2)$ whenever $b_j = 1$, for $0 \le j \le k$. For example when $N = 14$, there are six ordinary (1, 1) merges, three ordinary (2, 2) merges, one ordinary (4, 4) merge, and the special merges deal with subfiles of sizes (1, 1), (4, 2), (8, 6).

It follows that, regardless of the input distribution, we have $A = \lceil \log_2 N \rceil$, $B = N - 1$, $C' + D'' = \sum_{0 \le j \le k} b_j 2^j (1 + \frac{1}{2}j)$, $C'' + D' = \sum_{0 \le j \le k} b_j (1 + 2^j(\frac{1}{2}j + b_{j+1} + \cdots + b_k))$; hence only B', C', D' need to be analyzed further.

If the input to Algorithm L is random, each of the merging operations satisfies the conditions of exercise 2, and is independent of the behavior of the other merges; so the distribution of B', C', D' is the convolution of their individual distributions for each subfile merge. The average values for such a merge are $B' = n/(m+n)$, $C' = mn/(n+1)$, $D' = n/(m+1)$. Sum these over all relevant (m, n) to get the exact average values.

When $N = 2^k$ we have, of course, the simplest situation; $B'_{\text{ave}} = \frac{1}{2}B$, $C'_{\text{ave}} = \frac{1}{2}C_{\text{ave}}$, $C + D = kN$, and $D_{\text{ave}} = \sum_{1 \le j \le k} (2^{k-j} \cdot 2^j/(2^{j-1} + 1)) = \alpha' N + O(1)$, where $\alpha' = \sum_{n \ge 0} 1/(2^n + 1) = \alpha + \frac{1}{2} - 2\sum_{n \ge 1} 1/(4^n - 1) = 1.26449\ 97803\ 48444\ 20919\ 13197\ 47255\ 49848\ 25577$– can be evaluated to high precision as in exercise 5.2.3–27. This special case was first analyzed by A. Gleason [unpublished, 1956] and H. Nagler [*CACM* **3** (1960), 618–620].

In Table 3 we have $A = 4$, $B' = 6$, $B'' = 9$, $C' = 22$, $C'' = 22$, $D' = 10$, $D'' = 10$, total time $= 761u$. (The comparable Program 5.2.1L takes only $433u$, when improved as in exercise 5.2.1–33, so we can see that merging isn't especially efficient when N is small.)

14. Set $D = B$ in exercise 13 to maximize C.

15. Make extra copies of steps L3, L4, L6 for the cases that L_s is known to equal p or q. [A *further* improvement can also be made, removing the assignment $s \leftarrow p$ (or $s \leftarrow q$) from the inner loop, by simply renaming the registers! For example, change lines 20, 21 to "`LD3 INPUT,1(L)`" and continue with p in rI3, s in rI1 and L_s known

to equal p. With twelve copies of the inner loop, corresponding to the different permutations of (p, q, r) with respect to (rI1, rI2, rI3), and the different knowledge about L_s, we can cut the average running time to $8N \log_2 N + O(N)$.]

16. (The result will be slightly faster than Algorithm L, cf. exercise 5.2.3–28.)

17. Consider the new record as a subfile of length 1. Repeatedly merge the smallest two subfiles if they have the same length. (The resulting sorting algorithm is essentially the same as Algorithm L, but the subfiles are merged at different relative times.)

18. Yes, but it seems to be a complicated job. The simplest known method uses the following ingenious construction [*Dokladi Akad. Nauk SSSR* **186** (1969), 1256–1258]: Let n be $\approx \sqrt{N}$. Divide the file into $m+2$ "zones" $Z_1 \ldots Z_m Z_{m+1} Z_{m+2}$, where Z_{m+2} contains (N mod n) records while each other zone contains exactly n records. Interchange the records of Z_{m+1} with the zone containing R_M; the file now takes the form $Z_1 \ldots Z_m A$, where each of $Z_1 \ldots Z_m$ contains exactly n records in order and where A is an auxiliary area containing s records, for some s, where $n \le s < 2n$.

Find the zone with smallest leading element, and exchange that entire zone with Z_1. (This takes $O(m+n)$ operations.) Then find the zone with next smallest leading element, and exchange it with Z_2, etc. Finally in $O(m(m+n)) = O(N)$ operations we will have rearranged the m zones so that their leading elements are in order. Furthermore, because of our original assumptions about the file, each of the keys in $Z_1 \ldots Z_m$ now has less than n inversions.

We can merge Z_1 with Z_2, using the following trick: Interchange Z_1 with the first n elements A' of A; then merge Z_2 with A' in the usual way but exchanging elements with the elements of $Z_1 Z_2$ as they are output. For example, if $n = 3$ and $x_1 < y_1 < x_2 < y_2 < x_3 < y_3$, we have

	Zone 1	Zone 2	Auxiliary
Initial contents:	$x_1\ x_2\ x_3$	$y_1\ y_2\ y_3$	$a_1\ a_2\ a_3$
Exchange Z_1:	$a_1\ a_2\ a_3$	$y_1\ y_2\ y_3$	$x_1\ x_2\ x_3$
Exchange x_1:	$x_1\ a_2\ a_3$	$y_1\ y_2\ y_3$	$a_1\ x_2\ x_3$
Exchange y_1:	$x_1\ y_1\ a_3$	$a_2\ y_2\ y_3$	$a_1\ x_2\ x_3$
Exchange x_2:	$x_1\ y_1\ x_2$	$a_2\ y_2\ y_3$	$a_1\ a_3\ x_3$
Exchange y_2:	$x_1\ y_1\ x_2$	$y_2\ a_2\ y_3$	$a_1\ a_3\ x_3$
Exchange x_3:	$x_1\ y_1\ x_2$	$y_2\ x_3\ y_3$	$a_1\ a_3\ a_2$

(The merge is always complete when the nth element of the auxiliary area has been exchanged; this method generally permutes the auxiliary records.)

The above trick is used to merge Z_1 with Z_2, then Z_2 with Z_3, ..., Z_{m-1} with Z_m, requiring a total of $O(mn) = O(N)$ operations. Since no element has more than n inversions, the $Z_1 \ldots Z_m$ portion of the file has been completely sorted.

For the final "cleanup," we sort $R_{N+1-2s} \ldots R_N$ by insertion, in $O(s^2) = O(N)$ steps; this brings the s largest elements into area A. Then we merge $R_1 \ldots R_{N-2s}$ with $R_{N+1-2s} \ldots R_{N-s}$, using the above trick with auxiliary storage area A (but interchanging the roles of right and left, less and greater, throughout). Finally, we sort $R_{N+1-s} \ldots R_N$ by insertion.

19. We may number the input cars so that the final permutation has them in order, 1 2 . . . 2^n; so this is essentially a sorting problem. First move the first 2^{n-1} cars through $n - 1$ stacks, putting them in decreasing order, and transfer them to the nth stack so that the smallest is on top. Then move the other 2^{n-1} cars through $n - 1$ stacks, putting them into increasing order and leaving them positioned just before the nth stack. Finally, merge the two sequences together in the obvious way.

20. For further information, see R. E. Tarjan, *JACM* **19** (1972), 341–346.

SECTION 5.2.5

1. No, because radix sorting doesn't work at all unless the distribution sorting is stable, after the first pass. (But the suggested distribution sort *could* be used in a most-significant-digit-first radix sorting method, generalizing radix exchange, as suggested in the last paragraph of the text.)

2. It is "anti-stable," just the opposite; elements with equal keys appear in reverse order, since the first pass goes through the records from R_N to R_1. (This proves to be convenient because of lines 28 and 20 of Program R, equating Λ with 0, but of course it is not necessary to make the first pass go backwards.)

3. If pile 0 is not empty, `BOTM[0]` already points to the first element; if it is empty, we set `P` ← `LOC(BOTM[0])` and later make `LINK(P)` point to the bottom of the first nonempty pile.

4. When there are an even number of passes remaining, take pile 0 first (top to bottom), followed by pile 1, . . . , pile $(M - 1)$; the result will be in order with respect to the digits examined so far. When there are an odd number of passes remaining, take pile $(M - 1)$ first, then pile $(M - 2)$, . . . , pile 0; the result will be in *reverse* order with respect to the digits examined so far. (This rule was apparently first published by E. H. Friend [*JACM* **3** (1956), 156, 165–166]. See also an article by Donald W. Johnson [*Library Resources and Technical Services* **3** (1959), 300–310], who proposed radix sorting as a manual aid for putting library cards in order. Johnson says the University of California library at Berkeley found that radix sorting made it possible to alphabetize 2000 cards by hand in only 4.8 hours instead of 8.5 hours by previous methods.)

5. (a) There are k empty piles after the $(N + 1)$st element is placed iff (i) the $(N + 1)$st element falls into a previously empty pile, with probability $((k + 1)/M) \times p_{MN(k+1)}$; or (ii) it falls into a nonempty pile, with probability $((M - k)/M)p_{MNk}$. The recurrence

$$p_{M,N+1,k} = \frac{k+1}{M} p_{M,N,k+1} + \frac{M-k}{M} p_{M,N,k}$$

is equivalent to the stated formula. (b) The nth derivative satisfies $g^{(n)}_{M,N+1}(z) = (1 - n/M)g^{(n)}_{M,N}(z) + ((1 - z)/M)g^{(n+1)}_{M,n}(z)$, by induction on n. Setting $z = 1$, we find $g^{(n)}_{M,N}(1) = (1 - n/M)^N M^{\underline{n}}$, since $g_{M0}(z) = z^M$. Hence mean $(g_{MN}) = (1 - 1/M)^N M$, var $(g_{MN}) = (1 - 2/M)^N M(M - 1) + (1 - 1/M)^N M - (1 - 1/M)^{2N} M^2$. (Note that the generating function for E in Program R is $(g_{MN}(z))^p$.)

6. Change line 04 to "`ENT3 7`", and change the `R3SW` and `R5SW` tables to:

```
R3SW    LD2  KEY,1(1:1)
        LD2  KEY,1(2:2)
        LD2  KEY,1(3:3)
        LD2  KEY,1(4:4)
        LD2  KEY,1(5:5)
        LD2  INPUT,1(1:1)
        LD2  INPUT,1(2:2)
        LD2  INPUT,1(3:3)
R5SW    LD1  INPUT,1(LINK)
        ...  (repeat previous line six more times)
        DEC1 1
```

The new running time is found by changing "3" to "8" everywhere; it amounts to $(11p - 1)N + 16pM + 12p - 4E + 2$, for $p = 8$.

7. Let R = radix sort, RX = radix exchange. Some of the important similarities and differences: RX goes from most significant digit to least significant, while R goes the other way. Both methods sort by digit inspections, without making comparisons of keys. RX always has $M = 2$ (but see exercise 1). The running time for R is almost unvarying, while RX is sensitive to the distribution of the digits. In both cases the running time is $O(N \log K)$, where K is the range of keys, but the constant of proportionality is higher for RX; on the other hand, when the keys are uniformly distributed in their leading digits, RX has an average running time of $O(N \log N)$ regardless of the size of K. R requires link fields while RX runs in "minimal storage." The inner loop of R is more suited to "pipeline" computers.

8. On the final pass, the piles should be hooked together in another order; for example, if $M = 256$, pile $(10000000)_2$ comes first, then pile $(10000001)_2$, . . . , pile $(11111111)_2$, pile $(00000000)_2$, pile $(00000001)_2$, . . . , pile $(01111111)_2$. This change in hooking order can be done easily by modifying Algorithm H, or (in Table 1) by changing the storage allocation strategy, on the last pass.

9. We could first separate the negative keys from the positive keys, as in exercise 5.2.2–33; or we could change the keys to complement notation on the first pass. Alternatively, after the last pass we could separate the positive keys from the negative ones, reversing the order of the latter, although the method of exercise 5.2.2–33 no longer applies.

11. Without the first pass the method would still sort perfectly, because (by coincidence) 503 already precedes 509. Without the first two passes, the number of inversions would be $1 + 1 + 0 + 0 + 0 + 1 + 1 + 1 + 0 + 0 = 5$.

12. After exchanging R_k with $R[P]$ in step M4 (exercise 5.2–12), we can compare K_k to K_{k-1}. If K_k is less, we compare it to K_{k-2}, K_{k-3}, . . . , until finding $K_k \geq K_j$. Then set $(R_{j+1}, \ldots, R_{k-1}, R_k) \leftarrow (R_k, R_{j+1}, \ldots, R_{k-1})$, *without* changing the LINK fields. It is convenient to place an artificial key K_0, which is $\leq$ all other keys, at the left of the file.

14. If the original permutation of the cards requires k readings, in the sense of exercise 5.1.3–20, and if we use m piles per pass, we must make at least $\lceil \log_m k \rceil$ passes. (Consider going back from a sorted deck to the original one; the number of readings increases

by at most a factor of m on each pass.) The given permutation requires 4 increasing readings, 10 decreasing readings, so decreasing order requires 4 passes with two piles or 3 passes with three piles.

Conversely, this optimum number of passes can be achieved: Number the cards from 0 to $k - 1$ according to which reading it belongs to, and use a radix sort (least significant digit first in radix m). [Cf. *Martin Gardner's Sixth Book of Mathematical Games* (San Francisco: W. H. Freeman, 1971), 111–112.]

15. Let there be k readings and m piles. The order is reversed on each pass; if there are k readings in one order, the number of readings in the opposite order is $n + 1 - k$. The minimum number of passes is either the smallest even number greater than or equal to $\log_m k$ or the smallest odd number greater than or equal to $\log_m (n + 1 - k)$. (Going backwards, there are at most m decreasing readings after one pass, m^2 increasing readings after two passes, etc.) The example can be sorted into increasing order in $\min(2, 5) = 2$ passes, into decreasing order in $\min(3, 4) = 3$ passes, using only two piles.

SECTION 5.3.1

1. a) 
where A_{ij} = either 
or 
and B_{ijk} = 
External path length is 112 (optimum).

b) Here A_{ij} = 
where C_{ijkl} = 
External path length is 112 (optimum).

2. In the notation of exercise 5.2.4–14, $L(n) - B(n) = \sum_{1\le k\le t}\big((e_k+k-1)2^{e_k} - (e_1+1)2^{e_k}\big) + 2^{e_1+1} - 2^{e_t} = 2^{e_1} - 2^{e_t} - \sum_{2\le k\le t}(e_1 - e_k + 2 - k)2^{e_k} \ge 2^{e_1} -$

$(2^{e_1-1}+\cdots+2^{e_1-t+1}+2^{e_t})\geq 0$, with equality iff $n=2^k-2^j$ for some $k>j\geq 0$.

3. When $n>0$, the number of outcomes such that the smallest key appears exactly k times is $\binom{n}{k}P_{n-k}$. Thus $2P_n=\sum_k\binom{n}{k}P_{n-k}$, for $n>0$, and we have $2P(z)=e^zP(z)+1$. (Cf. Eq. 1.2.9–10.)

Another proof comes from the fact that $P_n=\sum_{k\geq 0}\left\{{n\atop k}\right\}k!$, since $\left\{{n\atop k}\right\}$ is the number of ways to partition n elements into k nonempty parts and these parts can be permuted in $k!$ ways. Thus $\sum_{n\geq 0}P_nz^n/n!=\sum_{k\geq 0}(e^z-1)^k=1/(2-e^z)$ by Eq. 1.2.9–23.

Still *another* proof, perhaps the most interesting, arises if we arrange the elements in sequence in a "stable" manner, so that K_i precedes K_j if and only if $K_i<K_j$ or $(K_i=K_j$ and $i<j)$. Among all P_n outcomes, a given arrangement $K_{a_1}\ldots K_{a_n}$ now occurs exactly 2^{k-1} times if the permutation $a_n\ldots a_1$ contains k runs; hence P_n can be expressed in terms of the Eulerian numbers, $P_n=\sum_k\left\langle{n\atop k}\right\rangle 2^{k-1}$. Eq. 5.1.3–20 with $z=2$ now establishes the desired result.

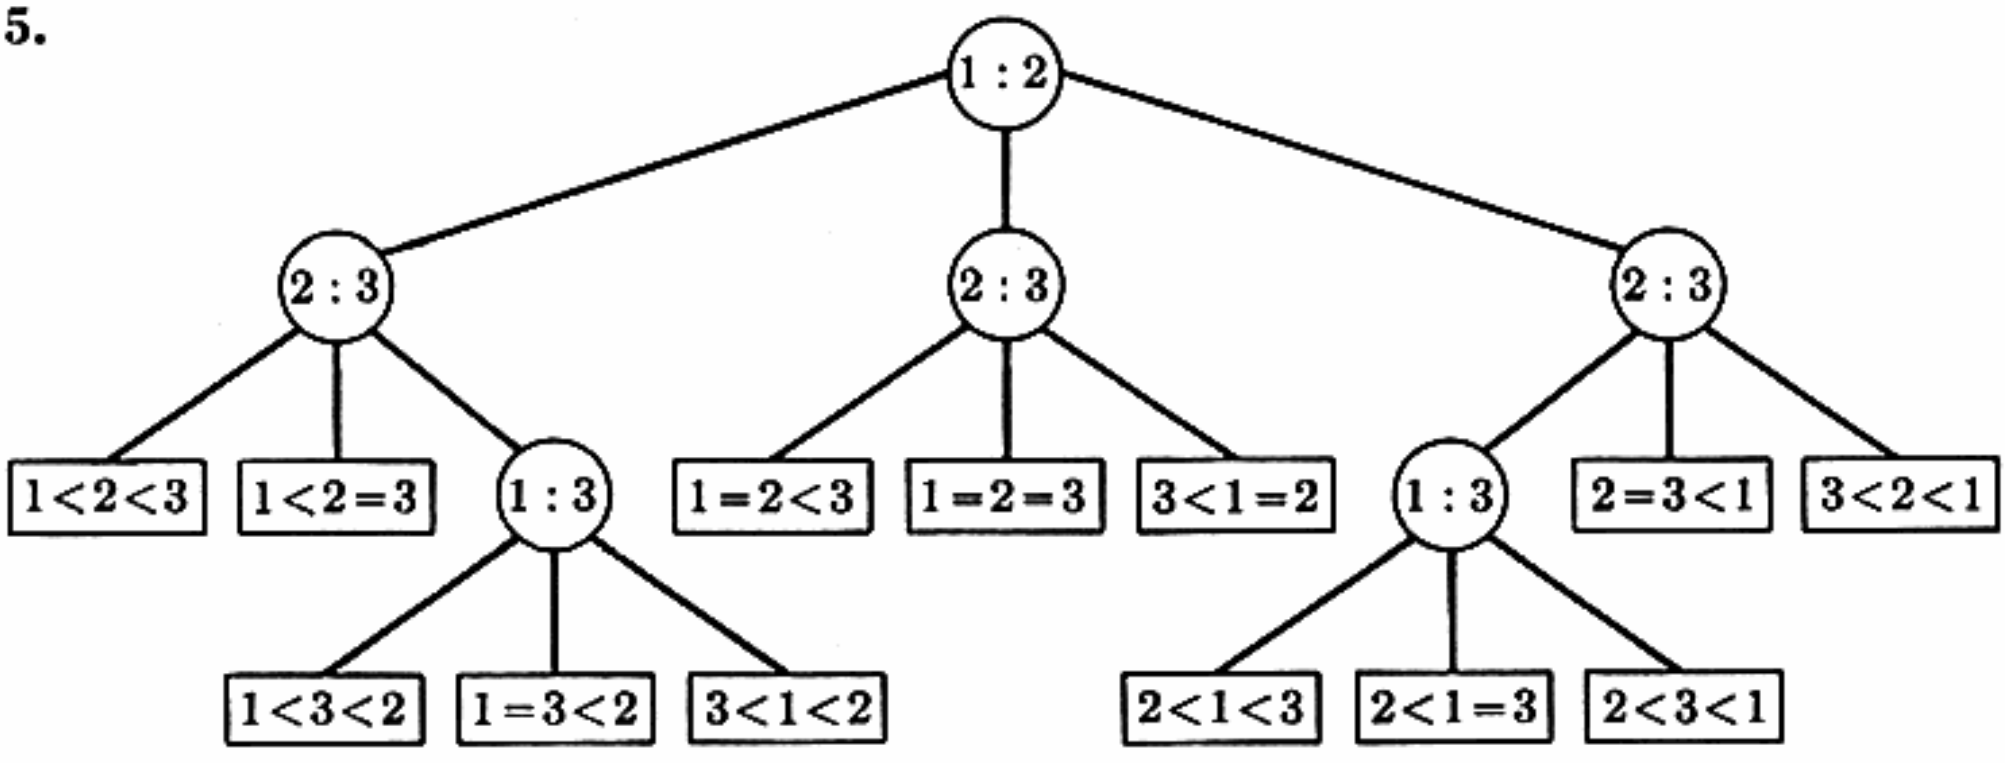
This generating function was obtained by A. Cayley [*Phil. Mag.* **18** (1859), 374–378] in connection with the enumeration of an imprecisely defined class of trees. See also J. Touchard, *Ann. Soc. Sci. Bruxelles* **53** (1933), 21–31. A table of $P_1,\ldots,P_{14}$ appears in O. A. Gross, *AMM* **69** (1962), 4–8; Gross gives the interesting formula $P_n=\sum_{k\geq 1}k^n/2^{1+k}$, $n\geq 1$.

4. The representation

$$2P(z)=\tfrac{1}{2}(1-i\cot(i(z-\ln 2)/2))$$
$$=\frac{1}{2}-\frac{1}{z-\ln 2}-\sum_{k\geq 1}\left(\frac{1}{z-\ln 2-2\pi ik}+\frac{1}{z-\ln 2+2\pi ik}\right)$$

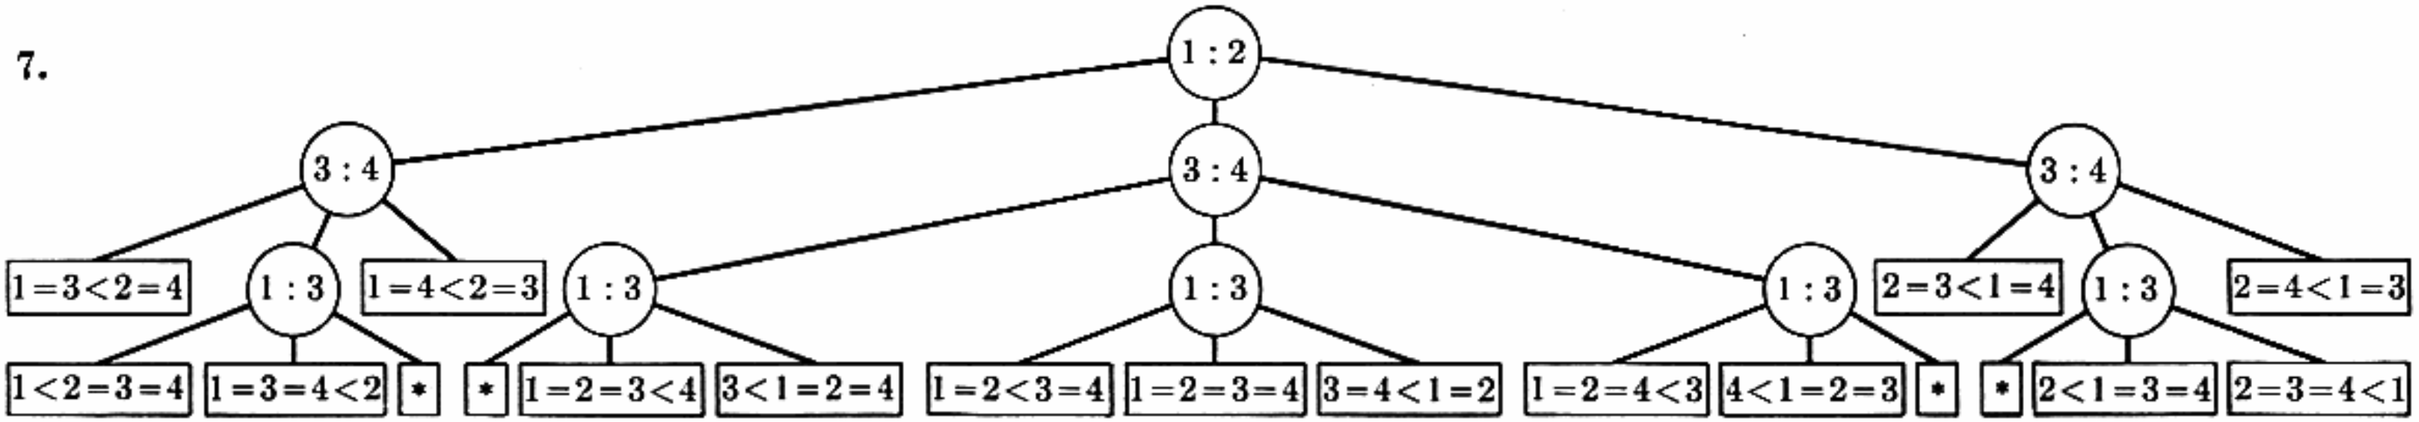
yields a convergent series $P_n/n!=\frac{1}{2}(\ln 2)^{-n-1}+\sum_{k\geq 1}\Re((\ln 2+2\pi ik)^{-n-1})$.

5.



6. $S'(n)\geq S(n)$, since the keys might all be distinct; thus we must show that $S'(n)\leq S(n)$. Given a sorting algorithm which takes $S(n)$ steps on distinct keys, we can construct a sorting algorithm for the general case by defining the $=$ branch to be identical to the $<$ branch, removing redundancies. When an external node appears, we know all of the equality relations, since we have $K_{a_1}\leq K_{a_2}\leq\cdots\leq K_{a_n}$ and an explicit comparison $K_{a_i}:K_{a_{i+1}}$ has been made for $1\leq i<n$.

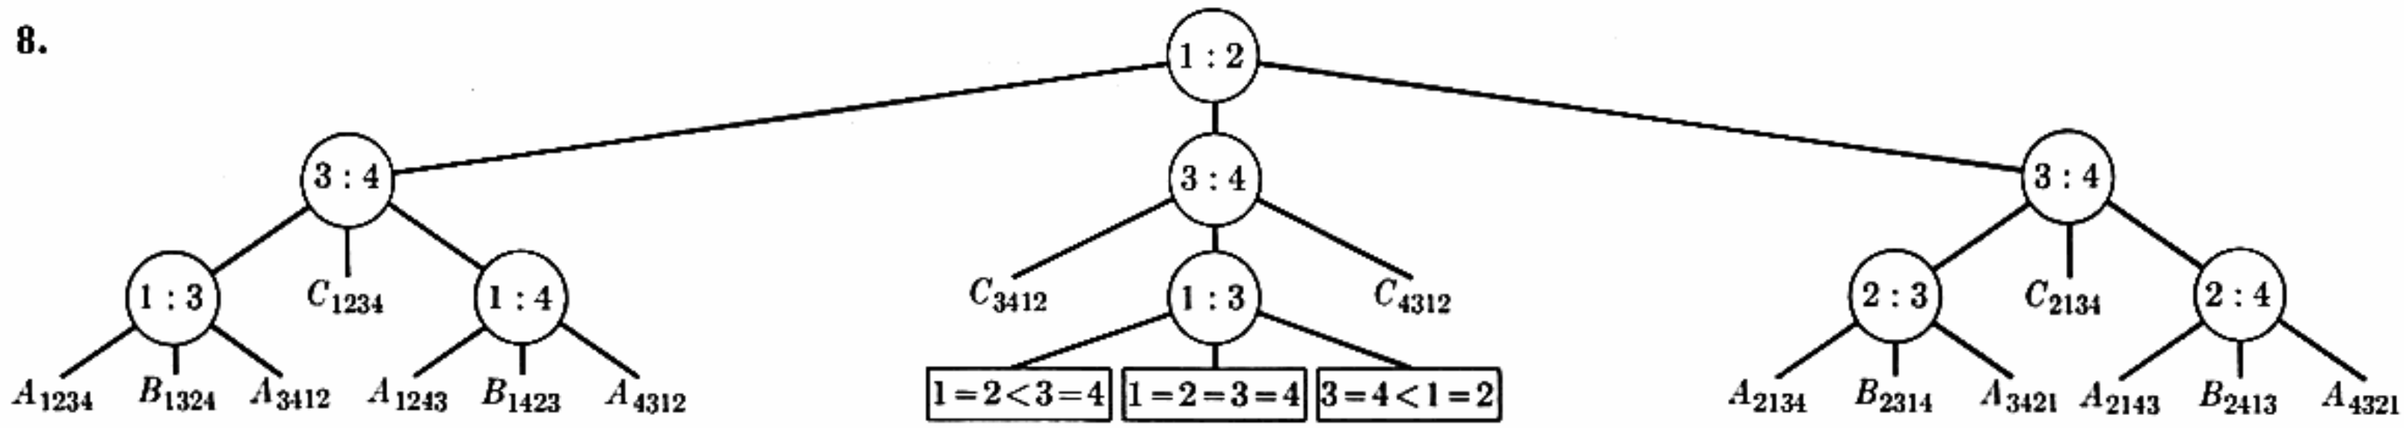
7.



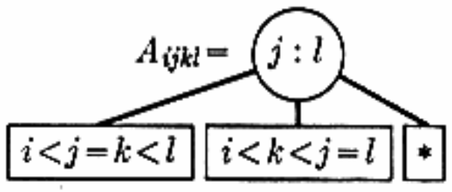
(* denotes an impossible case.)

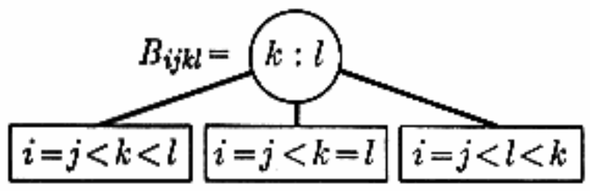
The average number of comparisons is $(2+3+3+2+3+3+3+6+3+3+3+2+3+3+2)/16 = 2\frac{3}{4}$.

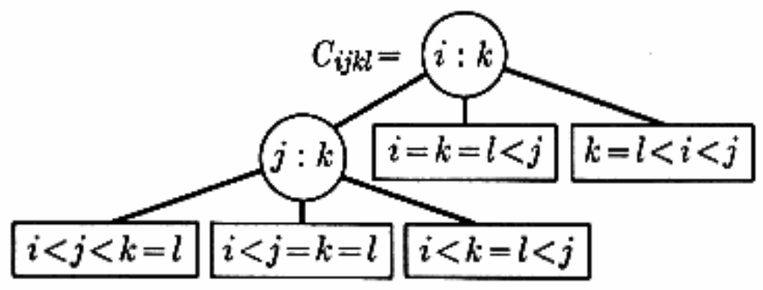
8.



where







Average number of comparisons is $3\frac{56}{81}$.

9. We need at least $n - 1$ comparisons to discover that all keys are equal, if they are. Conversely, $n - 1$ always suffices, since we can always deduce the final ordering after comparing K_1 with all of the other keys!

10. Let $f(n)$ be the desired function, and let $g(n)$ be the minimum average number of comparisons needed to sort $n + k$ elements when $k > 0$ and exactly k of the elements have known values (0 or 1). Then $f(0) = f(1) = g(0) = 0$, $g(1) = 1$; $f(n) = 1 + \frac{1}{2}f(n-1) + \frac{1}{2}g(n-2)$, $g(n) = 1 + \min\left(g(n-1), \frac{1}{2}g(n-1) + \frac{1}{2}g(n-2)\right) = 1 + \frac{1}{2}g(n-1) + \frac{1}{2}g(n-2)$, for $n \geq 2$. (Thus the best strategy is to compare two unknown elements whenever possible.) It follows that $f(n) - g(n) = \frac{1}{2}\big(f(n-1) - g(n-1)\big)$ for $n \geq 2$, and $g(n) = \frac{2}{3}\big(n + \frac{1}{3}(1 - (-\frac{1}{2})^n)\big)$ for $n \geq 0$. Hence the answer is $\frac{2}{3}n + \frac{2}{9} - \frac{2}{9}(-\frac{1}{2})^n - (\frac{1}{2})^{n-1}$, for $n \geq 1$. (This exact formula may be compared with the information-theoretic lower bound, $\log_3 (2^n - 1) \approx 0.6309n$.)

11. Binary insertion proves that $S_m(n) \leq B(m) + (n - m)\lceil \log_2 (m+1) \rceil$, for $n \geq m$. On the other hand $S_m(n) \geq \lceil \log_2 \sum_{1 \leq k \leq m} \left\{ {n \atop k} \right\} k! \rceil$ and this is asymptotically $n \log_2 m$ (cf. Eq. 1.2.6–49).

12. (a) If there are no redundant comparisons, we can arbitrarily assign an order to keys which are actually equal, when they are first compared, since no order can be deduced from previously made comparisons. (b) Assume that the tree strongly sorts every sequence of zeros and ones; we shall prove that it strongly sorts every permutation of $\{1, 2, \ldots, n\}$. Suppose it doesn't, so that there is a permutation for which it claims that $K_{a_1} \leq K_{a_2} \leq \cdots \leq K_{a_n}$ whereas in fact $K_{a_i} > K_{a_{i+1}}$ for some i. Replace all elements $< K_{a_i}$ by 0 and all elements $\geq K_{a_i}$ by 1; by assumption the method will now sort when we take the path which leads to $K_{a_1} \leq K_{a_2} \leq \cdots \leq K_{a_n}$, a contradiction.

13. If n is even, $F(n) - F(n-1) = 1 + F(\lfloor n/2 \rfloor) - F(\lfloor n/2 \rfloor - 1)$ so we must prove that $w_{k-1} < \lfloor n/2 \rfloor \leq w_k$; this is obvious since $w_{k-1} = \lfloor w_k/2 \rfloor$. If n is odd, $F(n) - F(n-1) = G(\lceil n/2 \rceil) - G(\lfloor n/2 \rfloor)$, so we must prove that $t_{k-1} < \lceil n/2 \rceil \leq t_k$; this is obvious since $t_{k-1} = \lceil w_k/2 \rceil$.

14. By exercise 1.2.4–42, the sum is $n\lceil \log_2 (\frac{3}{4}n) \rceil - (w_1 + \cdots + w_j)$ where $w_j < n \leq w_{j+1}$. The latter sum is $w_{j+1} - \lfloor j/2 \rfloor - 1$. $F(n)$ can therefore be written $n\lceil \log_2 (\frac{3}{4})n \rceil - \lfloor 2^{\lfloor \log_2 (6n) \rfloor}/3 \rfloor + \lfloor \frac{1}{2} \log_2 (6n) \rfloor$ (and in many other ways).

15. If $\lceil \log_2 (\frac{3}{4}n) \rceil = \log_2 (\frac{3}{4}n) + \theta$, $F(n) = n \log_2 n - (3 - \log_2 3)n + n(\theta + 1 - 2^\theta) + O(\log n)$. If $\lceil \log_2 n \rceil = \log_2 n + \theta$, $B(n) = n \log_2 n - n + n(\theta + 1 - 2^\theta) + O(\log n)$. [Note that $\log_2 n! = n \log_2 n - n/(\ln 2) + O(\log n)$; $1/(\ln 2) \approx 1.443$; $3 - \log_2 3 \approx 1.415$.]

17. The number of cases with $b_k < a_p < b_{k+1}$ is

$$\binom{m - p + n - k}{m - p} \binom{p - 1 + k}{p - 1},$$

and the number of cases with $a_j < b_q < a_{j+1}$ is

$$\binom{n - q + m - j}{n - q} \binom{q - 1 + j}{q - 1}.$$

18. No, since we are considering only the less efficient branch of the tree below each comparison. One of the more efficient branches might turn out to be harder to handle.

20. Let L be the maximum level on which an external node appears, and let l be the minimum such level. If $L \geq l+2$, we can remove two nodes from level L and place them below a node at level l; this decreases the external path length by $l+2L-(L-1+2(l+1)) = L-l-1 \geq 1$. Conversely, if $L \leq l+1$, let there be k external nodes on level $l-1$ and $N-k$ on level l, where $0 < k \leq N$. By exercise 2.3.4.5–3, $k2^{-l+1} + (N-k)2^{-l} = 1$; hence $N+k = 2^l$. The inequalities $N < 2^l \leq 2N$ now show that $l = \lfloor \log_2 N \rfloor + 1$; this defines k and yields the external path length (33).

21. Let $r(x)$ be the root of x's right subtree. We need $\lceil \log_2 t(l(x)) \rceil \leq \lceil \log_2 t(x) \rceil - 1$ and $\lceil \log_2 t(r(x)) \rceil \leq \lceil \log_2 t(x) \rceil - 1$. The first condition is equivalent to $2t(l(x)) - t(x) \leq 2^{\lceil \log_2 t(x) \rceil} - t(x)$, and the second condition is equivalent to $t(x) - 2t(l(x)) \leq 2^{\lceil \log_2 t(x) \rceil} - t(x)$.

22. By exercise 20, the conditions $\lfloor \log_2 t(l(x)) \rfloor, \lfloor \log_2 t(r(x)) \rfloor \geq \lfloor \log_2 t(x) \rfloor - 1$ and $\lceil \log_2 t(l(x)) \rceil, \lceil \log_2 t(r(x)) \rceil \leq \lceil \log_2 t(x) \rceil - 1$ are necessary and sufficient. Arguing as in exercise 21, we can prove them equivalent to the stated conditions. [Cf. Martin Sandelius, *AMM* **68** (1961), 133–134.] See exercise 33 for a generalization.

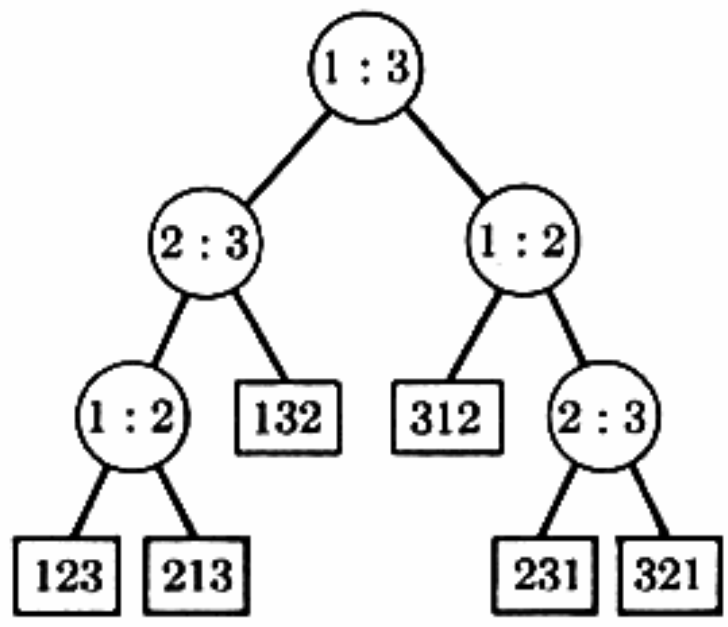
23. Multiple list insertion assumes that the keys are uniformly distributed in a known range, so it isn't a "pure comparison" method satisfying the restrictions considered in this section.

24. First proceed as if sorting five elements, until after five comparisons we reach one of the configurations in (6). In the first three cases, complete sorting the five elements in two more comparisons, then insert the sixth element f. In the latter case, first compare $f:b$, insert f into the main chain, then insert c. [*Théorie des Questionnaires*, p. 116.]

25. Since $N = 7! = 5040$ and $q = 13$, there would be $8192 - 5040 = 3152$ external nodes on level 12 and $5040 - 3152 = 1888$ on level 13.

26. (The best methods known to date have an external path length of 62416.)

27.



is the *only* way to recognize the two most frequent permutations with two comparisons, even though the first comparison produces a .27–.73 split!

28. Lun Kwan has constructed an 873-line program whose average running time is $38.925u$. Its maximum running time is $43u$; the latter appears to be optimal since it is the time for 7 compares, 7 tests, 6 loads, 5 stores.

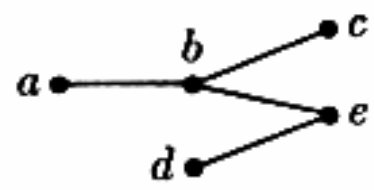
29. We must make at least $S(n)$ comparisons, because it is impossible to know whether a permutation is even or odd unless we have made enough comparisons to determine it uniquely. For we can assume that enough comparisons have been made to narrow things down to two possibilities that depend on whether or not a_i is less than a_j, for some i and j; one of the two possibilities is even, the other is odd. [On the other hand

there *is* an $O(n)$ algorithm for this problem, which simply counts the number of cycles and uses no comparisons at all; see exercise 5.2.2–2.]

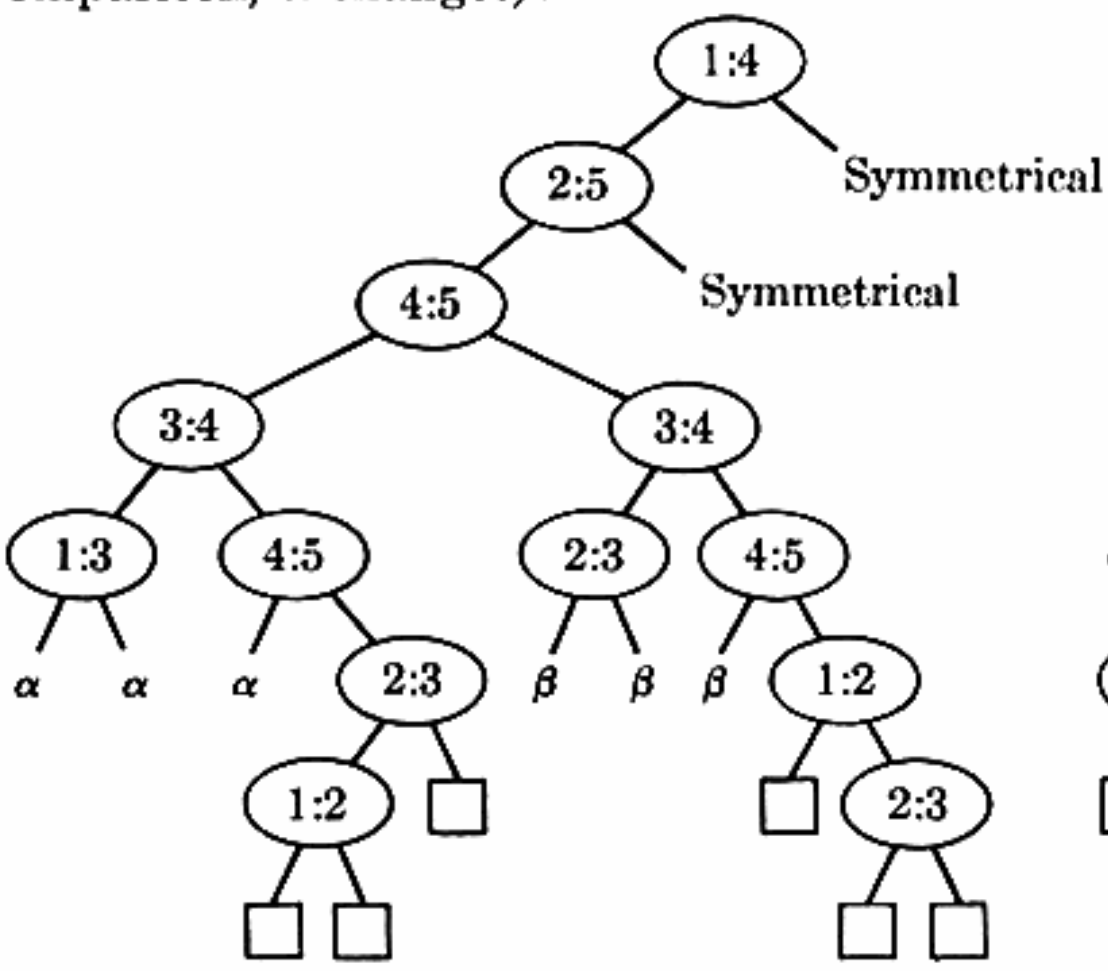
30. Start with an optimal comparison tree of height $S(n)$; repeatedly interchange $i \leftrightarrow j$ in the right subtree of a node labeled $i{:}j$, from top to bottom. Interpreting the result as a comparison-exchange tree, every terminal node defines a unique permutation which can be sorted by at most $n - 1$ more comparison-exchanges (by exercise 5.2.2–2).

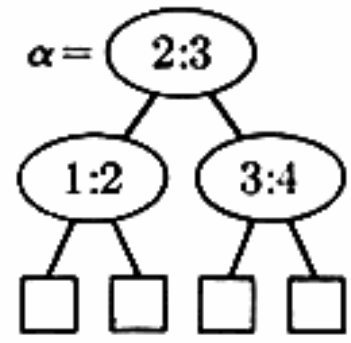
[The idea of a comparison-exchange tree is due to T. N. Hibbard.]

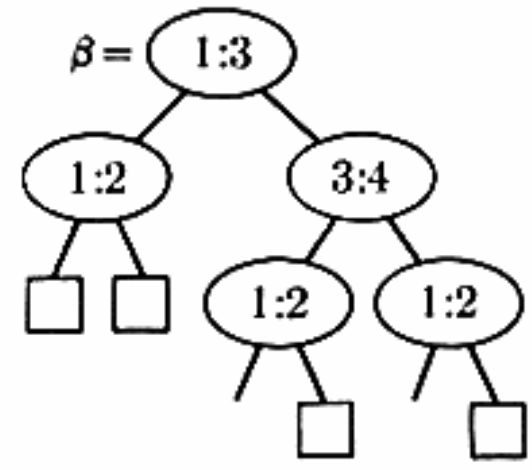
31. At least 8 are required, since every tree of height 7 will produce the configuration



(or its dual) in some branch after 4 steps, with $a \neq 1$. This configuration cannot be sorted in 3 more comparison/exchange operations. On the other hand the following tree achieves the desired bound (and perhaps also the minimum *average* number of comparison/exchanges):







33. Simple operations applied to any tree of order x and resolution 1 can be applied to yield another whose weighted path length is no greater and such that (a) all external nodes lie on levels k and $k - 1$ for some k; (b) at most one external node is non-integer, and if it is present it lies on level k. The weighted path length of any such tree has the stated value, so this must be minimal. Conversely if (iv) and (v) hold in any real-valued search tree it is possible to show by induction that the weighted path length has the stated value, since there is a simple formula for the weighted path length of a tree in terms of the weighted path lengths of the two subtrees of the root.

SECTION 5.3.2

1. $S(m+n) \leq S(m) + S(n) + M(m, n)$.

2. The internal node which is kth in symmetric order corresponds to the comparison $A_1 : B_k$.

3. Strategy $B(1, l)$ is no better than strategy $A(1, l+1)$, and strategy $B'(1, l)$ no

better than $A'(1, l-1)$; hence we must solve the recurrence

$$.M.(1,n) = \min_{1\le j\le n} \max\left(\max_{1\le l\le j} (1+.M.(1,l-1)), \max_{j\le l\le n} (1+.M.(1,n-l)) \right), \qquad n \ge 1;$$

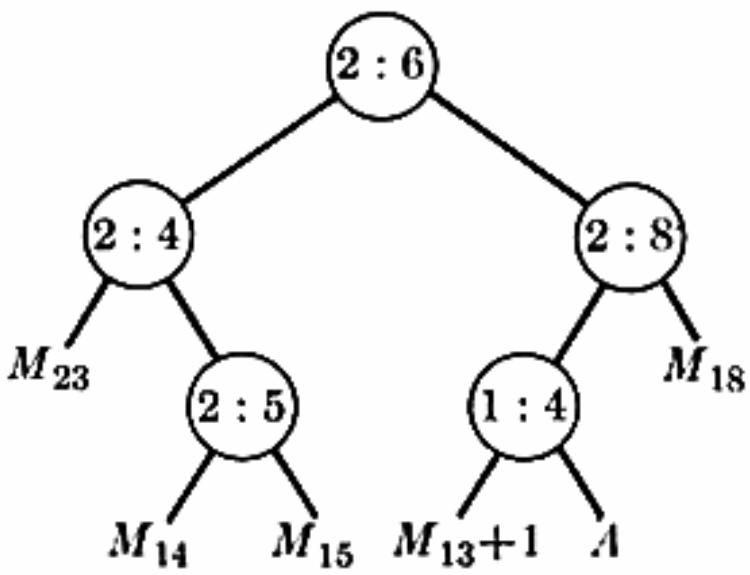
$.M.(1,0) = 0$. It is not difficult to verify that $\lceil \log_2 (n+1) \rceil$ satisfies this recurrence.

6. Strategy $A'(i, i+1)$ can be used when $j = i+1$, except when $i \le 2$. And we can use strategy $A(i, i+2)$ when $j \ge i+2$.

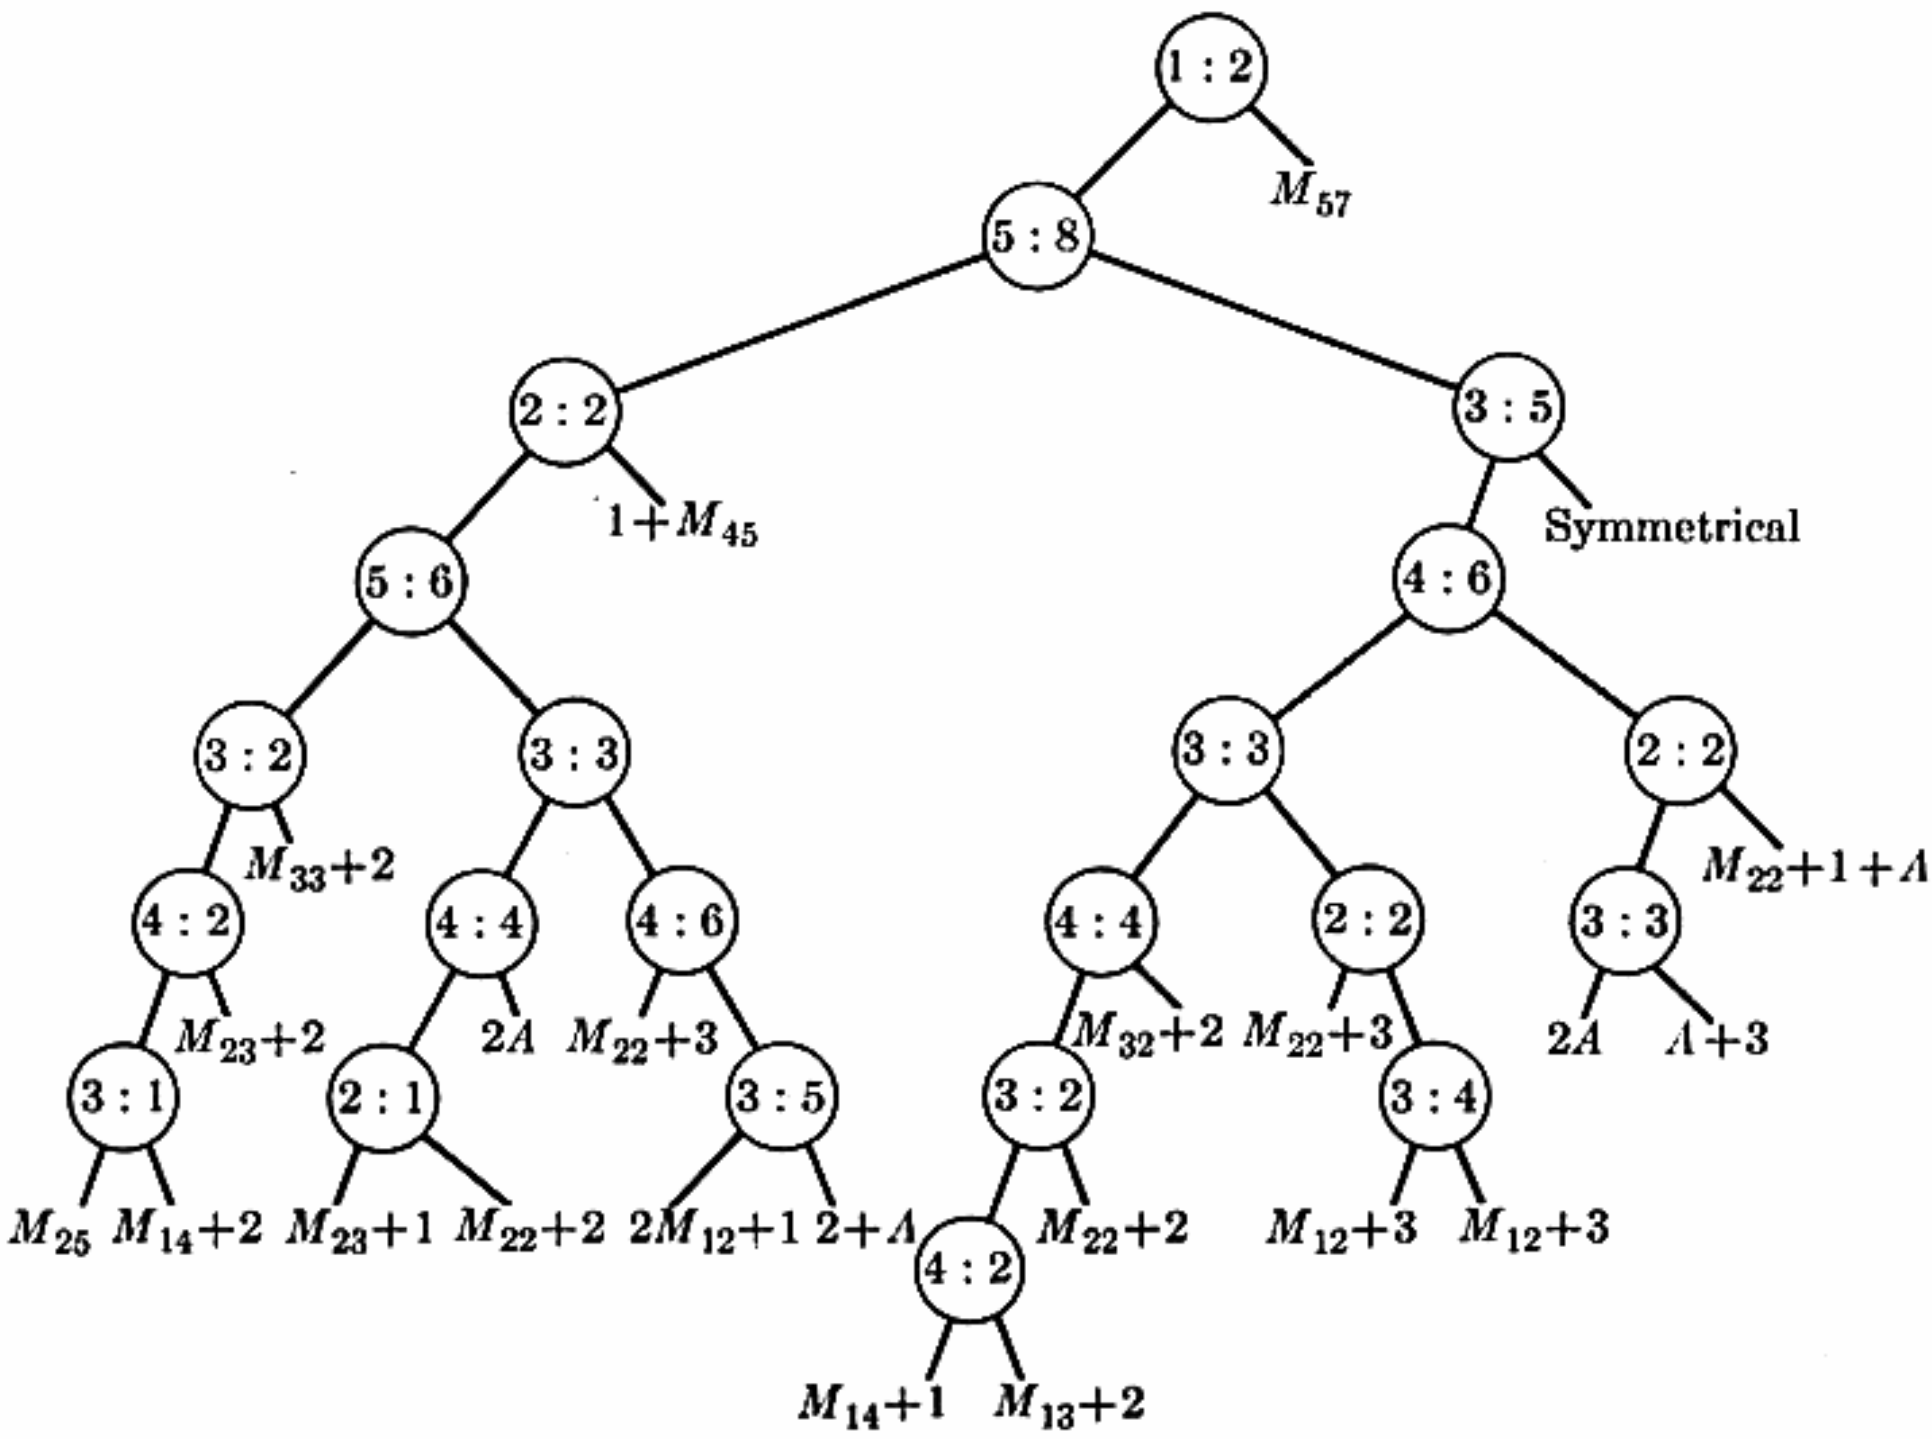
7. To insert $k+m$ elements among n others, independently insert k elements and m elements. (When k and m are large, an improved procedure is possible, see exercise 19.)

8. In the following diagrams, $i{:}j$ denotes the comparison $A_i{:}B_j$, M_{ij} denotes merging i elements with j in $M(i, j)$ steps, and A denotes sorting the pattern or in three steps.

9.



10.



11. Let $n = g_t$ as in the hint. We may assume that $t \geq 6$. Without loss of generality let $A_2{:}B_j$ be the first comparison. If $j > g_{t-1}$, the outcome $A_2 < B_j$ will require $\geq t$ more steps. If $j \leq g_{t-1}$, the outcome $A_2 < B_j$ would be no problem, so only the case $A_2 > B_j$ needs study, and we get the most information when $j = g_{t-1}$. If $t = 2k + 1$, we might have to merge A_2 with the $g_t - g_{t-1} = 2^{k-1}$ elements $> B_{g_{t-1}}$, and merge A_1 with the g_{t-1} others, but this requires $k + (k + 1) = t$ further steps. On the other hand if $n = g_t - 1$, we could merge A_2 with $2^{k-1} - 1$ elements, then A_1 with n elements, in $(k - 1) + (k + 1)$ further steps, hence $M(2, g_t - 1) \leq t$.

The case $t = 2k$ is considerably more difficult; note that $g_t - g_{t-1} \geq 2^{k-2}$. After $A_2 > B_{g_{t-1}}$, suppose we compare $A_1{:}B_j$. If $j > 2^{k-1}$ the outcome $A_1 < B_j$ requires $k + (k - 1)$ further comparisons (too many). If $j \leq 2^{k-1}$, we can argue as before that $j = 2^{k-1}$ gives most information. After $A_1 > B_{2^{k-1}}$, the next comparisons with A_1 might as well be with $B_{2^{k-1}+2^{k-2}}$, then $B_{2^{k-1}+2^{k-2}+2^{k-3}}$; since $2^{k-1} + 2^{k-2} + 2^{k-3} > g_{t-1}$, we are left with merging $\{A_1, A_2\}$ with $n - (2^{k-1} + 2^{k-2} + 2^{k-3})$ elements. Of course we needn't make any comparisons with A_1 right away; we could instead compare $A_2{:}B_{n+1-j}$. If $j \leq 2^{k-3}$, we consider the case $A_2 < B_{n+1-j}$, while if $j > 2^{k-3}$ we consider $A_2 > B_{n+1-j}$. The latter case requires at least $(k - 2) + (k + 1)$ more steps. Continuing, we find that the *only* potentially fruitful line is $A_2 > B_{g_{t-1}}$, $A_2 < B_{n+1-2^{k-3}}$, $A_1 > B_{2^{k-1}}$, $A_1 > B_{2^{k-1}+2^{k-2}}$, $A_1 > B_{2^{k-1}+2^{k-2}+2^{k-3}}$, but then we have exactly g_{t-5} elements left! Conversely, if $n = g_t - 1$, this line works. [*Acta Informatica* 1 (1971), 145–158.]

12. The first comparison must be either $\alpha{:}X_k$ for $1 \leq k \leq i$, or (symmetrically) $\beta{:}X_{n-k}$ for $1 \leq k \leq j$. In the former case the response $\alpha < X_k$ leaves us with $R_n(k - 1, j)$ more comparisons to make; the response $\alpha > X_k$ leaves us with the problem of sorting $\alpha < \beta$, $Y_1 < \cdots < Y_{n-k}$, $\alpha < Y_{i-k+1}$, $\beta > Y_{n-k-j}$, where $Y_r = X_{r-k}$.

13. [*Computers in Number Theory* (New York: Academic Press, 1971), 397–404.]

15. Double m until it exceeds n. This involves $\lfloor \log_2 (n/m) \rfloor + 1$ doublings.

16. All except $(m, n) = (2, 8)$, $(3, 6)$, $(3, 8)$, $(3, 10)$, $(4, 8)$, $(4, 10)$, $(5, 9)$, $(5, 10)$, when it's one over.

17. Assume that $m \leq n$ and let $t = \log_2 (n/m) - \theta$. Then $\log_2 \binom{m+n}{m} > \log_2 n^m - \log_2 m! \geq m \log_2 n - (m \log_2 m - m + 1) = m(t + \theta) + m - 1 = H(m, n) + \theta m - \lfloor 2^\theta m \rfloor \geq H(m, n) + \theta m - 2^\theta m \geq H(m, n) - m$. (The inequality $m! \leq m^m 2^{1-m}$ is a consequence of the fact that $k(m - k) \leq (m/2)^2$ for $1 \leq k < m$.)

19. First merge $\{A_1, \ldots, A_m\}$ with $\{B_2, B_4, \ldots, B_{2\lfloor n/2 \rfloor}\}$. Then we must insert the odd elements B_{2i-1} among a_i of the A's for $1 \leq i \leq \lceil n/2 \rceil$, where $a_1 + a_2 + \cdots + a_{\lceil n/2 \rceil} \leq m$. The latter operation requires $\leq a_i$ operations for each i, so at most m more comparisons will finish the job.

20. Apply (12).

23. The oracle keeps an $n \times n$ matrix X whose entries x_{ij} are initially all 1. When the algorithm asks if $A_i = B_j$, the oracle sets x_{ij} to 0. The answer is "No," unless the permanent of X has just become zero. In the latter case, the oracle answers "Yes," (as it must, lest the algorithm terminate immediately!), and deletes row i and column j from X; the resulting $(n - 1) \times (n - 1)$ matrix will have a nonzero permanent. The oracle continues in this way until only a 0×0 matrix is left.

One can show (for example by using Philip Hall's theorem, cf. Chapter 7) that at least n zeroes are deleted when the oracle first answers "Yes," and $n - 1$ the second

time, etc. The algorithm will terminate only after receiving n "Yes" answers to non-redundant questions, and after asking at least $n + (n - 1) + \cdots + 1$ questions.

SECTION 5.3.3

1. Player *11* lost to *05*, so *13* was known to be worse than *05*, *11*, *12*.

2. Let x be the tth largest, and let S be the set of all elements y such that the comparisons made are insufficient to prove either that $x < y$ or $y < x$. There are permutations, consistent with all the comparisons made, in which all elements of S are less than x; for we can stipulate that all elements of S are less than x and embed the resulting partial ordering in a linear ordering. Similarly there are consistent permutations in which all elements of S are greater than x. Hence we don't know the rank of x unless S is empty.

3. An oracle may regard the loser of the first comparison as the worst player of all. [R. W. Floyd has used a similar approach to show that the values in Table 1 are exact for all $n \leq 7$.]

4. There are at least $n^{\underline{t}}$ outcomes.

5. In fact, $W_t(n) \leq V_t(n) + S(t-1)$, by exercise 2.

6. Let $g(l_1, l_2, \ldots, l_m) = m - 2 + \log_2 (2^{l_1} + 2^{l_2} + \cdots + 2^{l_m})$, and assume that $f = g$ whenever $l_1 + l_2 + \cdots + l_m + 2m < N$. We shall prove that $f = g$ when $l_1 + l_2 + \cdots + l_m + 2m = N$. We may assume that $l_1 \geq l_2 \geq \cdots \geq l_m$. There are only a few possible ways to make the first comparison:

Strategy $A(j, k)$, *for* $j < k$. Compare the largest element of group j with the largest of group k. This gives the relation

$$\begin{aligned} f(l_1, \ldots, l_m) &\leq 1 + g(l_1, \ldots, l_{j-1}, l_j + 1, l_{j+1}, \ldots, l_{k-1}, l_{k+1}, \ldots, l_m) \\ &= g(l_1, \ldots, l_{j-1}, l_j, l_{j+1}, \ldots, l_{k-1}, l_j, l_{k+1}, \ldots, l_m) \geq g(l_1, \ldots, l_m). \end{aligned}$$

Strategy $B(j, k)$, *for* $l_k > 0$. Compare the largest element of group j with one of the small elements of group k. This gives the relation

$$f(l_1, \ldots, l_m) \leq 1 + \max(\alpha, \beta) = 1 + \beta,$$

where

$$\begin{aligned} \alpha &= g(l_1, \ldots, l_{j-1}, l_{j+1}, \ldots, l_m) \leq g(l_1, \ldots, l_m) - 1, \\ \beta &= g(l_1, \ldots, l_{k-1}, l_k - 1, l_{k+1}, \ldots, l_m) \geq g(l_1, \ldots, l_m) - 1. \end{aligned}$$

Strategy $C(j, k)$, *for* $j \leq k$, $l_j > 0$, $l_k > 0$. Compare a small element from group j with a small element from group k. The corresponding relation is

$$f(l_1, \ldots, l_m) \leq 1 + g(l_1, \ldots, l_{k-1}, l_k - 1, l_{k+1}, \ldots, l_m) \geq g(l_1, \ldots, l_m).$$

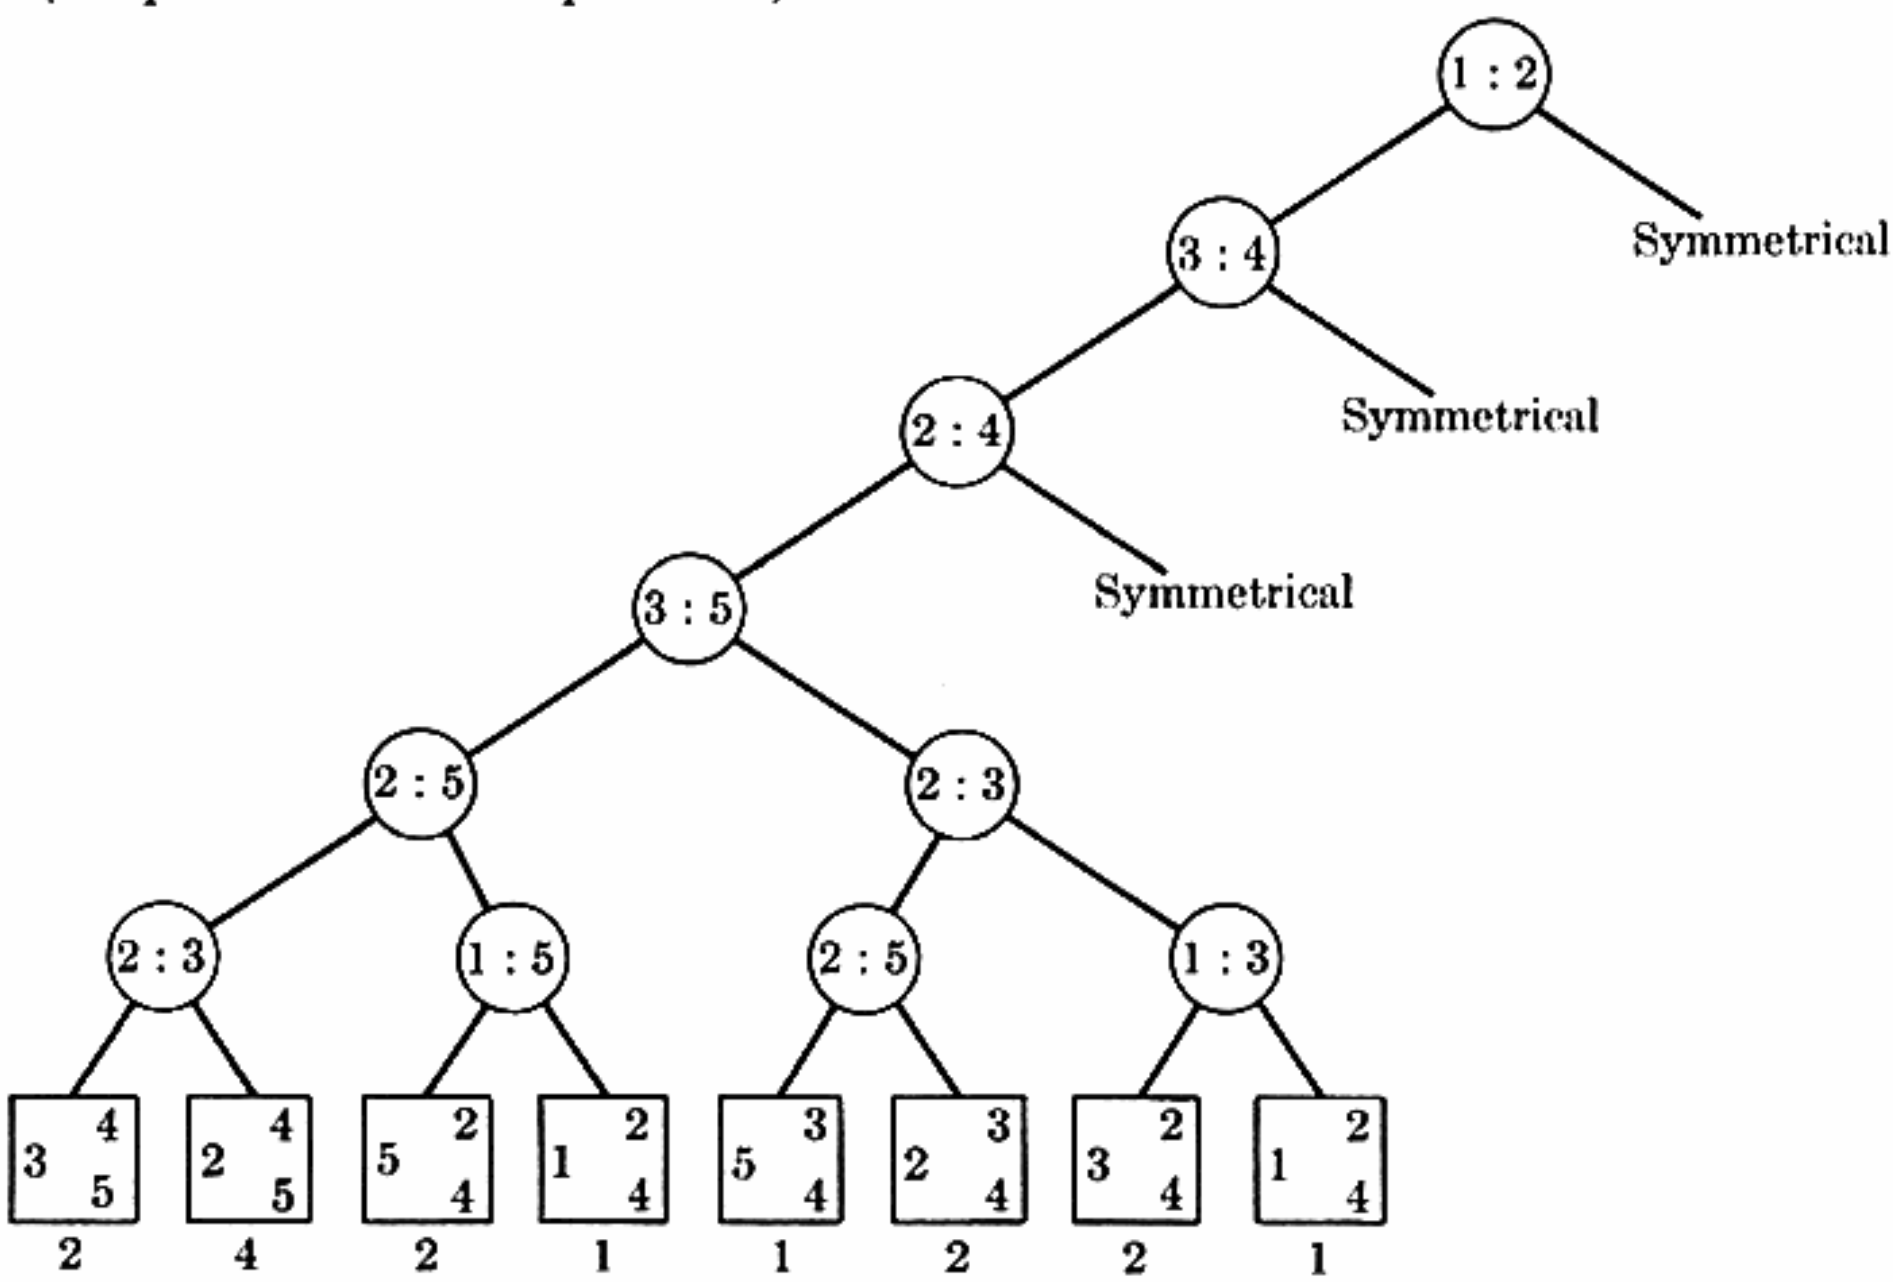
The value of $f(l_1, \ldots, l_m)$ is found by taking the minimum right-hand side over all these strategies; hence $f(l_1, \ldots, l_m) \geq g(l_1, \ldots, l_m)$. When $m > 1$, Strategy $A(m-1, m)$ shows that $f(l_1, \ldots, l_m) \leq g(l_1, \ldots, l_m)$, since $g(l_1, \ldots, l_{m-1}, l_m) = g(l_1, \ldots, l_{m-1}, l_{m-1})$ when $l_1 \geq \cdots \geq l_m$. (*Proof*: $\lceil \log_2 (M + 2^a) \rceil = \lceil \log_2 (M + 2^b) \rceil$ for $0 \leq a \leq b$, when M is a positive multiple of 2^b.) When $m = 1$, use Strategy $C(1, 1)$.

[S. S. Kislitsyn's paper determined the optimum strategy $A(m-1, m)$ and evaluated $f(l, l, \ldots, l)$ in closed form; the general formula for f and this simplified proof were discovered by Floyd in 1970.]

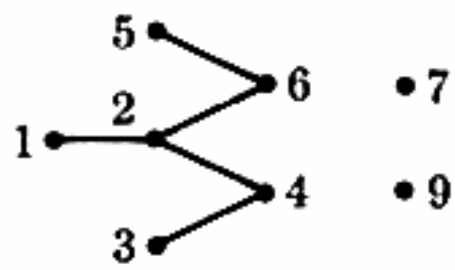
7. For $j > 1$, if $j+1$ is in α', c_j is 1 plus the number of comparisons needed to select the next largest element of α'. Similarly if $j+1$ is in α''; and c_1 is always 0, since the tree always looks the same at the end.

8. In other words, is there an extended binary tree with n external nodes such that the sum of the distances to the $t-1$ farthest internal nodes from the root is less than the corresponding sum for the complete binary tree? The answer is no, since it is not hard to show that the kth largest element of $\mu(\alpha)$ is $\geq \lfloor \log_2 (n-k) \rfloor$ for all α.

9. (All paths use six comparisons.)



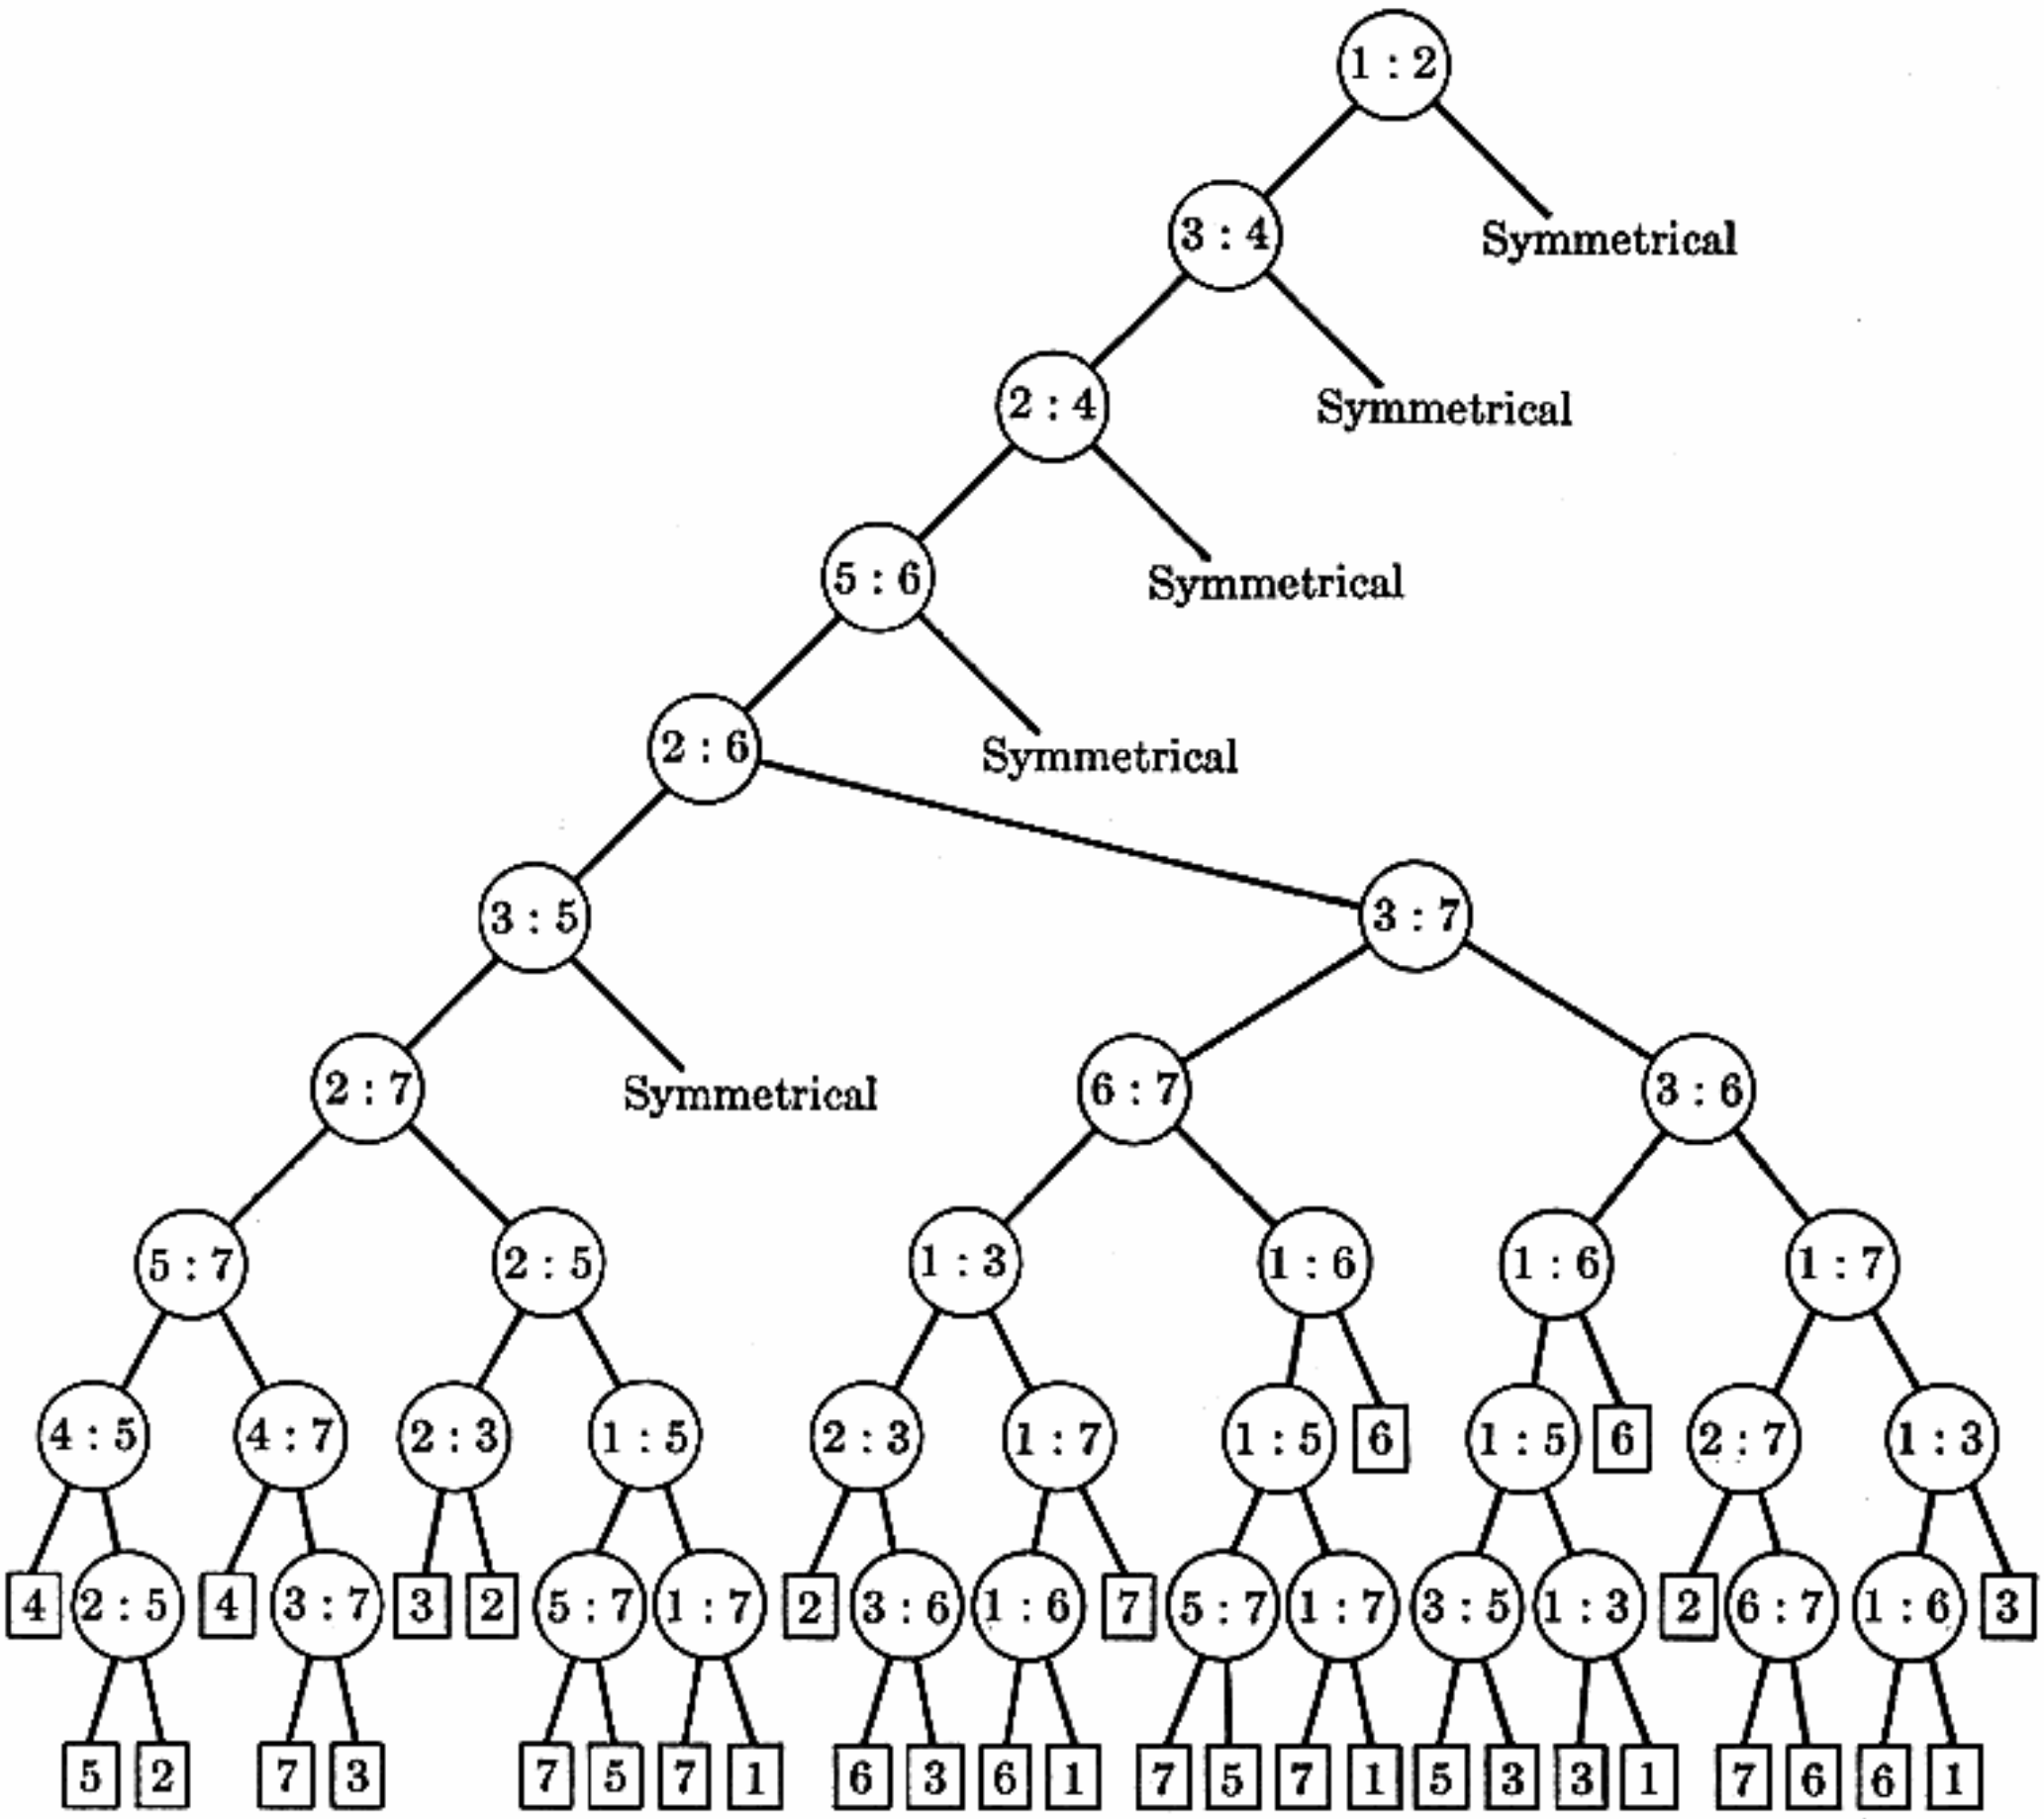
10. After the first seven comparisons in Doren's method, we may discard X_8, and so we must find the fourth largest of



This is more information than we knew after four steps of Doren's method, so at most $12 - 4 = 8$ more comparisons are required.

11. After discarding the smallest of $\{X_1, X_2, X_3, X_4\}$, we have the configuration •—• plus $n-3$ isolated elements; the third largest of these can be found in $V_3(n-1) - 1$ further steps.

12. (Found manually by trial and error, using exercise 6 to help find fruitful lines.)



13. After finding the median of the first $f(n)$ elements, say X_j, compare it to each of the others; this splits the elements into approximately $n/2 - k$ less than X_j and $n/2 + k$ greater than X_j, for some k. It remains to find the $|k|$th largest or smallest element of the bigger set, which requires $n/2 + O(|k| \log n)$ further comparisons. The average value of $|k|$ (consider points uniformly distributed in [0, 1]) is $O(1/\sqrt{n}) + O(n/\sqrt{f(n)})$. Let $T(n)$ be the average number of comparisons when $f(n) = n^{2/3}$; $T(n) - n = T(n^{2/3}) - n^{2/3} + n/2 + O(n^{2/3})$, and the result follows.

It is interesting to note that when $n = 5$, this method requires only $5\frac{13}{15}$ comparisons on the average, slightly better than the tree of exercise 9.

14. In general, the t largest can be found in $V_t(n-1) + 1$ comparisons, by finding the tth largest of $\{X_1, \ldots, X_{n-1}\}$ and comparing it with X_n, because of exercise 2.

15. $\min(t, n + 1 - t)$. Assuming that $t \leq n + 1 - t$, if we don't save each of the first t words when they are first read in, we may have forgotten the tth largest, depending on the subsequent values still unknown to us. Conversely, t locations are sufficient, since we can compare a newly input item with the previous tth largest, storing the register iff it is greater.

16. The algorithm starts with $(a, b, c, d) = (n, 0, 0, 0)$ and ends with $(0, 1, 1, n-2)$. If the oracle avoids "surprising" outcomes, the only transitions possible after each comparison are from (a, b, c, d) to itself or to

$$\begin{array}{cc} (a-2, b+1, c+1, d), & \text{if } a \geq 2; \\ (a-1, b, c+1, d) \quad \text{or} \quad (a-1, b+1, c, d), & \text{if } a \geq 1; \\ (a, b-1, c, d+1), & \text{if } b \geq 2; \\ (a, b, c-1, d+1), & \text{if } c \geq 2. \end{array}$$

It follows that $\lceil \frac{3}{2}a \rceil + b + c - 2$ comparisons are needed to get from (a, b, c, d) to $(0, 1, 1, a+b+c+d-2)$. [*CACM* **15** (1972), 462–464.]

17. Use (6) first for the largest, then for the smallest, noting that $\lfloor n/2 \rfloor$ of the comparisons are common to both.

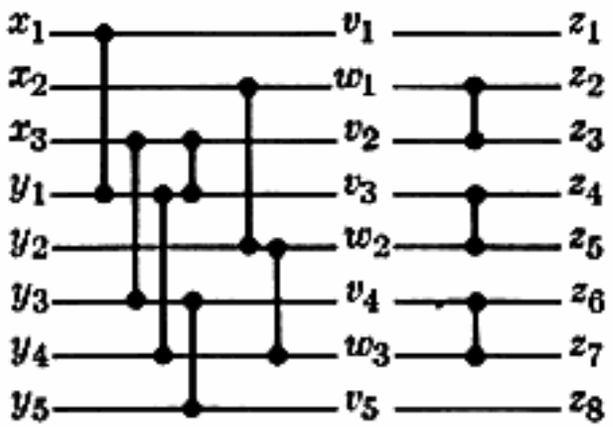
18. $V_t(n) \leq 18n - 151$, for all sufficiently large n.

21. Let the elements be $\{x_1, \ldots, x_n, y, z\}$, where $n = 2^k$. Find the two largest x's, say $b < a$, in $2^k + k - 2$ comparisons, using Kislitsyn's method; and compare $y:z$ (say $y < z$). Now if $z < b$, continue Kislitsyn's method, finding the third largest of the x's in $k-1$ comparisons, and compare it to z. On the other hand, if $z > b$, it is easy to finish in at most three more steps.

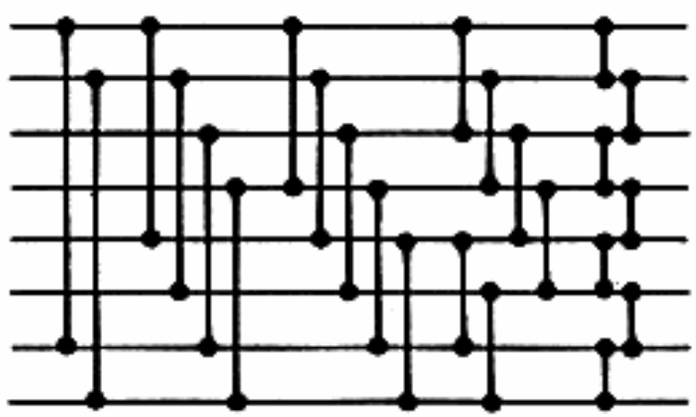
SECTION 5.3.4

1. (When m is odd it is best to have v_m followed by v_{m+1}, w_{m+1}, v_{m+2}, . . . instead of by w_{m+1}, v_{m+1}, w_{m+2}, . . . in the diagram.)

(3, 5) odd-even merge



Pratt eight-sort



2. See the above diagram for $n = 8$.

3. $C(m, m-1) = C(m, m) - 1$, for $m \geq 1$.

4. If $\hat{T}(6) = 4$, there would be three comparators acting at each time, since $\hat{S}(6) = 12$. But then removing the bottom line and its four comparators would give $\hat{S}(5) \leq 8$, a contradiction. [The same argument yields $\hat{T}(7) = \hat{T}(8) = 6$.]

5. Let $f(n) = f(\lceil n/2 \rceil) + 1 + \lceil \log_2 \lceil n/2 \rceil \rceil$, if $n \geq 2$; by exercises 1.2.4–34, 35, $f(n) = (1 + \lceil \log_2 \frac{1}{2}n \rceil) + (1 + \lceil \log_2 \frac{1}{4}n \rceil) + \cdots$.

6. We may assume that each stage makes $\lfloor n/2 \rfloor$ comparisons (extra comparisons can't hurt). Since $\hat{T}(6) = 5$, it suffices to show that $T(5) = 5$. After two stages when $n = 5$, we cannot avoid the partial orderings  or  which cannot be sorted in two more stages.

7. Assume that the input keys are $\{1, 2, \ldots, 10\}$. The key fact is that after the

first 16 comparators, lines 2–5 cannot contain 8 or 9, nor can they contain both 6 and 7.

8. Straightforward generalization of Theorem F.

9. $\hat{M}(3, 3) \geq \hat{S}(6) - 2\hat{S}(3)$; $\hat{M}(4, 4) \geq \hat{S}(8) - 2\hat{S}(4)$; $\hat{M}(5, 5) \geq 2\hat{M}(2, 3) + 3$ by exercise 8; and $\hat{M}(2, 3) \geq \hat{S}(5) - \hat{S}(2) - \hat{S}(3)$.

10. The hint follows by the method of proof in Theorem Z. Then show that the number of 0's in the even subsequence minus the number of 0's in the odd subsequence is ± 1.

11. (Solution by M. W. Green.) The network is symmetric in the sense that, whenever z_i is compared to z_j, there is a corresponding comparison of z_{2^p-1-j}:z_{2^p-1-i}. Any symmetric network capable of sorting a sequence $\langle z_0, \ldots, z_{2^p-1}\rangle$ will also sort the sequence $\langle -z_{2^p-1}, \ldots, -z_0\rangle$.

Batcher has observed that the network will actually sort any cyclic shift $\langle z_j, z_{j+1}, \ldots, z_{2^p-1}, z_0, \ldots, z_{j-1}\rangle$ of a bitonic sequence. This is a consequence of the 0-1 principle.

12. $x \vee y$ is (consider 0-1 sequences), but not $x \vee y$ (consider $\langle 3, 1, 4, 5\rangle \wedge \langle 6, 7, 8, 2\rangle$).

13. A perfect shuffle has the effect of replacing z_i by z_j, where the binary representation of j is that of i rotated cyclically to the right one place (cf. exercise 3.4.2–13). Consider shuffling the comparators instead of the lines; then the first column of comparators acts on the pairs $z[i]$ and $z[i \oplus 2^{r-1}]$, the next column on $z[i]$ and $z[i \oplus 2^{r-2}]$, ..., the tth column on $z[i]$ and $z[i \oplus 1]$, the $(t+1)$st column on $z[i]$ and $z[i \oplus 2^{r-1}]$ again, etc. Here "$\oplus$" denotes exclusive-or on the binary representation. This shows that Fig. 57 is equivalent to Fig. 56; after s stages we have groups of 2^s elements which are alternately sorted and reverse-sorted.

14. After l levels the input x_1 can be in at most 2^l different places. After merging is complete, x_1 can be in $n+1$ different places.

15. [1:4][3:2][1:3][2:4][2:3].

16. The process clearly terminates. Each execution of step T2 has the effect of interchanging the i_qth and j_qth outputs, so the result of the algorithm is to permute the output lines in some way. Since the resulting (standard) network makes no change to the input $\langle 1, 2, \ldots, n\rangle$, the output lines must have been returned to their original position.

17. Make the network standard by the algorithm of exercise 16; then by considering the input sequence $\langle 1, 2, \ldots, n\rangle$, we see that standard selection networks must take the t largest elements into the t highest-numbered lines; and a $\hat{V}_t(n)$ network must take the tth largest into line $n+1-t$. Apply the zero-one principle.

18. The proof in Theorem A shows that $\hat{V}_t(n) \geq (n-t)\lceil\log_2(t+1)\rceil + \lceil\log_2 t\rceil$.

19. The network $[1:n][2:n]\ldots[1:3][2:3]$ selects the smallest two elements with $2n-4$ comparators; add [1:2] for $\hat{V}_2(n)$. The lower bound comes from Theorem A (cf. exercise 18).

20. First note that $\hat{V}_3(n) \geq \hat{V}_3(n-1) + 2$ when $n \geq 4$; by symmetry the first comparator may be assumed to be $[1:n]$; after this must come a network to select the third largest of $\langle x_2, x_3, \ldots, x_n\rangle$, and another comparator touching line 1. On the other hand, $\hat{V}_3(5) \leq 7$, since four comparators find the min and max of $\{x_1, x_2, x_3, x_4\}$ and it remains to sort three elements.

21. By induction on the length of α, since $x_i \le y_i$ and $x_j \le y_j$ implies that $x_i \wedge x_j \le y_i \wedge y_j$ and $x_i \vee x_j \le y_i \vee y_j$.

22. By induction on the length of α, since $(x_i \wedge x_j)(y_i \wedge y_j) + (x_i \vee x_j)(y_i \vee y_j) \ge x_i y_i + x_j y_j$. [Consequently $\nu(x \wedge y) \le \nu(x\alpha \wedge y\alpha)$, an observation due to W. Shockley.]

23. Let $x_k = 1$ iff $p_k \ge j$, $y_k = 1$ iff $p_k > j$; then $(x\alpha)_k = 1$ iff $(p\alpha)_k \ge j$, etc.

24. The formula for l'_i is obvious and for l'_j take $z = x \wedge y$ as in the hint and observe that $(z\alpha)_i = (z\alpha)_j = 0$ by exercise 21. Adding additional 1's to z shows the existence of a permutation p with $(p\alpha')_j \le \zeta(z)$, by exercise 23. The relations for u'_i, u'_j follow by reversing the order.

25. Let $f(x) = (x\alpha)_k$; let z be a vector of 0's and 1's with $f(z) = 1$, having minimum $\nu(z)$ over all such vectors. (It follows that $\nu(z) = n + 1 - u_k$.) Let p in P_n be a permutation such that $f(p) = l_k$, and let p correspond to vectors x and y as in exercise 23. The following algorithm transforms x and y in such a way that the corresponding vectors p have $f(p)$ taking all the values from l_k to u_k, inclusive; each step of the algorithm makes x have at least one more component in common with z, while changing $\nu(x)$ by 0 or ± 1. (Note that if $z \not\le x$, there is some r with $z_r > x_r$ and some s with $x_s < z_s$ because of the minimality of $\nu(z)$.)

If the following hold:	Replace (x, y) by:
$z \not\le x$, $z_r > x_r$, $z_s < x_s$, and	
$f(y \vee e^{(r)}) = 0$	$(x \vee e^{(r)}, y \vee e^{(r)})$
$f(y \vee e^{(r)}) = 1$, $f(x \wedge \bar{e}^{(s)}) = 1$	$(x \wedge \bar{e}^{(s)}, y \wedge \bar{e}^{(s)})$
$f(y \vee e^{(r)}) = 1$, $f\big((x \vee e^{(r)}) \wedge \bar{e}^{(s)}\big) = 0$	$(x \vee e^{(r)}, (x \vee e^{(r)}) \wedge \bar{e}^{(s)})$
$f\big((x \vee e^{(r)}) \wedge \bar{e}^{(s)}\big) = 1$, $f\big((y \vee e^{(r)}) \wedge \bar{e}^{(s)}\big) = 0$	$\big((x \vee e^{(r)}) \wedge \bar{e}^{(s)}, (y \vee e^{(r)}) \wedge \bar{e}^{(s)}\big)$
$f\big((y \vee e^{(r)}) \wedge \bar{e}^{(s)}\big) = 1$	$\big((y \vee e^{(r)}) \wedge \bar{e}^{(s)}, y \wedge \bar{e}^{(s)}\big)$
$z \le x$, $z_s < x_s$	$(x \wedge \bar{e}^{(s)}, y \wedge \bar{e}^{(s)})$.

[Is there a simpler solution?]

26. There is a one-to-one correspondence which takes the element $\langle p_1, \ldots, p_n \rangle$ of $P_n\alpha$ into the "covering sequence" $x^{(0)}$ covers $x^{(1)}$ covers $\cdots$ covers $x^{(n)}$, where the $x^{(i)}$ are in $D_n\alpha$; in this correspondence, $x^{(i-1)} = x^{(i)} \vee e^{(j)}$ iff $p_j = i$. For example, $\langle 3, 1, 4, 2 \rangle$ corresponds to the sequence $\langle 1, 1, 1, 1 \rangle$ covers $\langle 1, 0, 1, 1 \rangle$ covers $\langle 1, 0, 1, 0 \rangle$ covers $\langle 0, 0, 1, 0 \rangle$ covers $\langle 0, 0, 0, 0 \rangle$.

27. If x and y denote different columns of a matrix whose rows are sorted, so that $x_i \le y_i$ for all i, and if $x\alpha$ and $y\alpha$ denote the result of sorting the columns, the sta td principle shows that $(x\alpha)_i \le (y\alpha)_i$ for all i, since we can choose i elements of x intehe same rows as any i given elements of y. [This principle was used in the text, to prove the invariance property of Shell's sort, Theorem 5.2.1K. Further exploitation of the idea appears in an interesting paper by David Gale and R. M. Karp, *J. Computer and System Sciences* **6** (1972), 103–115. The fact that column sorting does not mess up sorted rows was apparently first observed in connection with the manipulation of tableaux; cf. Hermann Boerner, *Darstellung von Gruppen* (Springer, 1955), 137.]

28. If $\{x_{i_1}, \ldots, x_{i_t}\}$ are the t largest elements, then $x_{i_1} \wedge \cdots \wedge x_{i_t}$ is the tth largest. If $\{x_{i_1}, \ldots, x_{i_t}\}$ are *not* the t largest, then $x_{i_1} \wedge \cdots \wedge x_{i_t}$ is *less than* the tth largest.

29. $\langle x_1 \wedge y_1, (x_2 \wedge y_1) \vee (x_1 \wedge y_2), (x_3 \wedge y_1) \vee (x_2 \wedge y_2) \vee (x_1 \wedge y_3), y_1 \vee (x_3 \wedge y_2) \vee$

$(x_2 \wedge y_3) \vee (x_1 \wedge y_4), y_2 \vee (x_3 \wedge y_3) \vee (x_2 \wedge y_4) \vee (x_1 \wedge y_5), y_3 \vee (x_3 \wedge y_4) \vee (x_2 \wedge y_5) \vee x_1, y_4 \vee (x_3 \wedge y_5) \vee x_2, y_5 \vee x_3\rangle$.

30. Applying the distributive and associative laws reduces any formula to $\vee$'s of $\wedge$'s; then the commutative, idempotent, and absorption laws lead to canonical form. The S_i are precisely those sets S such that the formula is 1 when ($x_j = 1$ iff $j \in S$) while the formula is 0 when ($x_j = 1$ iff $j \in S'$) for any proper subset S' of S.

31. $\delta_4 = 166$. R. Church [*Duke Math. J.* **6** (1940), 732–734] found $\delta_5 = 7579$, M. Ward [*Bull. Amer. Math. Soc.* **52** (1946), 423] found $\delta_6 = 7828352$, and W. F. Lunnon [unpublished, 1969] found $\delta_7 = 2208061288136$; the latter value has not yet been checked independently. No simple formula for δ_n is apparent; D. Kleitman [*Proc. Amer. Math. Soc.* **21** (1969), 677–682] proved that

$$\log_2 \delta_n \sim \binom{n}{\lfloor n/2 \rfloor},$$

using an extremely complicated argument.

32. G_{n+1} is also the set of all strings $\theta\psi$ where θ and ψ are in G_n and $\theta \le \psi$ as vectors of 0's and 1's. It follows that G_n is the set of all strings $z_0 \ldots z_{2^n-1}$ of 0's and 1's, where $z_i \le z_j$ whenever the binary representation of i is "$\le$" the binary representation of j in the 0-1 vector sense. Each element $z_0 \ldots z_{2^n-1}$ of G_n, except $00\ldots0$ and $11\ldots1$, represents a $\wedge$-$\vee$ function $f(x_1, \ldots, x_n)$ from D_n into $\{0, 1\}$, under the correspondence $f(x_1, \ldots, x_n) = z[(x_1 \ldots x_n)_2]$.

33. If such a network existed we would have $(x_1 \wedge x_2) \vee (x_2 \wedge x_3) \vee (x_3 \wedge x_4) = f(x_1 \wedge x_2, x_1 \vee x_2, x_3, x_4)$ or $f(x_1 \wedge x_3, x_2, x_1 \vee x_3, x_4)$ or $\ldots$ or $f(x_1, x_2, x_3 \wedge x_4, x_3 \vee x_4)$ for some function f. The choices $\langle x_1, x_2, x_3, x_4\rangle = \langle x, \bar{x}, 1, 0\rangle$, $\langle x, 0, \bar{x}, 1\rangle$, $\langle x, 1, 0, \bar{x}\rangle$, $\langle 1, x, \bar{x}, 0\rangle$, $\langle 1, x, 0, \bar{x}\rangle$, $\langle 0, 1, x, \bar{x}\rangle$ show that no such f exists.

34. Yes; after proving this, you are ready to tackle the $n = 16$ network in Fig. 49.

35. Otherwise the permutation in which only i and $i+1$ are misplaced would never be sorted.

36. (a) Each adjacent comparator reduces the number of inversions by 0 or 1, and $\langle n, n-1, \ldots, 1\rangle$ has $\binom{n}{2}$ inversions. (b) Let $\alpha = \beta[p{:}p+1]$, and argue by induction on the length of α. If $p = i$, then $j > p+1$, and $(x\beta)_p > (x\beta)_j$, $(x\beta)_{p+1} > (x\beta)_j$; hence $(y\beta)_p > (y\beta)_j$ and $(y\beta)_{p+1} > (y\beta)_j$. If $p = i-1$, then either $(x\beta)_p$ or $(x\beta)_{p+1}$ is $> (x\beta)_j$; hence either $(y\beta)_p$ or $(y\beta)_{p+1}$ is $> (y\beta)_j$. If $p = j-1$ or j, the arguments are similar. For other p the argument is trivial. [An amusing consequence of this exercise is that if α is sorting network consisting of $\binom{n}{2}$ adjacent comparators, so is α^R (the comparators in reverse order).]

37. It suffices to show that if each comparator is replaced by an *interchange* operation we obtain a "reflection network" which transforms $\langle x_1, \ldots, x_n\rangle$ into $\langle x_n, \ldots, x_1\rangle$. But in this interpretation it is not difficult to trace the route of x_k. (Note that the permutation $\pi = (1, 2)(3, 4)\ldots(2n-1, 2n)(2, 3)(4, 5)\ldots(2n-2, 2n-1) = (1, 3, 5, \ldots, 2n-1, 2n, 2n-2, \ldots, 2)$ satisfies $\pi^{n/2} = (1, 2n)(2, 2n-1)\ldots(n-1, n)$.) The odd-even transposition sort was mentioned briefly by H. Seward in 1954; it has been discussed by A. Grasselli [*IRE Trans.* **EC-11** (1962), 483] and by Kautz et al. [*IEEE Trans.* **C-17** (1968), 443–451].

38. Let u be the smallest element of $(x\alpha)_j$, and let $y^{(0)}$ be any vector in D_n such that

$(y^{(0)})_k = 0$ implies $(x\alpha)_k$ contains an element $\leq u$, $(y^{(0)})_k = 1$ implies $(x\alpha)_k$ contains an element $> u$. If $\alpha = \beta[p:q]$, it is possible to find a vector $y^{(1)}$ satisfying the same conditions but with α replaced by β, and such that $y^{(1)}[p:q] = y^{(0)}$. Starting with $(y^{(0)})_i = 1$, $(y^{(0)})_j = 0$, we eventually have a vector $y = y^{(r)}$ satisfying the desired condition.

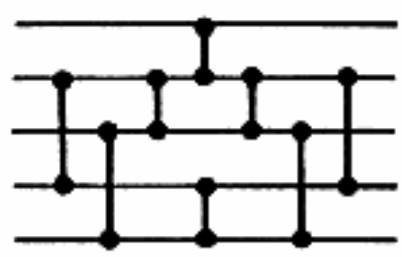
39. Both $(x \veebar y) \veebar z$ and $x \veebar (y \veebar z)$ represent the largest m elements of the multiset $x \uplus y \uplus z$; $(x \wedge y) \wedge z$ and $x \wedge (y \wedge z)$ represent the smallest m. If $x = y = z = \{0, 1\}$, $(x \wedge z) \veebar (y \wedge z) = (x \wedge y) \veebar (x \wedge z) \veebar (y \wedge z) = \{0, 0\}$ while (middle elements of $\{0, 0, 0, 1, 1, 1\}$) $= (x \veebar y) \wedge z = \{0, 1\}$. Sorting networks for three elements and the result of exercise 38 imply that the middle elements of $x \uplus y \uplus z$ may be expressed either as $((x \veebar y) \wedge z) \veebar (x \wedge y)$ or $((x \wedge y) \veebar z) \wedge (x \veebar y)$ or any other formula obtained by permuting x, y, z in these expressions. (There seems to be no "symmetrical" formula for the middle elements.)

40. Let $\alpha' = \alpha[i:j]$, and let k be an index $\neq i, j$. If $(x\alpha)_i \leq (x\alpha)_k$ for all x, then $(x\alpha')_i \leq (x\alpha')_k$; if $(x\alpha)_k \leq (x\alpha)_i$ and $(x\alpha)_k \leq (x\alpha)_j$ for all x, the same holds when α is replaced by α'; if $(x\alpha)_k \leq (x\alpha)_i$ for all x, then $(x\alpha')_k \leq (x\alpha')_j$. In this way we see that α' has at least as many known relations as α, plus one more if $[i:j]$ isn't redundant. [*Bell System Tech. J.* **49** (1970), 1627–1644.]

41. (a) Let $y_{i_s} = x_{j_s}$, $y_{j_s} = x_{i_s}$, $y_k = x_k$ for $i_s \neq k \neq j_s$; then $y\alpha^s = x\alpha$. (b) This is obvious unless the set $\{i_s, j_s, i_t, j_t\}$ has only three distinct elements; suppose that $i_s = i_t$. Then if $s < t$ the first $s - 1$ comparators have (i_s, j_s, j_t) replaced, respectively, by (j_s, j_t, i_s) in both $(\alpha^s)^t$ and $(\alpha^t)^s$. (c) $(\alpha^s)^s = \alpha$, and $\alpha^1 = \alpha$, so we can assume that $s_1 > s_2 > \cdots > s_k > 1$. (d) Let $\beta = \alpha[i:j]$; then $g_\beta(x_1, \ldots, x_n) = (\bar{x}_i \vee x_j) \wedge (g_\alpha(x_1, \ldots, x_i, \ldots, x_j, \ldots, x_n) \vee g_\alpha(x_1, \ldots, x_j, \ldots, x_i, \ldots, x_n))$. Iterating this identity yields the result. (e) $f_\alpha(x) = 1$ iff no path in G_α goes from i to j where $x_i > x_j$. If α is a sorting network, the conjugates of α are also; and $f_\alpha(x) = 0$ for all x with $x_i > x_{i+1}$. Take $x = e^{(i)}$; this shows that G has an arc from i to k_1 for some $k_1 \neq i$. If $k_1 \neq i + 1$, $x = e^{(i)} \vee e^{(k_1)}$ shows that G has an arc from i or k_1 to k_2 for some $k_2 \notin \{i, k_1\}$. If $k_2 \neq i + 1$, continue in the same way until finding a path in G from i to $i + 1$. Conversely if α is not a sorting network, let x be a vector with $x_i > x_{i+1}$ and $g_\alpha(x) = 1$. Some conjugate α' has $f_{\alpha'}(x) = 1$, so $G_{\alpha'}$ can have no path from i to $i + 1$. [In general, $(x\alpha)_i \leq (x\alpha)_j$ for all x iff $G_{\alpha'}$ has an oriented path from i to j for all α' conjugate to α.]

42. There must exist a path of length $\lceil \log_2 n \rceil$ or more, from some input to the largest output (consider m_n in Theorem A); when that input is set to ∞, the comparators on this path have a predetermined behavior, and the remaining network must be an $(n - 1)$-sorter. [*IEEE Trans. on Computers* **C–21** (1972), 612–613.]

43.



[If $P(n)$ denotes the minimum number of switches needed in a permutation network, it is clear that $P(n) \geq \lceil \log_2 n! \rceil$. A. Waksman and M. Green have proved that $P(n) \leq B(n)$ for all n, where $B(n)$ is the binary insertion function of Eq. 5.3.1–3; cf. *IEEE Trans.* **C-17** (1968), 447; Green also has proved that $P(5) = 8$.]

52. If $h[k + 1] = h[k] + 1$ and the file is not in order, something must happen to it

on the next pass; this decreases the number of inversions, by exercise 5.2.2–1, hence the file will eventually become sorted. But if $h[k+1] \geq h[k]+2$ for $1 \leq k < m$, the smallest key will never move into its proper place if it is initially in R_2.

53. We use the hint, and also regard $K_{N+1} = K_{N+2} = \cdots = 1$. If $K_{h[1]+j} = \cdots = K_{h[m]+j} = 1$ at step j, and if $K_i = 0$ for some $i > h[1]+j$, we must have $i < h[m]+j$ since there are less than n 1's. Suppose k and i are minimal such that $h[k]+j < i < h[k+1]+j$ and $K_i = 0$. Let $s = h[k+1]+j-i$; we have $s < h[k+1]-h[k] \leq k$. At step $j-s$, at least $k+1$ 0's must have been under the heads, since $K_i = K_{h[k+1]+j-s}$ was set to zero at that step; s steps later, there are at least $k+1-s \geq 2$ 0's remaining between $K_{h[1]+j}$ and K_i, inclusive, contradicting the minimality of i.

The second pass gets the next $n-1$ elements into place, etc. If we start with the permutation $N\ (N-1)\ \ldots\ 2\ 1$, the first pass changes it to $(N+1-n)\ (N-n)\ \ldots\ 1\ (N+2-n)\ \ldots\ (N-1)\ N$, since $K_{h[1]+j} \leftarrow K_{h[m]+j}$ whenever $1 \leq h[1]+j$ and $h[m]+j \leq N$; therefore the bound is best possible.

54. Suppose that $h[k+1]-s > h[k]$ and $h[k] \leq s$; the smallest key ends in position R_i for $i > 1$ if it starts in R_{n-s}. Therefore $h[k+1] \leq 2h[k]$ is necessary; it is also sufficient, by the special case $t = 0$ of the

Theorem. *If $n = N$ and if $K_1 \ldots K_N$ is a permutation of $\{1, 2, \ldots, n\}$, a single sorting pass will set $K_i = i$ for $1 \leq i \leq t+1$, if $h[k+1] \leq h[k]+h[k-i]+i$ for $1 \leq k < m$ and $0 \leq i \leq t$.* (By convention, let $h[k] = k$ when $k \leq 0$.)

Proof. By induction on t; if step t does not find the key $t+1$ under the heads, we may assume that it appears in position $R_{h[k+1]+t-s}$ for some $s > 0$, where $h[k+1]-s < h[k]$; hence $h[k-t]+t-s > 0$. But this is impossible if we consider step $t-s$, which presumably placed the element $t+1$ into position $R_{h[k+1]+t-s}$ although there were at least $t+1$ lower heads active. ∎

(The condition is necessary for $t = 0, 1$, but not for $t = 2$.)

55. If the numbers $\{1, \ldots, 23\}$ are being sorted, the theorem in the previous exercise shows that $\{1, 2, 3, 4\}$ find their true destination. When 0's and 1's are being sorted it is possible to verify that it is impossible to have all heads reading 0 while all positions not under the heads contain 1's, at steps -2, -1, and 0; hence the proof in the previous exercise can be extended to show that $\{5, 6, 7\}$ find their true destination. Finally $\{8, \ldots, 23\}$ must be sorted, by the argument in exercise 53.

57. When $r \leq m-2$, the heads take the string $0^p1^101^301^70 \ldots 01^{2^r-1}01^q$ into $0^{p+1}1^101^301^70 \ldots 01^{2^{r-1}-1}01^{2^{r-1}+q}$; hence $m-2$ passes are necessary. [When the heads are at positions $1, 2, 3, 5, \ldots, 1+2^{m-2}$, Pratt has discovered a similar result: the string $0^p1^a01^{2^b-1}01^{2^{b+1}-1}0 \ldots 01^{2^r-1}01^q$, $1 \leq a \leq 2^{b-1}$, goes into $0^{p+1}1^{a-1}01^{2^b-1}01^{2^{b+1}-1}0 \ldots 01^{2^{r-1}-1}01^{2^r+q}$, hence at least $m - \lceil \log_2 m \rceil - 1$ passes are necessary in the worst case for this sequence of heads. The latter head sequence is of special interest since it has been used as the basis of a very ingenious sorting device invented by P. N. Armstrong [cf. *U.S. Patent 3399383*]. Pratt conjectures that these input sequences provide the true worst case, over all inputs.]

58. During quicksort, each key $K_2, \ldots, K_N$ is compared with K_1; let $A = \{i | K_i < K_1\}$, $B = \{j | K_j > K_1\}$. Subsequent operations quicksort A and B independently; all comparisons $K_i:K_j$ for i in A and j in B are suppressed, by both quicksort and the

restricted uniform algorithm, and no other comparisons are suppressed by the unrestricted uniform algorithm.

In this case we could restrict the algorithm even further, omitting Cases 1 and 2 so that arcs are added to G only when comparisons are explicitly made, yet considering only paths of length 2 when testing for redundancy. Another way to solve this problem is to consider the equivalent tree insertion sorting algorithm of Section 6.2.2, which makes precisely the same comparisons as the uniform algorithm in the same order.

59. (a) The probability that K_{a_i} is compared with K_{b_i} is the probability that c_i other specified keys do not lie between K_{a_i} and K_{b_i}; this is the probability that two numbers chosen at random from $\{1, 2, \ldots, c_i + 2\}$ are consecutive, namely

$$(c_i + 1) \Big/ \binom{c_i + 2}{2}.$$

(b) The first $n - 1$ values of c_i are zero, then come $(n - 2)$ 1's, $(n - 3)$ 2's, etc.; hence the average is $2\sum_{1\le k\le n} (n-k)/(k+1) = 2\sum_{1\le k\le n} \big((n+1)/(k+1) - 1\big) = 2(n+1)(H_{n+1} - 1) - 2n$. (c) The "bipartite" nature of merging shows that the restricted uniform algorithm is the same as the uniform algorithm for this sequence. The pairs involving vertex N have c's equal to $0, 1, \ldots, N - 2$, respectively; so the average number of comparisons is exactly the same as quicksort.

60. No; when $N = 5$ no pair sequence ending in (1, 5)(1, 2)(2, 3)(3, 4)(4, 5) will require 10 comparisons. [An interesting research problem: For all N, find a (restricted) uniform sorting method whose worst case is as good as possible.]

62. An item can lose at most one inversion per pass, so the minimum number of passes is at least the maximum number of inversions of any item in the input permutation. The bubble sort strategy achieves this bound, since each pass decreases the inversion count of every inverted item by one (cf. 5.2.2–1). An additional pass may be needed to determine whether or not sorting is complete, but the wording of this exercise allows us to overlook such considerations.

It is perhaps unfortunate that the first result in the study of computational complexity via automata established the "optimality" of a sorting method which is so poor from a programming standpoint! The situation is analogous to the history of random number generation, which took several backward steps when generators that are "optimum" from one particular point of view were recommended for general use. The moral is that optimality results are often heavily dependent on the abstract model; although the results are very interesting, they must be applied wisely in practice.

[Demuth went on to consider a generalization to an r-register machine (saving a factor of r), and to a Turing-like machine in which the direction of scan could oscillate between left-right and right-left at will. He observed that the latter type of machine can do the straight insertion and the cocktail shaker sorts; but any such 1-register machine must go through at least $\frac{1}{4}N^2$ steps on the average, since each step reduces the total number of inversions by at most one. Finally he considered r-register random-access machines and the question of minimum-comparison sorting.]

SECTION 5.4

1. We could omit the internal sorting phase, but that would generally be much

slower since it would increase the number of times each piece of data is read and written on the external memory.

2. The runs are distributed as in (1), then Tape 3 is set to $R_1 \ldots R_{2000}$; $R_{2001} \ldots R_{4000}$; $R_{4001} \ldots R_{5000}$. After all tapes are rewound, a "one-way merge" sets T_1 and T_2 to the respective contents of T_3 and T_4 in (2). Then T_1 and T_2 are merged to T_3, and the information is copied back and merged once again, for a total of five passes. In general, the procedure is like the four-tape balanced merge, but with copy passes between each of the merge passes, so one less than twice as many passes are performed.

3. (a) $\lceil \log_P S \rceil$. (b) $\log_B S$, where $B = \sqrt{P(T-P)}$ is called the "effective power of the merge." When $T = 2P$ the effective power is P; when $T = 2P - 1$ the effective power is $\sqrt{P(P-1)} = P - \frac{1}{2} - \frac{1}{8}P^{-1} + O(P^{-2})$, slightly less than $\frac{1}{2}T$.

4. $\frac{1}{2}T$. If T is odd and P must be an integer, both $\lceil T/2 \rceil$ and $\lfloor T/2 \rfloor$ give the same maximum value. It is best to have $P \geq T - P$, according to exercise 3, so we should choose $P = \lceil T/2 \rceil$ for balanced merging.

SECTION 5.4.1

1.

$$087\ 154\ 170\ 426\begin{cases}503\begin{cases}503\ \infty\\908\ \infty\end{cases}\\426\begin{cases}426\ 653\ \infty\\612\ \infty\end{cases}\end{cases}$$

2. The path (061) — (154) — (087) — (512) — [061] would be changed to (087) — (154) — (512) — (612) — [612]. (We are essentially doing a "bubble sort" from bottom to top along the path!)

3. `and fourscore our seven years/ ago brought fathers forth on this/ a conceived continent in liberty nation new the to/ and dedicated men proposition that/ all are created equal.`

4. (The problem is slightly ambiguous; in this interpretation we do not clear the internal memory until the reservoir is about to overflow.)

`and fourscore on our seven this years/ ago brought continent fathers forth in liberty nation new to/ a and conceived dedicated men proposition that the/ all are created equal.`

5. False, the complete binary tree with P external nodes is defined for all $P \geq 1$.

6. Insert "If T = LOC(X[0]) then go to R2, otherwise" at the beginning of step R6, and delete the similar clause from step R7.

7. There is no output, and RMAX stays equal to 0.

8. If the first actual key were ∞ the record would be lost. To avoid ∞, we could set a switch, initially avoiding the test involving LASTKEY in step R4. Then when RQ $\neq$ 0 in step R3 for the first time, the switch is changed so that R4 tests LASTKEY and R3 no longer tests RQ.

9. Assume, for example, that the current run is ascending, while the next should be

descending. Then the steps of Algorithm R will work properly except for one change: In step R6 if RN(T) = RQ > RC, reverse the test on KEY(LOSER(T)) vs. KEY(Q).

When RC changes, the key tests of steps R4 and R6 should change appropriately.

10. Let $\cdot j \equiv \mathtt{LOC}(\mathtt{X}[j])$. The mechanism of Algorithm R ensures that the following conditions are true whenever we reach step R3, if we set first $\mathtt{LOSER}(\cdot 0) \leftarrow \mathtt{Q}$ and $\mathtt{RN}(\cdot 0) \leftarrow \mathtt{RQ}$: The values of $\mathtt{LOSER}(\cdot 0), \ldots, \mathtt{LOSER}\big(\cdot(P-1)\big)$ are a permutation of $\{\cdot 0, \cdot 1, \ldots, \cdot(P-1)\}$; and there exists a permutation of the pointers $\{\mathtt{LOSER}(\cdot j) \mid \mathtt{RN}(\cdot j) = 0\}$ which corresponds to an actual tournament. In other words when $\mathtt{RN}(\cdot j) = 0$, the value of $\mathtt{KEY}\big(\mathtt{LOSER}(\cdot j)\big)$, and therefore also of $\mathtt{LOSER}(\cdot j)$, is irrelevant; we may permute such "Losers" among themselves. After P steps all $\mathtt{RN}(\cdot j)$ will be nonzero, so the entire tree will be consistent. (The answer to the hint is "yes.")

11. True. (Both keys are from the same subsequence in the proof of Theorem K.)

13. The keys left in memory when the first run has ended tend to be smaller than average, since they didn't make it into the first run. Thus the second run can output more of the smaller keys.

14. Assume that the snow suddenly stops when the snowplow is at a random point u, $0 \le u < 1$, after it has reached its "steady state." Then the second-last run contains $(1 + 2u - u^2)P$ records, and the last run contains u^2P. Integrating this times du yields an average time of $(2 - \frac{1}{3})P$ records in the penultimate run, $\frac{1}{3}P$ in the last.

15. False, the last run can be arbitrarily long; but only in the comparatively rare circumstance that all records in memory belong to the same run when the input is exhausted.

16. Iff each element has less than P inversions. (Cf. Sections 5.1.1, 5.4.8.) The probability is 1 when $N \le P$, $P^{N-P}P!/N!$ when $N \ge P$, by considering inversion tables. (In actual practice, however, a one-pass sort is not too uncommon, since people tend to sort a file even when they suspect it might be in order, as a precautionary measure.)

17. Exactly $\lceil N/P \rceil$ runs, all but the last of length P. (The "worst case.")

18. Nothing changes on the second pass, since it is possible to show that the kth record of a run is less than at least $P + 1 - k$ records of the preceding run, for $1 \le k \le P$. (However, there seems to be no simple way to characterize the result of P-way replacement selection followed by P'-way replacement selection when $P' > P$.)

19. Argue as in the derivation of (2) that $h(x, t)\,dx = KL\,dt$, where this time $h(x, t) = I + Kt$ for all x, and $P = IL$. This implies $x(t) = L \ln\big((I + Kt)/I\big)$, so that when $x(T) = L$ we have $KT = (e - 1)I$. The amount of snowfall since $t = 0$ is therefore $(e - 1)IL = (e - 1)P$.

20. As in exercise 19, we have $(I + Kt)\,dx = K(L - x)\,dt$; hence $x(t) = LKt/(I + Kt)$. The reservoir contents is $IL = P = P' = \int_0^T x(t)K\,dt = L\big(KT - I \ln\big((I + KT)/I\big)\big)$, hence $KT = \alpha I$, where $\alpha \approx 2.1461$ is the root of $1 + \alpha = e^{\alpha - 1}$. The run length is the total amount of snowfall during $0 \le t \le T$, namely $KLT = \alpha P$.

21. Proceed as in the text, but after each run wait for $P - P'$ snowflakes to fall before the plow starts out again. This means that $h\big(x(t), t\big)$ is now KT_1, instead of KT, where $T_1 - T$ is the amount of time taken by the extra snowfall. The run length is LKT_1, $x(t) = L(1 - e^{-t/T_1})$, $P = LKT_1e^{-T/T_1}$, and $P' = \int_0^T x(t)K\,dt = P + LK(T - T_1)$. In other words, a run length of $e^\theta P$ is obtained when $P' = \big(1 - (1 - \theta)e^\theta\big)P$, for $0 \le \theta \le 1$.

22. For $0 \le t \le (\kappa - 1)T$, $dx \cdot h = K\,dt\big(x(t+T) - x(t)\big)$, and for $(\kappa - 1)T \le t \le T$, $dx \cdot h = K\,dt\big(L - x(t)\big)$, where h is seen to be constantly equal to KT at the position of the plows. It follows that for $0 \le j \le k$, $0 \le u \le 1$, and $t = (\kappa - j - u)T$, we have $x(t) = L\big(1 - e^{u-\theta}F_j(u)/F(\kappa)\big)$. The run length is KTL, the amount of snowfall between the times that consecutive snowplows leave point 0 in the steady state; P is the amount cleared during each snowplow's last burst of speed, namely $KT\big(L - x(\kappa T)\big) = KTLe^{-\theta}/F(\kappa)$; and $P' = \int_0^{\kappa T} x(t)K\,dt$ can be shown to have the stated form.

[*Notes:* It turns out that the stated formulas are valid also for $k = 0$. When $k \ge 1$ the number of elements per run which go into the reservoir *twice* is $P'' = \int_0^{(\kappa-1)T} x(t)K\,dt$, and it is easy to show that (run length) $- P' + P'' = (e-1)P$, a phenomenon noticed by Frazer and Wong. Is it a coincidence that the generating function for $F_k(\theta)$ is so similar to that in exercise 5.1.3–11?]

23. Let $P = pP'$ and $q = 1 - p$. For the first T_1 units of time the snowfall comes from the qP' elements remaining in the reservoir after the first pP' have been initially removed in random order; and when the old reservoir is empty, uniform snow begins to fall again. We choose T_1 so that $KLT_1 = qP'$. For $0 \le t \le T_1$, $h(x, t) = (p + qt/T_1)g(x)$, where $g(x)$ is the height of snow put into the reservoir from position x; for $T_1 \le t \le T$, $h(x, t) = g(x) + (t - T_1)K$. For $0 \le t \le T_1$, $g\big(x(t)\big)$ is $\big(q(T_1 - t)/T_1\big)g\big(x(t)\big) + (T - T_1)K$; and for $T_1 \le t \le T$, $g\big(x(t)\big) = (T - t)K$. Hence $h\big(x(t), t\big) = (T - T_1)K$ for $0 \le t \le T$, and $x(t) = L\big(1 - \exp\big(-t/(T - T_1)\big)\big)$. The total run length is $(T - T_1)KL$; the total amount "recycled" from the reservoir back again (cf. exercise 22) is T_1KL; and the total amount cleared after time T is $P = KT\big(L - x(T)\big)$.

So the assumptions of this exercise give runs of length $(e^s/s)P$ when the reservoir size is $\big(1 + (s-1)e^s/s\big)P$. This is considerably worse than the results of exercise 22, since the reservoir contents are being used in a more advantageous order in that case.

(The fact that $h\big(x(t), t\big)$ is constant in so many of these problems is not surprising, since it is equivalent to saying that the elements of each run obtained during a steady state of the system are uniformly distributed.)

24. (a) Essentially the same proof works, each of the subsequences has runs in the same direction as the output runs. (b) The stated probability is the probability that the run has length $n + 1$ and is followed by y; it equals $(1 - x)^n/n!$ when $x > y$, and it is $(1 - x)^n/n! - (y - x)^n/n!$ when $x \le y$. (c) Induction. For example if the nth run is ascending, the $(n - 1)$st was descending with probability p, so the first integral applies. (d) We find that $f'(x) = f(x) - c - pf(1 - x) - qf(x)$, then $f''(x) = -2pc$, which ultimately leads to $f(x) = c(1 - qx - px^2)$, $c = 6/(3 + p)$. (e) If $p > eq$ then $pe^x + qe^{1-x}$ is monotone increasing for $0 \le x \le 1$, and $\int_0^1 |pe^x + qe^{1-x} - e^{1/2}|\,dx = (p - q)(e^{1/2} - 1)^2 < 0.43$. If $q \le p < eq$ then $pe^x + qe^{1-x}$ lies between $2\sqrt{pqe}$ and $p + qe$, so $\int_0^1 |pe^x + qe^{1-x} - \frac{1}{2}(p + qe + 2\sqrt{pqe})|\,dx \le \frac{1}{2}(\sqrt{p} - \sqrt{qe})^2 < 0.4$; and if $p < q$ we may use a symmetrical argument. Thus for all p and q there is a constant C such that $\int_0^1 |pe^x + qe^{1-x} - C|\,dx < 0.43$. Let $\delta_n(x) = f_n(x) - f(x)$. Then $\delta_{n+1}(y) = (1 - e^{y-1})\int_0^1 (pe^x + qe^{1-x} - C)\delta_n(x)\,dx + p\int_0^{1-y} e^{y-1+x}\delta_n(x)\,dx + q\int_y^1 e^{y-x}\delta_n(x)\,dx$; hence if $\delta_n(y) \le \alpha_n$, $|\delta_{n+1}(y)| \le (1 - e^{y-1})(1.43)\alpha_n < 0.91\alpha_n$. (f) For all $n \ge 0$, $(1 - x)^n/n!$ is the probability that the run length is $> n$. (g) $\int_0^1 (pe^x + qe^{1-x})f(x)\,dx = 6/(3 + p)$.

26. (a) Consider the number of permutations with $n + r + 1$ elements and n left-to-right minima, where the rightmost element is not the smallest. (b) Use the fact that

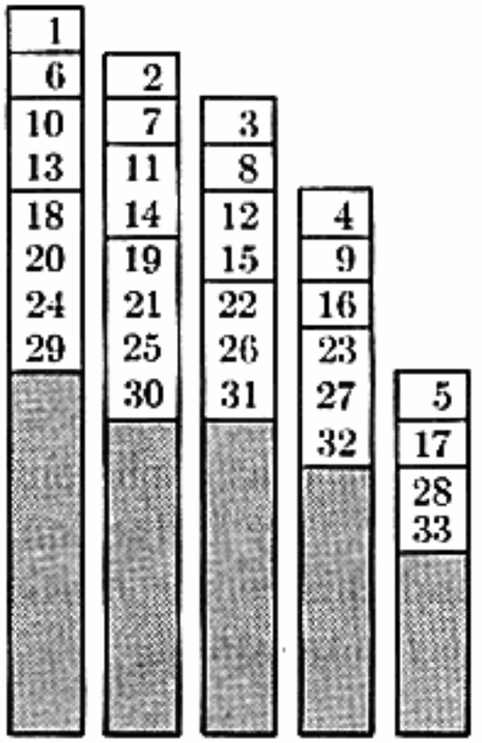
$$\sum_{1\le k<n} \begin{bmatrix} k \\ k-r \end{bmatrix} k = \begin{bmatrix} n \\ n-r-1 \end{bmatrix},$$

by the definition of Stirling numbers in the Index to Notations. (c) Add $r+1$ to the mean, using the fact that $\sum_{n\ge 0} \left[{n+r \atop n}\right](n+r)/(n+r+1)! = 1$, to get $\sum_{n\ge 0} \left[{n+r \atop n}\right]/(n+r-1)!$.

27. For multiway merging there is comparatively little problem, since P stays constant and records are processed sequentially on each file; but when forming initial runs, we would like to vary the number of records in memory depending on their lengths. We could keep a heap of as many records as will fit in memory, using dynamic storage allocation as described in Section 2.5. M. A. Goetz [*Proc. AFIPS Joint Computer Conf.* **25** (1964), 602–604] has suggested another approach, breaking each record into fixed-size parts which are linked together; they occupy space at the leaves of the tree, but only the leading part participates in the tournament.

SECTION 5.4.2

1.



2. After the first merge phase, all remaining dummies are on tape T, and there are at most $a_n - a_{n-1} \le a_{n-1}$ of them. Therefore they all disappear during the second merge phase.

3. We have $(\mathtt{D}[1], \mathtt{D}[2], \ldots, \mathtt{D}[T]) = (a_n - a_{n-P}, a_n - a_{n-P+1}, \ldots, a_n - a_n)$, so the condition follows from the fact that the a's are nondecreasing. The condition is important to the validity of the algorithm, since steps D2 and D3 never decrease $\mathtt{D}[j+1]$ more often than $\mathtt{D}[j]$.

4. $(1 - z - \cdots - z^5)a(z) = 1$ because of (3). Also, $t(z) = \sum_{n\ge 1} (a_n + b_n + c_n + d_n + e_n)z^n = (z + \cdots + z^5)a(z) + (z + \cdots + z^4)a(z) + \cdots + za(z) = (5z + 4z^2 + 3z^3 + 2z^4 + z^5)a(z)$. [Cf. (16).]

5. Let $g_p(z) = (z-1)f_p(z) = z^{p+1} - 2z^p + 1$, and let $h_p(z) = z^{p+1} - 2z^p$. Let $\phi^{-1} > \epsilon > 0$; Rouche's theorem tells us that $h_p(z)$ and $g_p(z)$ have the same number of roots inside the circle $|z| = 1 + \epsilon$, provided $|h_p(z)| > |h_p(z) - g_p(z)| = 1$ on the circle. We have $|h_p(z)| \ge (1+\epsilon)^p(1-\epsilon) > (1+\phi^{-1})^2(1-\phi^{-1}) = 1$. Hence g_p has p roots of magnitude ≤ 1. They are distinct, since $\gcd\big(g_p(z), g_p'(z)\big) = \gcd\big(g_p(z), (p+1)z - 2p\big) = 1$. [*AMM* **67** (1960), 745–752.]

6. Let $c_0 = -\alpha p(\alpha^{-1})/q'(\alpha^{-1})$. Then $p(z)/q(z) - c_0/(1 - \alpha z)$ is analytic in $|z| \le R$ for some $R > |\alpha|^{-1}$; hence the coefficient of z^n in $p(z)/q(z)$ is $c_0\alpha^n + O(R^{-n})$. Thus, $\ln S = n \ln \alpha + \ln c_0 + O((\alpha R)^{-n})$; and $n = (\ln S/\ln \alpha) + O(1)$ implies that $O((\alpha R)^{-n}) = O(S^{-\epsilon})$. Similarly, let $c_1 = \alpha^2 p(\alpha^{-1})/q'(\alpha^{-1})^2$, $c_2 = -\alpha p'(\alpha^{-1})/q'(\alpha^{-1})^2 + \alpha p(\alpha^{-1})q''(\alpha^{-1})/q'(\alpha^{-1})^3$, and consider $p(z)/q(z)^2 - c_1/(1 - \alpha z)^2 - c_2/(1 - \alpha z)$.

7. Let $\alpha_p = 2(1 - t)$, and $z = 2^{-p-1}$. Then $z = t(1 - t)^p$, and reversion of this series (Algorithm 4.7*R*) gives a power series for t in terms of z, yielding the asymptotic expansion $\alpha_p = 2 - 2^{-p} - p2^{-2p-1} + O(p^2 2^{-3p})$.

Note: It follows that the quantity ρ in exercise 6 becomes approximately $\log_4 S$ as p increases. Similarly, for both Table 5 and Table 6, the coefficient c approaches $1/((\phi + 2) \ln \phi)$ on a large number of tapes.

8. Evidently $N_0^{(p)} = 1$, $N_m^{(p)} = 0$ for $m < 0$, and by considering the different possibilities for the first summand we have $N_m^{(p)} = N_{m-1}^{(p)} + \cdots + N_{m-p}^{(p)}$ when $m > 0$. Hence $N_m^{(p)} = F_{m+p-1}^{(p)}$. [*Lehrbuch der Combinatorik* (Leipzig: Teubner, 1901), 136–137.]

9. Consider the position of the leftmost 0, if there is one; we find $K_m^{(p)} = F_{m+p}^{(p)}$. *Note:* There is a simple one-to-one correspondence between such sequences of 0's and 1's and the representations of $m + 1$ considered in exercise 8: Place a 0 at the right end of the sequence, and look at the positions of all the 0's.

10. *Lemma:* If $n = F_{j_1}^{(p)} + \cdots + F_{j_m}^{(p)}$ is such a representation, with $j_1 > \cdots > j_m \ge p$, we have $n < F_{j_1+1}^{(p)}$. *Proof:* The result is obvious if $m < p$; otherwise let k be minimal with $j_k > j_{k+1} + 1$; we have $k < p$, and by induction $F_{j_{k+1}}^{(p)} + \cdots + F_{j_m}^{(p)} < F_{j_k-1}^{(p)}$, hence $n < F_{j_1}^{(p)} + \cdots + F_{j_1-k-1}^{(p)} \le F_{j_1+1}^{(p)}$.

The stated result can now be proved, by induction on n. If $n > 0$ let j be maximal such that $F_j^{(p)} \le n$. The lemma shows that each representation of n must consist of $F_j^{(p)}$ plus a representation of $n - F_j^{(p)}$. By induction, $n - F_j^{(p)}$ has a unique representation of the desired form, and this representation does not include all of the numbers $F_{j-1}^{(p)}, \ldots, F_{j-p+1}^{(p)}$ because j is maximal.

Notes: The case $p = 2$, which is due to E. Zeckendorf [cf. *Simon Stevin* **29** (1952), 190–195], has been considered in exercise 1.2.8–34. There is a simple algorithm to go from the representation of n to that of $n + 1$, working on the sequence $c_j \ldots c_1 c_0$ of 0's and 1's such that $n = \sum c_j F_{j+p}^{(p)}$: For example, if $p = 3$, we look at the rightmost digits, changing $\ldots 0$ to $\ldots 1$, $\ldots 01$ to $\ldots 10$, $\ldots 011$ to $\ldots 100$; then we "carry" to the left if necessary, replacing "$\ldots 0111 \ldots$" by "$\ldots 1000 \ldots$". See the sequences of 0's and 1's in exercise 9, in the order listed. A similar number system has been studied by W. C. Lynch [*Fibonacci Quarterly* **8** (1970), 6–22], who found a very interesting way to make it govern both the distribution and merge phases of a polyphase sort.

12. The kth power contains the perfect distributions for levels $k - 4$ through k, on successive rows, with the largest elements to the right.

13. By induction on the level.

14. (a) $n(1) = 1$, so assume that $k > 1$. The law $T_{nk} = T_{n-1,k-1} + \cdots + T_{n-P,k-1}$ shows that $T_{nk} \le T_{n+1,k}$ iff $T_{n-P,k-1} \le T_{n,k-1}$. Let r be any positive integer, and let n' be minimal such that $T_{n'-r,k-1} > T_{n',k-1}$; then $T_{n-r,k-1} \ge T_{n,k-1}$ for all $n \ge n'$, since it is trivial for $n \ge n(k - 1) + r$ and otherwise $T_{n-r,k-1} \ge T_{n'-r,k-1} \ge T_{n',k-1} \ge T_{n,k-1}$. (b) The same argument with $r = n - n'$ shows that $T_{n'k'} < T_{nk'}$

implies $T_{n'-j,k'} \le T_{n-j,k'}$ for all $j \ge 0$; hence the recurrence implies that $T_{n'-j,k} \le T_{n-j,k}$ for all $j \ge 0$ and $k \ge k'$. (c) Let $\ell(S)$ be the least n such that $\Sigma_n(S)$ assumes its minimum value. The sequence M_n exists as desired iff $\ell(S) \le \ell(S+1)$ for all S. Suppose $n = \ell(S) > \ell(S+1) = n'$, so that $\Sigma_n(S) < \Sigma_{n'}(S)$ and $\Sigma_n(S+1) \ge \Sigma_{n'}(S+1)$. There is some smallest S' such that $\Sigma_n(S') < \Sigma_{n'}(S')$, and we have $m = \Sigma_n(S') - \Sigma_n(S'-1) < \Sigma_{n'}(S') - \Sigma_{n'}(S'-1) = m'$. Then $\sum_{1\le k\le m} T_{n'k} < S' \le \sum_{1\le k\le m} T_{nk}$; hence there is some $k' \le m$ such that $T_{n'k'} < T_{nk'}$. Similarly we have $l = \Sigma_n(S+1) - \Sigma_n(S) > \Sigma_{n'}(S+1) - \Sigma_{n'}(S) = l'$; hence $\sum_{1\le k\le l'} T_{n'k} \ge S+1 > \sum_{1\le k\le l'} T_{nk}$. Since $l' \ge m' > m$, there is some $k > m$ such that $T_{n'k} > T_{nk}$. But this contradicts part (b).

15. This theorem has been proved by D. A. Zave, whose article was cited in the text.

16. D. A. Zave has shown that the number of records input (and output) is $S \log_{T-1} S + O(S\sqrt{\log S})$.

17. Let $T = 3$; $A_{11}(x) = 6x^6 + 35x^7 + 56x^8 + \cdots$, $B_{11}(x) = x^6 + 15x^7 + 35x^8 + \cdots$, $T_{11}(x) = 7x^6 + 50x^7 + 91x^8 + 64x^9 + 19x^{10} + 2x^{11}$. The optimum distribution for $S = 144$ requires 55 runs on T2, and this forces a nonoptimum distribution for $S = 145$. D. A. Zave has studied near-optimum procedures of this kind.

18. Let $S = 9$, $T = 3$, and consider the following two patterns.

Optimum Polyphase:

T1	T2	T3	Cost
$0^2 1^6$	$0^2 1^3$	—	
1^3	—	$0^2 2^3$	6
—	$1^2 3^1$	2^2	5
3^2	3^1	—	6
3^1	—	6^1	6
—	9^1	—	9
			32

Alternative:

T1	T2	T3	Cost
$0^1 1^6$	$0^1 1^3$	—	
1^3	—	$0^1 2^3$	6
—	$1^1 3^2$	2^1	7
3^1	3^2	—	3
—	3^1	6^1	6
9^1	—	—	9
			31

(Still another way to improve on "optimum" polyphase is to reconsider where dummy runs appear on the output tape of every merge phase. For example, the result of merging $0^2 1^3$ with $0^2 1^3$ might be regarded as $2^1 0^1 2^1 0^1 2^1$ instead of $0^2 2^3$. Thus, many unresolved questions of optimality remain.)

19.

Level	T1	T2	T3	T4	Total	Final output on
0	1	0	0	0	1	T1
1	0	1	1	1	3	T6
2	1	1	1	0	3	T5
3	1	2	1	1	5	T4
4	2	2	2	1	7	T3
5	2	4	3	2	11	T2
6	4	5	4	2	15	T1
7	5	8	6	4	25	T6
. . . . .						
n	a_n	b_n	c_n	d_n	t_n	T(k)
$n+1$	b_n	$c_n + a_n$	$d_n + a_n$	a_n	$t_n + 2a_n$	T($k-1$)

20. $a(z) = 1/(1 - z^2 - z^3 - z^4)$, $t(z) = (3z + 3z^2 + 2z^3 + z^4)/(1 - z^2 - z^3 - z^4)$, $\sum_{n\geq 1} T_n(x)z^n = x(3z + 3z^2 + 2z^3 + z^4)/\big(1 - x(z^2 + z^3 + z^4)\big)$. $D_n = A_{n-1} + 1$, $C_n = A_{n-1}A_{n-2} + 1$, $B_n = A_{n-1}A_{n-2}A_{n-3} + 1$, $A_n = A_{n-2}A_{n-3}A_{n-4} + 1$.

21. 333343333332322 33334333333323 33334333333 3333433 333323 T5

22. $t_n - t_{n-1} - t_{n-2} = 2$ when $n \bmod 3 = 1$, and it is -1 otherwise. (This Fibonacci-like relation follows from the fact that $1 - z^2 - 2z^3 - z^4 = (1 - \phi z)(1 - \hat{\phi} z)(1 - \omega z)(1 - \bar{\omega} z)$, where $\omega^3 = 1$.)

23. In place of (25), the run lengths during the first half of the nth merge phase are s_n, and on the second half they are t_n, where

$$s_n = t_{n-2} + t_{n-3} + s_{n-3} + s_{n-4}, \qquad t_n = t_{n-2} + s_{n-2} + s_{n-3} + s_{n-4}.$$

Here we regard $s_n = t_n = 1$ for $n \leq 0$. [In general, if v_{n+1} is the sum of the first $2r$ terms of $u_{n-1} + \cdots + v_{n-P}$, we have $s_n = t_n = t_{n-2} + \cdots + t_{n-r} + 2t_{n-r-1} + t_{n-r-2} + \cdots + t_{n-P}$; if v_{n+1} is the sum of the first $2r - 1$, we have $s_n = t_{n-2} + \cdots + t_{n-r-1} + s_{n-r-1} + \cdots + s_{n-P}$, $t_n = t_{n-2} + \cdots + t_{n-r} + s_{n-r} + \cdots + s_{n-P}$.]

In place of (27) and (28), $A_n = (U_{n-1}V_{n-1}U_{n-2}V_{n-2}U_{n-3}V_{n-3}U_{n-4}V_{n-4}) + 1$, $\ldots$, $D_n = (U_{n-1}V_{n-1}) + 1$, $E_n = (U_{n-2}V_{n-2}U_{n-3}) + 1$; $V_{n+1} = (U_{n-1}V_{n-1}U_{n-2}) + 1$, $U_n = (V_{n-2}U_{n-3}V_{n-3}U_{n-4}V_{n-4}) + 1$.

16^1	16^1	8^0	R
R	16^1	—	24^0
16^1	16^1	R	$24^0 32^0$
16^0	16^0	32^1	(R)

26. When 2^n are sorted, $n \cdot 2^n$ initial runs are processed while merging; each half phase (with few exceptions) merges 2^{n-2} and rewinds 2^{n-1}. When $2^n + 2^{n-1}$ are sorted, $n \cdot 2^n + (n - 1) \cdot 2^{n-1}$ initial runs are processed while merging; each half phase (with few exceptions) merges 2^{n-2} or 2^{n-1} and rewinds $2^{n-1} + 2^{n-2}$.

27. It works if and only if the gcd of the distribution numbers is 1. For example, let there be six tapes; if we distribute (a, b, c, d, e) to T1 through T5, where $a \geq b \geq c \geq d \geq e > 0$, the first phase leaves a distribution $(a - e, b - e, c - e, d - e, e)$, and $\gcd(a - e, b - e, c - e, d - e, e) = \gcd(a, b, c, d, e)$. (Any common divisor of one set of numbers divides the others too.) The process decreases the number of runs at each phase until $\gcd(a, b, c, d, e)$ runs are left on a single tape.

[Note that these nonpolyphase distributions sometimes turn out to be superior to polyphase under certain configurations of dummy runs, as shown in exercise 18. This property was first observed by B. Sackman about 1963.]

28. We get any such (a, b, c, d, e) by starting with $(1, 0, 0, 0, 0)$ and doing the following operation exactly n times: Choose x in $\{a, b, c, d, e\}$, and add x to each of the other four elements of (a, b, c, d, e).

To show that $a + b + c + d + e \leq t_n$, we shall prove by induction that if $a \geq b \geq c \geq d \geq e$ we always have $a \leq a_n$, $b \leq b_n$, $c \leq c_n$, $d \leq d_n$, $e \leq e_n$. Assuming that this holds for level n, it must hold also for level $n + 1$, since the level $n + 1$

distributions are $(b+a,\ c+a,\ d+a,\ e+a,\ a)$, $(a+b,\ c+b,\ d+b,\ e+b,\ b)$, $(a+c, b+c, d+c, e+c, c)$, $(a+d, b+d, c+d, e+d, d)$, $(a+e, b+e, c+e, d+e, e)$.

30. The following table has been computed by J. A. Mortenson.

Level	$T=5$	$T=6$	$T=7$	$T=8$	$T=9$	$T=10$	
1	2	2	2	2	2	2	M_1
2	4	5	6	7	8	9	M_2
3	4	5	6	7	8	9	M_3
4	8	8	10	12	14	16	M_4
5	10	14	18	17	20	23	M_5
6	18	20	26	27	32	31	M_6
7	26	32	46	47	56	42	M_7
8	44	53	74	82	92	92	M_8

10	112	134	206	140	177	196	M_{10}
11	178	197	317	324	208	241	M_{11}
12	290	350	401	488	595	288	M_{12}
13	466	566	933	640	838	860	M_{13}
14	756	917	1371	769	1064	1177	M_{14}

SECTION 5.4.3

1. Comparing the average number of times each record is processed, in Table 5.4.2–6, the tape-splitting polyphase is superior when there are 6, 7, or 8 tapes.

2. The methods are essentially identical when the number of initial runs is a Fibonacci number; but the manner of distributing dummy runs in other cases is better with polyphase. The cascade algorithm puts 1 on T1, then 1 on T2, 1 on T1, 2 on T2, 3 on T1, 5 on T2, etc. and step D8 never finds $D[p-1] = M[p-1]$ when $p = 2$. In effect, all dummies are on one tape, and this is less efficient than the method of Algorithm 5.4.2D.

3. (Distribution stops after putting 12 runs on T3 during Step (3, 3).)

T1	T2	T3	T4	T5	T6
1^{26}	1^{21}	1^{24}	1^{14}	1^{15}	—
1^{5}	—	1^{12}	$1^{2}2^{7}$	1^{15}	$2^{2}4^{12}$
8^{4}	$6^{2}9^{3}$	5^{2}	6^{3}	1^{1}	—
—	9^{1}	23^{1}	17^{1}	25^{1}	26^{1}
100^{1}	—	—	—	—	—

4. Induction. (Cf. exercise 5.4.2–28.)

5. When there are a_n initial runs, the kth pass outputs a_{n-k} runs of length a_k, then b_{n-k} of length b_k, etc.

6.
$$\begin{pmatrix} 1 & 1 & 1 & 1 & 1 \\ 1 & 1 & 1 & 1 & 0 \\ 1 & 1 & 1 & 0 & 0 \\ 1 & 1 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 & 0 \end{pmatrix}$$

7. $e_2e_{n-2} + e_3e_{n-3} + \cdots + e_ne_0$ initial run lengths (cf. exercise 5), which may also be written $a_1a_{n-3} + a_2a_{n-4} + \cdots + a_{n-2}a_0$; it is the coefficient of z^{n-2} in $A(z)^2 - A(z)$.

8. The denominator of $A(z)$ has distinct roots and greater degree than the numerator, hence $A(z) = \sum q_3(\rho)/(1 - \rho z)\rho(1 - q_4'(\rho))$ summed over all roots ρ of $q_4(\rho) = \rho$. The special form of ρ is helpful in evaluating $q_3(\rho)$ and $q_4'(\rho)$.

9. The formulas hold for all *large* n, by (8) and (12), in view of the value of $q_m(2 \sin \theta_k)$. To show that they hold for all n we need to know that $q_{m-1}(z)$ is the quotient when $q_{r-1}(z)q_m(z)$ is divided by $q_r(z) - z$, for $0 \leq m < r$. This can be proved either by (a) using (10) and noting that cancellations bring down the degree of $q_{r-1}(z)q_m(z) - q_r(z)q_{m-1}(z)$; or (b) the result of exercise 5 implies that $A(z)^2 + B(z)^2 + \cdots + E(z)^2 \to 0$ as $z \to \infty$; or (c) it is possible to find an explicit formula for the numerators of $B(z)$, $C(z)$, etc.

10. $E(z) = r_1(z)A(z)$; $D(z) = r_2(z)A(z) - r_1(z)$; $C(z) = r_3(z)A(z) - r_2(z)$; $B(z) = r_4(z)A(z) - r_3(z)$; $A(z) = r_5(z)A(z) + 1 - r_4(z)$. Thus $A(z) = \big(1 - r_4(z)\big)/\big(1 - r_5(z)\big)$. [Note that $r_m(2 \sin \theta) = \sin (2m\theta)/\cos \theta$; $r_m(z)$ is the Chebyshev polynomial $(-1)^{m+1}U_{2m-1}(z/2)$.]

11. Prove that $f_m(z) = q_{\lfloor m/2 \rfloor}(z) - r_{\lceil m/2 \rceil}(z)$ and that $f_m(z)f_{m-1}(z) = 1 - r_m(z)$. Then use the result of exercise 10.

SECTION 5.4.4

1. When writing an ascending run, *first* write a sentinel record containing $-\infty$ before outputting the run. (And a $+\infty$ sentinel should be written at the end of the run as well, if the output is ever going to be read forward, e.g., on the final pass.) For descending runs, interchange the roles of $-\infty$ and $+\infty$.

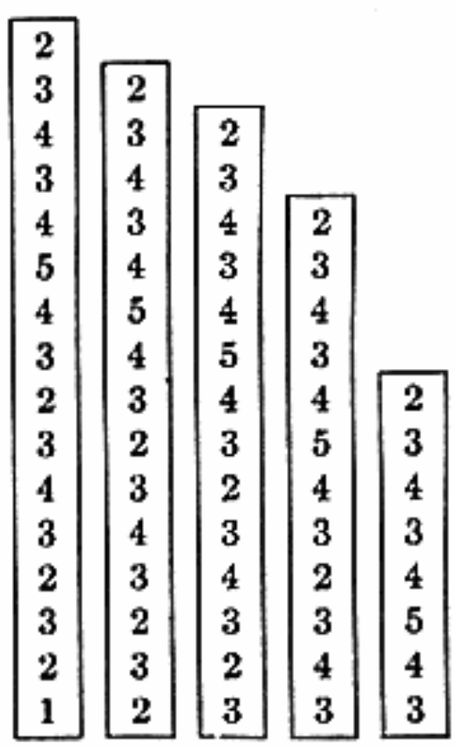
2. The smallest number on level $n+1$ is equal to the largest on level n; hence the columns are nondecreasing, regardless of the way we permute the numbers in any particular row.

3. In fact, during the merge process the first run on T2–T6 will always be descending, and the first on T1 will always be ascending. (By induction.)

4. It requires several "copy" operations on the second and third phases; the approximate extra cost is $(\log 2)/(\log \rho)$ passes, where ρ is the "growth ratio" in Table 5.4.2–1.

5. If α is a string, let α^R denote its left-right reversal.

Level	T1	T2	T3	T4	T5
0	0	—	—	—	—
1	1	1	1	1	1
2	12	12	12	12	2
3	1232	1232	1232	232	32
4	12323432	12323432	2323432	323432	3432
. . .	. . .	. . .	. . .	. . .	. . .
n	A_n	B_n	C_n	D_n	E_n
$n+1$	$B_n(A_n^R+1)$	$C_n(A_n^R+1)$	$D_n(A_n^R+1)$	$E_n(A_n^R+1)$	A_n^R+1



$$E_n = A^R_{n-1} + 1,$$
$$D_n = A^R_{n-2}A^R_{n-1} + 1,$$
$$C_n = A^R_{n-3}A^R_{n-2}A^R_{n-1} + 1,$$
$$B_n = A^R_{n-4}A^R_{n-3}A^R_{n-2}A^R_{n-1} + 1,$$
$$A_n = A^R_{n-5}A^R_{n-4}A^R_{n-3}A^R_{n-2}A^R_{n-1} + 1 = n - Q_n,$$

where

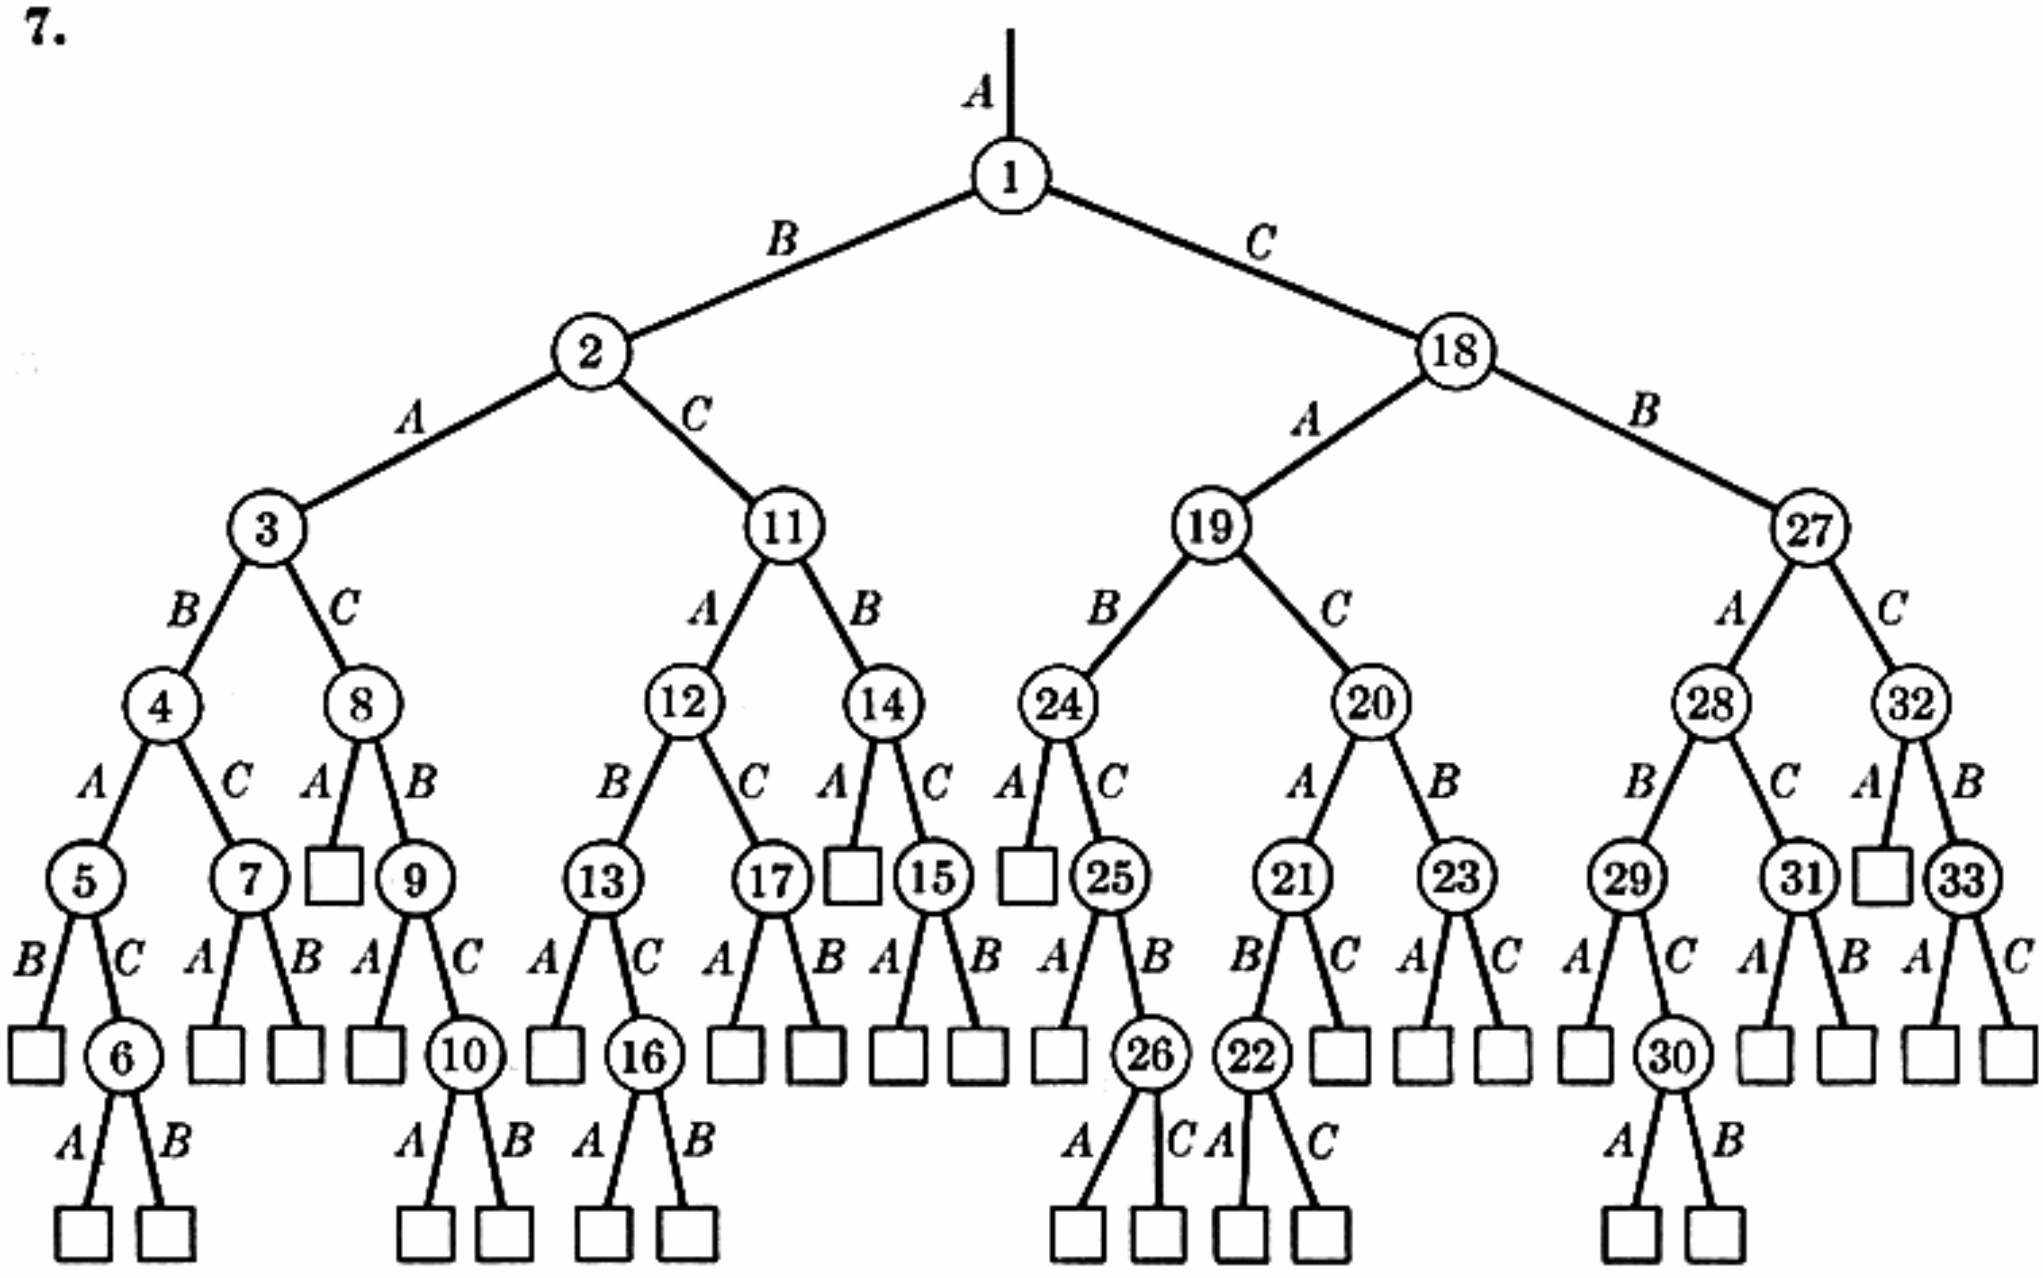
$$Q^R_n = Q_{n-1}(Q_{n-2}+1)(Q_{n-3}+2)(Q_{n-4}+3)(Q_{n-5}+4), \qquad n \geq 1.$$

Q_0 = '0', and Q_n is null for $n < 0$. In place of 5.4.2–12 we could consider a doubly infinite string which contains Q^R_1, Q_2, Q^R_3, Q_4, Q^R_5, etc. near its center.

These strings A_n, B_n, etc. contain the same entries as the corresponding strings in Section 5.4.2, but in another order. Note that adjacent merge numbers always differ by 1. An initial run must be A iff its merge number is even, D iff odd. Simple distribution schemes such as Algorithm 5.4.2D are not quite as effective at placing dummies into high-merge-number positions; therefore it is probably advantageous to compute Q_n between phases 1 and 2, in order to help control dummy run placement (assuming S is small enough that Q_n will fit comfortably in memory).

6. $y^{(4)} = (+1, +1, -1, +1)$
$y^{(3)} = (+1, \ 0, -1, \ 0)$
$y^{(2)} = (+1, -1, +1, +1)$
$y^{(1)} = (-1, +1, +1, +1)$
$y^{(0)} = (\ 1, \ 0, \ 0, \ 0)$

7.



Incidentally, 34 is apparently the smallest Fibonacci number F_n for which polyphase doesn't produce the optimum read-backwards merge for F_n initial runs on three tapes. This tree has external path length 178, which beats polyphase by two.

8. For $T = 4$, the tree with external path length 13 is not T-lifo, and every tree with external path length 14 includes a one-way merge.

9. We may consider a complete $(T - 1)$-ary tree, by the result of exercise 2.3.4.5–6; the degree of the "last" internal node is between 2 and $T - 1$. When there are $(T - 1)^q - m$ external nodes, $\lfloor m/(T - 2) \rfloor$ of them are on level $q - 1$, and the rest are on level q.

11. True by induction on the number of initial runs. If there is a valid distribution with S runs and two adjacent runs in the same direction, then there is one with $< S$ runs; but there is none when $S = 1$.

12. Conditions (a), (b) are obvious. If either configuration in (4) is present, for some tape name A and some $i < j < k$, node j must be in a subtree below node i and to the left of node k, by the definition of preorder. Hence the "$j - l$" case can't be present, and A must be the "special" name since it appears on an external branch. But this contradicts the fact that the special name is supposed to be on the leftmost branch below node i.

13. Nodes now numbered 4, 7, 11, 13 could be external instead of one-way merges. (This gives an external path length one higher than the polyphase tree.)

15. Let the tape names be A, B, and C. We shall construct several species of trees, botanically identified by their root and leaf (external node) structure:

Type $r(A)$. Root A.
Type $s(A, C)$. Root A, no C leaves.
Type $t(A)$. Root A, no A leaves.
Type $u(A, C)$. Root A, no C leaves, no compound B leaves.
Type $v(A, C)$. Root A, no C leaves, no compound A leaves.
Type $w(A, C)$. Root A, no A leaves, no compound C leaves.

A "compound leaf" is a leaf whose brother is not a leaf. We can grow a 3-lifo type $r(A)$ tree by first growing its left subtree as a type $s(B, C)$, then growing the right subtree as type $r(C)$. Similarly, type $s(A, C)$ comes from a type $s(B, C)$ then $t(C)$; type $u(A, C)$ from $v(B, C)$ and $w(C, B)$; type $v(A, C)$ from $u(B, C)$ and $w(C, A)$. We can grow a 3-lifo type $t(A)$ tree whose left subtree is type $u(B, A)$ and whose right subtree is type $s(C, A)$, by first letting the left subtree grow except for its (non-compound) C leaves and its right subtree; at this point the left subtree has only A and B leaves, so we can grow the right subtree of the whole tree, then grow off the A leaves of the left left subtree, and finally grow the left right subtree. Similarly, a type $w(A, C)$ tree can be fabricated from a $u(B, A)$ and a $v(C, A)$. [The tree of exercise 7 is an $r(A)$ tree constructed in this manner.]

Let $r(n), \ldots, w(n)$ denote the minimum external path length over all n-leaf trees of the relevant type, when they are constructed by such a procedure. We have $r(1) = s(1) = u(1) = 0$, $r(2) = t(2) = w(2) = 2$, $t(1) = v(1) = w(1) = s(2) = u(2) = v(2) = \infty$; and for $n \geq 3$,

$$r(n) = n + \min_k \big(s(k) + r(n - k)\big), \qquad u(n) = n + \min_k \big(v(k) + w(n - k)\big),$$
$$s(n) = n + \min_k \big(s(k) + t(n - k)\big), \qquad v(n) = n + \min_k \big(u(k) + w(n - k)\big),$$
$$t(n) = n + \min_k \big(u(k) + s(n - k)\big), \qquad w(n) = n + \min_k \big(u(k) + v(n - k)\big).$$

It follows that $r(n) \le s(n) \le u(n)$, $s(n) \le v(n)$, and $r(n) \le t(n) \le w(n)$ for all n; furthermore $s(2n) = t(2n+1) = \infty$. (The latter is evident *a priori*.)

Let $A(n)$ be the function defined by the laws $A(1) = 0$, $A(2n) = 2n + 2A(n)$, $A(2n+1) = 2n+1+A(n)+A(n+1)$; then $A(2n) = 2n + A(n-1) + A(n+1) -$ (0 or 1) for all $n \ge 2$. Let C be a constant such that, for $4 \le n \le 8$,

i) n even implies that $w(n) \le A(n) + Cn - 1$.
ii) n odd implies that $u(n)$ and $v(n)$ are $\le A(n) + Cn - 1$.

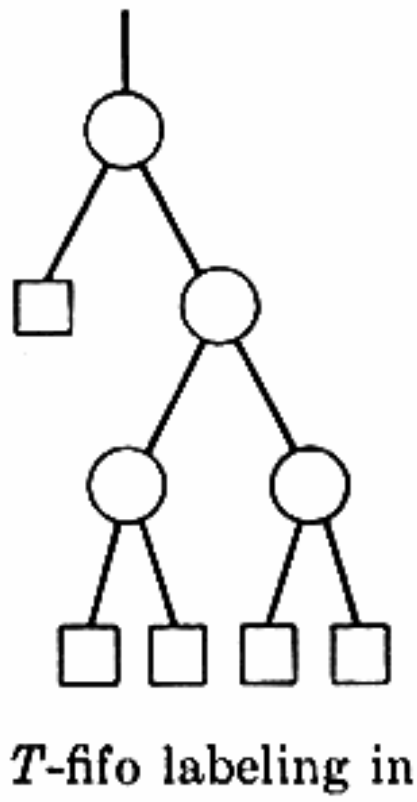
(This actually works for all $C \ge \frac{5}{6}$.) Then an inductive argument, choosing k to be $\lfloor n/2 \rfloor \pm 1$ as appropriate, shows that the relations are valid for *all* $n \ge 4$. But $A(n)$ is the lower bound in (9) when $T = 3$, and $r(n) \le \min\big(u(n), v(n), w(n)\big)$, hence we have proved that $A(n) \le K_3(n) \le r(n) \le A(n) + \frac{5}{6}n - 1$. [The constant $\frac{5}{6}$ can be lowered here.]

17.

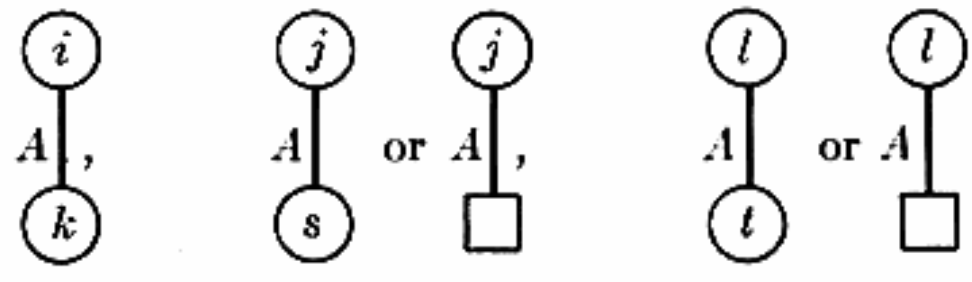
Level	T1	T2	T3	T4	T5
0	1	0	0	0	0
1	5	4	3	2	1
2	55	50	41	20	15
. . .	. . .	. . .	. . .	. . .	. . .
n	a_n	b_n	c_n	d_n	e_n
$n+1$	$5a_n + 4b_n + 3c_n + 2d_n + e_n$	$4a_n + 4b_n + 3c_n + 2d_n + e_n$	$3a_n + 3b_n + 3c_n + 2d_n + e_n$	$2a_n + 2b_n + 2c_n + 2d_n + e_n$	$a_n + b_n + c_n + d_n + e_n$

To get from level n to level $n+1$ during the initial distribution, insert k_1 "sublevels" with (4, 4, 3, 2, 1) runs added respectively to tapes (T1, T2, . . . , T5), k_2 "sublevels" with (4, 3, 3, 2, 1) runs added, k_3 with (3, 3, 2, 2, 1), k_4 with (2, 2, 2, 1, 1), k_5 with (1, 1, 1, 1, 0), where $k_1 \le a_n$, $k_2 \le b_n$, $k_3 \le c_n$, $k_4 \le d_n$, $k_5 \le e_n$. [If $(k_1, \ldots, k_5) = (a_n, \ldots, e_n)$ we have reached level $n+1$.] Add dummy runs if necessary to fill out a sublevel. Then merge $k_1 + k_2 + k_3 + k_4 + k_5$ runs from (T1, . . . , T5) to T6, merge $k_1 + \cdots + k_4$ from (T1, . . . , T4) to T5, . . . , merge k_1 from T1 to T2; and merge k_1 from (T2, . . . , T6) to T1, k_2 from (T3, . . . , T6) to T2, . . . , k_5 from T6 to T5. [This method was used in the UNIVAC III sort program, about 1962, and presented at the ACM Sort Symposium that year.]

19.

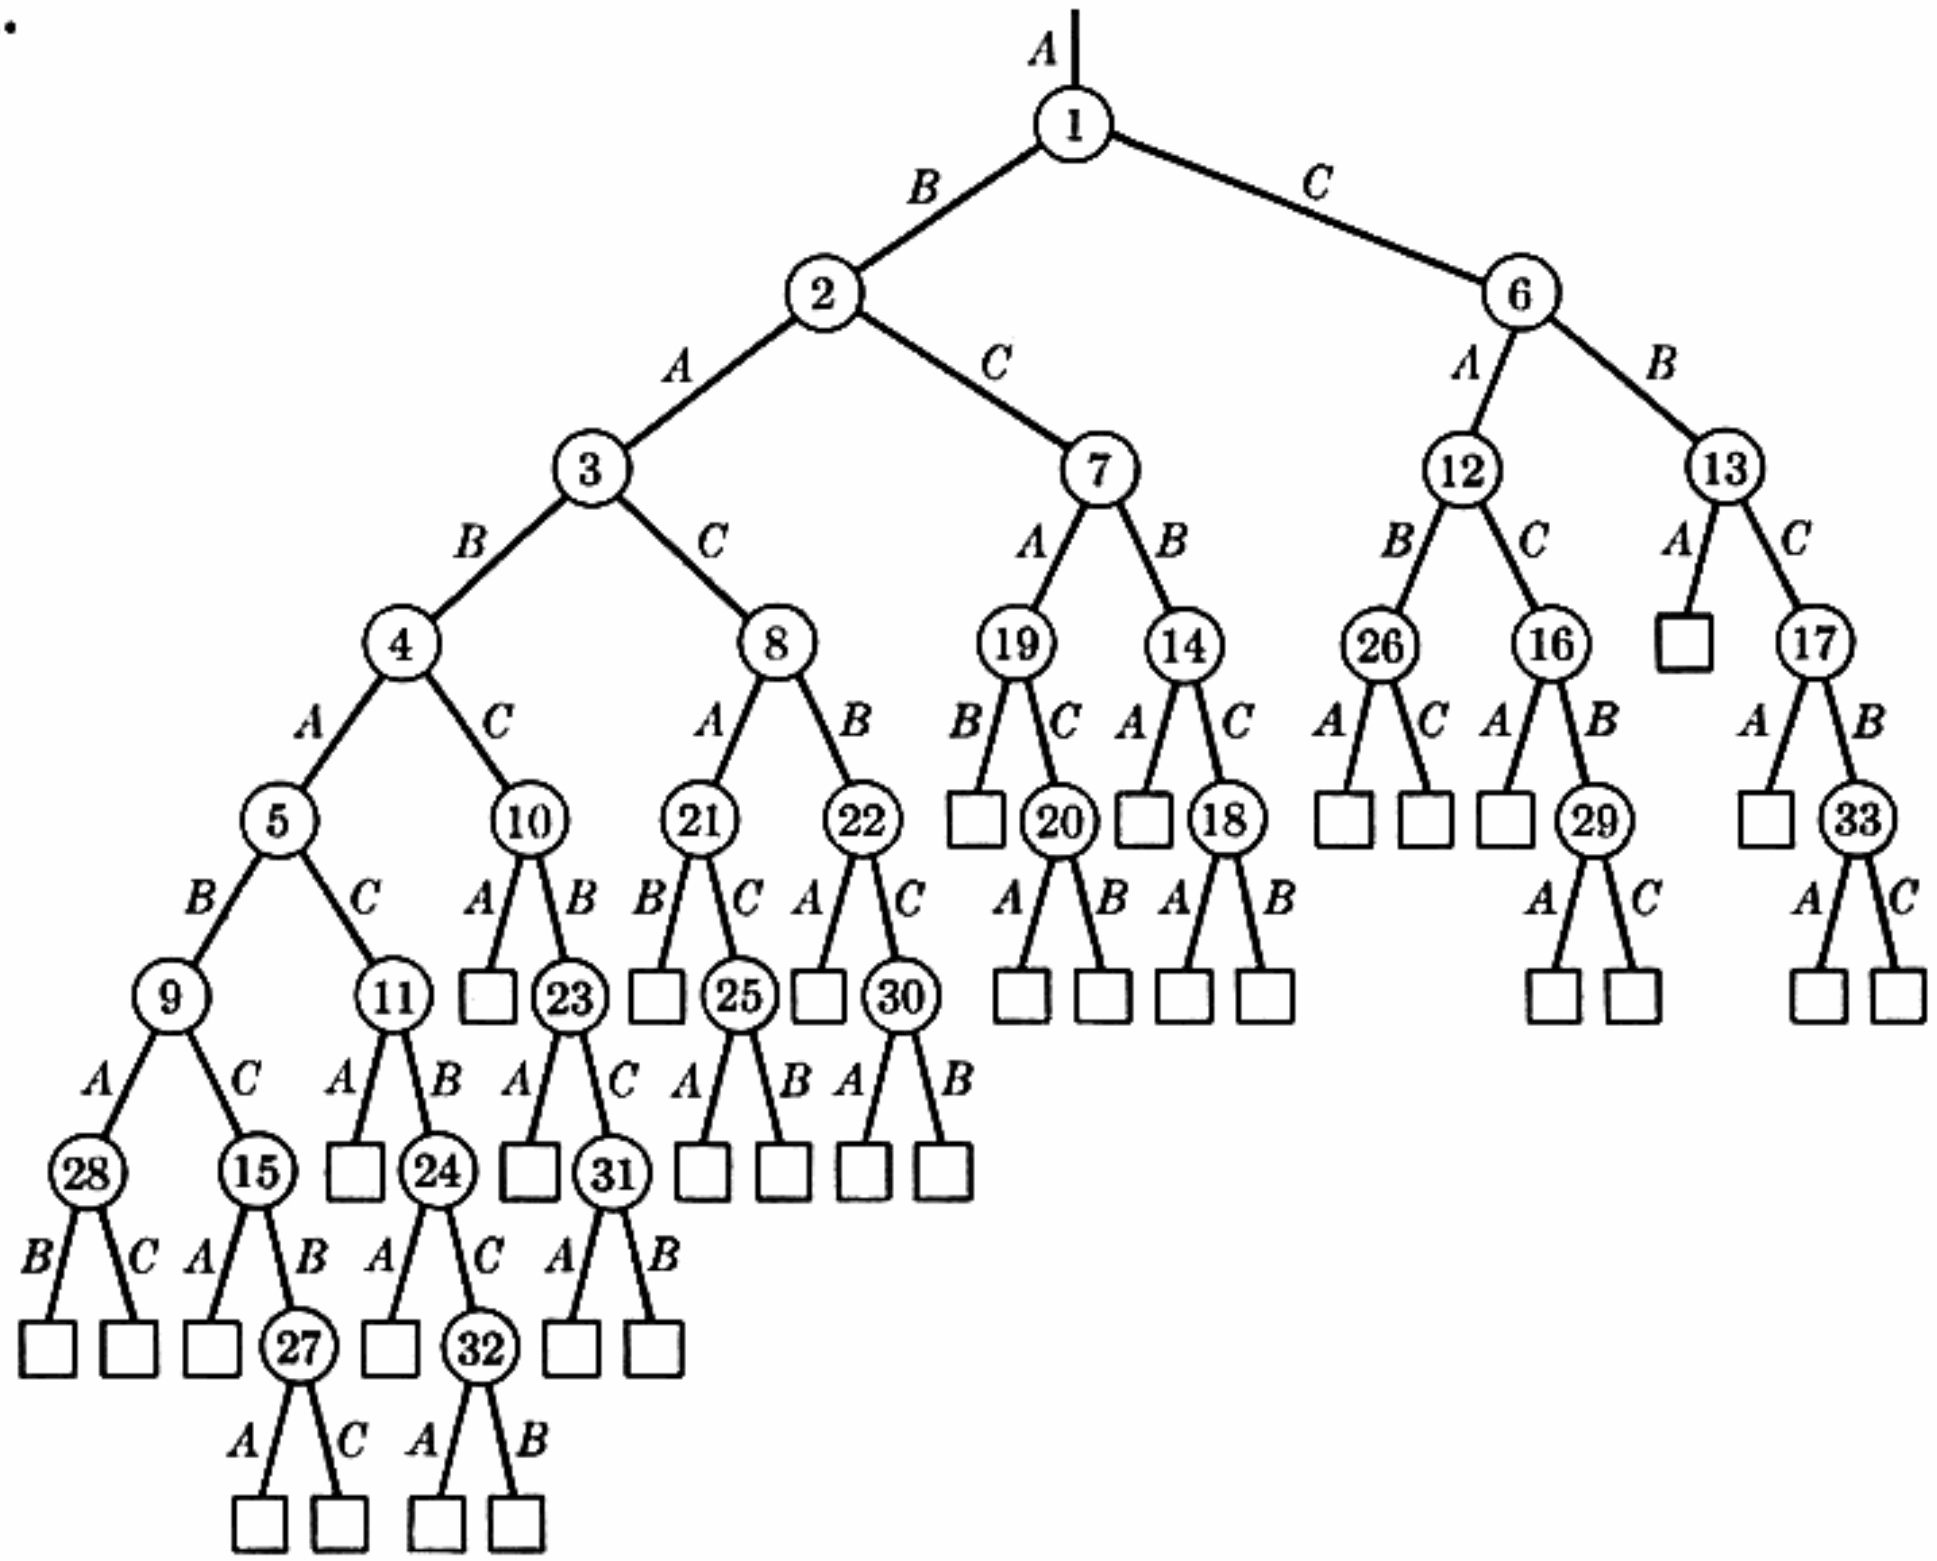


20. A strongly T-fifo tree has a T-fifo labeling in which there are no three branches having the respective forms



for some tape name A and some $i < j < k < l < s$. Informally, when we "grow on" an A, we must grow on all other A's before creating any new A's.

21.



which is very weakly fifo.

22. This occurs for any tree representations formed by successively replacing all occurrences of,

e.g., 
by, e.g., 
for some fixed tape names A, B, C, D.

Since all occurrences are replaced by the same pattern, the lifo or fifo order makes no difference in the structure of the tree.

Stating the condition in terms of the vector model: Whenever ($y^{(k+1)} \neq y^{(k)}$ or $k = m$) and $y_j^{(k)} = -1$, we have $y_j^{(k)} + \cdots + y_j^{(1)} + y_j^{(0)} = 0$.

23. (a) Assume that $v_1 \leq v_2 \leq \cdots \leq v_T$; the "cascade" stage $(1, \ldots, 1, -1)^{v_T}$ $(1, \ldots, 1, -1, 0)^{v_{T-1}} \ldots (1, -1, 0, \ldots, 0)^{v_2}$ takes $C(v)$ into v. (b) Immediate, since $C(v)_k \leq C(w)_k$ for all k. (c) If v is obtained in q stages, we have $u \to u^{(1)} \to \cdots \to u^{(q)} = v$ for some unit vector u, and some other vectors $u^{(1)}, \ldots$. Hence $u^{(1)} \preceq C(u)$, $u^{(2)} \preceq C(C(u))$, $\ldots$, $v \preceq C^q(u)$. Hence $v_1 + \cdots + v_T$ is less than or equal to the sum of the elements of $C^q(u)$; and the latter is obtained in cascade merge. [This theorem generalizes the result of exercise 5.4.3–4. Unfortunately the concept of "stage" as defined here doesn't seem to have any practical significance.]

24. Let $y^{(m)} \dots y^{(l+1)}$ be a stage which reduces w to v. If $y_j^{(0)} = -1$, $y_j^{(t-1)} = 0$, $\dots$, $y_j^{(k+1)} = 0$, and $y_j^{(k)} = -1$, for some $k < i - 1$, we can insert $y^{(k)}$ between $y^{(i)}$ and $y^{(i-1)}$. Repeat this operation until all (-1)'s in each column are adjacent. Then if $y_j^{(0)} = 0$ and $y_j^{(t-1)} \neq 0$ it is possible to set $y_j^{(t)} \leftarrow 1$; ultimately each column consists of $+1$'s followed by -1's followed by 0's, and we have constructed a stage which reduces w' to v for some $w' \geq w$. Permuting the columns, this stage takes the form $(1, \dots, 1, -1)^{a_T} \dots (1, -1, 0, \dots, 0)^{a_2}(-1, 0, \dots, 0)^{a_1}$. The sequence of $T - 1$ relations

$$\begin{aligned}(x_1, \dots, x_T) &\preceq (x_1 + x_T, \dots, x_{T-1} + x_T, 0)\\ &\preceq (x_1 + x_{T-1} + x_T, \dots, x_{T-2} + x_{T-1} + x_T, x_T, 0)\\ &\preceq (x_1 + x_{T-2} + x_{T-1} + x_T, \dots, x_{T-3} + x_{T-2} + x_{T-1} + x_T,\\ &\qquad x_{T-1} + x_T, x_T, 0) \preceq \cdots\\ &\preceq (x_1 + x_2 + x_3 + \cdots + x_T, x_3 + \cdots + x_T, \dots, x_{T-1} + x_T, x_T, 0)\end{aligned}$$

now shows that the best choice of the a's is $a_T = v_T$, $a_{T-1} = v_{T-1}$, $\dots$, $a_2 = v_2$, $a_1 = 0$. And the result is best if we permute columns so that $v_1 \leq \cdots \leq v_T$.

25. (a) Assume that $v_{T-k+1} \geq \cdots \geq v_T \geq v_1 \geq \cdots \geq v_{T-k}$ and use $(1, \dots, 1, -1, 0, \dots, 0)^{v_T - v_{T-k+1}} \dots (1, \dots, 1, 0, \dots, 0, -1)^{v_T}$. (b) The sum of the l largest elements of $D_k(v)$ is $(l-1)s_k + s_{k+l}$, for $1 \leq l \leq T - k$. (c) If $v \Rightarrow w$ in a phase that uses k output tapes, we may obviously assume that the phase has the form $(1, \dots, 1, -1, 0, \dots, 0)^{a_1} \dots (1, \dots, 1, 0, \dots, 0, -1)^{a_k}$, with each of the other $T - k$ tapes used as input in each operation. Choosing $a_1 = v_{T-k+1}, \dots, a_k = v_T$ is best. (d) See exercise 22(c). We always have $k_1 = 1$; and $k = T - 2$ always beats $k = T - 1$ since we assume that at least one component of v is zero. Hence for $T = 3$ we have $k_1 \dots k_q = 1^q$ and the initial distribution $(F_{q+1}, F_q, 0)$. For $T = 4$ the undominated strategies and their corresponding distributions are found to be

$q = 2$	12 (3, 2, 0, 0)
$q = 3$	121 (5, 3, 3, 0); 122 (5, 5, 0, 0)
$q = 4$	1211 (8, 8, 5, 0); 1222 (10, 10, 0, 0); 1212 (11, 8, 0, 0)
$q = 5$	12121 (19, 11, 11, 0); 12222 (20, 20, 0, 0); 12112 (21, 16, 0, 0)
$q = 6$	122222 (40, 40, 0, 0); 121212 (41, 30, 0, 0)
$q \geq 7$	12^{q-1} $(5 \cdot 2^{q-3}, 5 \cdot 2^{q-3}, 0, 0)$

So for $T = 4$ and $q \geq 6$, the minimum-phase merge is like balanced merge, with a slight twist at the very end (going from (3, 2, 0, 0) to (1, 0, 1, 1) instead of to (0, 0, 2, 1)).

When $T = 5$ the undominated strategies are $1(32)^{n-1}2$, $1(32)^{n-1}3$ for $q = 2n \geq 2$; $1(32)^{n-1}32$, $1(32)^{n-1}22$, $1(32)^{n-1}23$ for $q = 2n + 1 \geq 3$. (The first strategy listed has most runs in its distribution.) On six tapes they are 13 or 14, 142 or 132 or 133, 1333 or 1423, then 13^{q-1} for $q \geq 5$.

SECTION 5.4.5

1. The following algorithm is controlled by a table A[L — 1] . . . A[1]A[0] that essentially represents a number in radix P notation. As we repeatedly add unity to this number, the "carries" tell us when to merge. Tapes are numbered from 0 to P.

O1. [Initialize.] Set $(\mathtt{A}[L-1], \ldots, \mathtt{A}[0]) \leftarrow (0, \ldots, 0)$ and $q \leftarrow 0$. (During this algorithm, q will equal $(\mathtt{A}[L-1] + \cdots + \mathtt{A}[0]) \bmod T$.)

O2. [Distribute.] Write an initial run on tape q, in ascending order. Set $l \leftarrow 0$.

O3. [Add one.] If $l = L$, stop; the output is on tape $(-L) \bmod T$, in ascending order iff L is even. Otherwise set $\mathtt{A}[l] \leftarrow \mathtt{A}[l] + 1$, $q \leftarrow (q+1) \bmod T$.

O4. [Carry?] If $\mathtt{A}[l] < P$, return to O2. Otherwise merge to tape $(q-l) \bmod T$, increase l by 1, set $\mathtt{A}[l] \leftarrow 0$ and $q \leftarrow (q+1) \bmod T$, and return to O3. ∎

2. Keep track of how many runs are on each tape. When the input is exhausted, add dummy runs if necessary until reaching a situation with at most one run on each tape and at least one tape empty. Then finish the sort in one more merge, rewinding some tapes first if necessary. (It is possible to deduce the orientation of the runs from the A table.)

3.

Op	T0	T1	T2
Dist	—	A_1	A_1A_1
Merge	D_2	—	A_1
Dist	D_2A_1	—	A_1
Merge	D_2	D_2	—
Dist	D_2	D_2A_1	A_1
Merge	D_2D_2	D_2	—
Merge	D_2	—	A_4

Op	T0	T1	T2
Dist	D_2A_1	A_1	A_4
Merge	D_2	—	A_4D_2
Merge	—	A_4	A_4
Dist	—	A_4	A_4A_1
Copy	—	A_4D_1	A_4
Copy	—	A_4	A_4A_1
Merge	D_5	—	A_4

At this point T2 would be rewound and a final merge would complete the sort. To avoid the useless copy operations, replace step B4 by:

B4′. [Ready to merge?] If $\mathtt{A}[l-1, q] = s$, go to step B5. Otherwise if the input is exhausted and $\mathtt{A}[l-1, q] - s$ is a positive even number *and* $\mathtt{A}[l-1, (2r-q) \bmod T] \neq \mathtt{A}[l-1, q] - 1$, set $s \leftarrow \mathtt{A}[l-1, q]$ and go to B5. Otherwise go back to step B3.

[This change avoids situations in which the runs are simply shifted back and forth. The first parenthesized comment in step B5 is no longer strictly correct, but the algorithm still works properly because the A table entries on level l will not be looked at. The smallest S for which this change makes any difference is $P^3 + 1$. When P is large, the change hardly ever makes much difference, but it does keep the computer from looking too foolish in some circumstances. The algorithm should also be changed to handle the case $S = 1$ more efficiently.]

4. We can, in fact, omit setting $A[0, 0]$ in step B1, $A[l, q]$ in steps B3 and B5. [But $A[l, r]$ *must* be set in step B3.]

5. $P^{2k} - (P-1)P^{2k-2} < S \leq P^{2k}$ for some $k > 0$.

SECTION 5.4.6

1. $\lfloor 23000480/(n+480) \rfloor n$.

2. At the instant shown, all the records in that buffer have been moved to the output. Step F2 insists that the test "Is output buffer full?" precede the test "Is input buffer empty?" while merging, otherwise we would have trouble (unless the changes of exercise 4 were made).

3. No, e.g., we might reach a state with P buffers $1/P$ full and $P - 1$ buffers full, if file i contains the keys i, $i + P$, $i + 2P$, ... for $1 \le i \le P$. This example shows that $2P$ input buffers are necessary for continuous output even if we allowed simultaneous reading, unless we reallocated memory for partial buffers or used a "scatter read" in some way. [Actually, if blocks contain less than $P - 1$ records, we need less than $2P$ buffers, but this is unlikely. Older computers would read a block of data into a special hardware buffer separate from the computer memory, and computation would stop while the contents of this buffer were transferred to memory. In such a situation, $2P - 1$ "software" buffers in memory would be sufficient.]

4. Set up **S** sooner (in steps **F1** and **F4** instead of **F3**).

5. If, for example, all keys of all files were equal, we couldn't simply make arbitrary decisions while forecasting; the forecast must be compatible with decisions made by the merging process. One safe way is to find the smallest possible m in steps F1 and F4, i.e. to consider a record from file $C[i]$ to be less than all records having the same key on file $C[j]$ whenever $i < j$. (In essence, the file number is appended to the key.)

6. In step C1 also set $\texttt{TAPE}[T + 1] \leftarrow T + 1$. In step C8 the merge should be to $\texttt{TAPE}[p + 2]$ instead of $\texttt{TAPE}[p + 1]$. In step C9, set $(\texttt{TAPE}[1], \ldots, \texttt{TAPE}[T + 1]) \leftarrow (\texttt{TAPE}[T + 1], \ldots, \texttt{TAPE}[1])$.

7. The method used in Chart A is $(A_1D_1)^4A_0D_0(A_1D_1)^2A_0D_0(A_1D_1)^3A_0$, $D_1(A_1D_1)^4A_0D_0(A_1D_1)^3A_0D_0\alpha A_0D_0A_0$, $D_1A_0D_0(A_1D_1)^3A_0D_0\alpha A_1D_1A_0$, $D_1A_1D_1\alpha A_1D_1A_0$, where $\alpha = (A_0D_0)^2A_1D_1A_0D_0(A_1D_1)^2(A_0D_0)^7A_1D_1(A_0D_0)^3A_1D_1A_0D_0$. The first merge phase writes $D_0A_3D_3A_1D_1A_4D_4A_0D_0A_1D_1A_1D_1A_4D_4A_0D_0A_1D_1A_0D_0(A_1D_1)^4$ on tape 5; the next writes $A_4D_4A_4D_4A_1D_1A_4D_4A_0D_0A_1D_1A_1D_1A_7$ on tape 1; the next, $D_{13}A_4D_4A_0D_0A_{10}$ on tape 4. The final phases are

$A_4D_4A_4$	—	$D_{19}A_3D_3A_{12}$	$D_{13}A_4D_4A_4$	D_0A_3
A_4	$D_{23}A_{11}$	$D_{19}A_3$	$D_{13}A_4$	—
—	D_{23}	D_{19}	D_{13}	D_{22}
A_{77}	—	—	—	—

8. No, since at most S stop/starts are saved, and since the speed of the input tape (not the output tapes) tends to govern the initial distribution time anyway. The other advantages of the distribution schemes used in Chart A outweigh this miniscule disadvantage.

9. $P = 5$, $B = 8300$, $B' = 734$, $S = \lceil (3 + 1/P)N/6P' \rceil + 1 = 74$, $\omega = 1.094$, $\alpha = 0.795$, $\beta = -1.136$, $\alpha' = \beta' = 0$; (9) = 855 seconds, to which we add the time for initial rewind, for a total of 958 seconds. The savings of about one minute in the merging does not compensate for the loss of time due to the initial rewinding and tape changing (unless perhaps we are in a multiprogramming environment).

10. The rewinds during standard polyphase merge are over about 54 percent of the file (the "pass/phase" column in Table 5.4.2–1), and the longest rewinds during standard cascade merge cover approximately $a_k a_{n-k}/a_n \approx (4/(2T - 1)) \cos^2 (\pi/(4T - 2)) < \frac{4}{11}$ of the file, by exercise 5.4.3–5 and Eq. 5.4.3–13.

11. Only initial and final rewinds get to make use of the "high-speed" feature, since the reel is only a little more than 10/23 full when it contains the whole example file.

Using $\pi = \lceil .946 \ln S - 1.204 \rceil$, $\pi' = 1/8$ in example 8, we get the following estimated totals for examples 1–9, respectively:

$$1115,\ 1296,\ 1241,\ 1008,\ 1014,\ 967,\ 891,\ 969,\ 856.$$

12. (a) An obvious solution with $4P + 4$ buffers simply reads and writes simultaneously from paired tapes. But note that three output buffers are sufficient (at a given moment we are performing the second half of a write from one, the first half of a write from another, and outputting into the third), and this suggests a corresponding improvement in the input buffer situation. It turns out that $3P$ input buffers and 3 output buffers are necessary and sufficient, using a slightly weakened "forecasting" technique. A simpler and superior approach, suggested by J. Sue, adds a "lookahead key" to each block, specifying the final key of the subsequent block. Sue's method requires $2P + 1$ input buffers and 4 output buffers, and it is a straightforward modification of Algorithm F.

(b) In this case the high value of α means that we must do between five and six passes over the data, which wipes out the advantage of double-quick merging. The idea works out much better on eight or nine tapes.

13. No, consider for example the situation just before $A_{16}\ A_{16}\ A_{16}\ A_{16}$. But two reelfulls *can* be handled.

14.
$$\det\begin{pmatrix} 0 & -p_0z & 0 & z-1 \\ 0 & 1-p_1z & -p_0z & z-1 \\ 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix} \Big/ \det\begin{pmatrix} 1-p_{\geq 1}z & -p_0z & 0 & z-1 \\ -p_{\geq 2}z & 1-p_1z & -p_0z & z-1 \\ 0 & -1 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}.$$

15. The A matrix has the form

$$A = \begin{pmatrix} B_{10}z & B_{11}z & \dots & B_{1n}z & 1-z \\ \vdots & & & & \vdots \\ B_{n0}z & B_{n1}z & \dots & B_{nn}z & 1-z \\ 0 \dots 0 & & 1 & 0 & 0 \\ 0 \dots 0 & & 0 & 0 & 0 \end{pmatrix}, \qquad \begin{aligned} B_{10} + B_{11} + \cdots + B_{1n} &= 1 \\ &\vdots \\ B_{n0} + B_{n1} + \cdots + B_{nn} &= 1 \end{aligned} \quad . \tag{11}$$

Therefore

$$\det(I - A) = \det\begin{pmatrix} 1-B_{10}z & -B_{11}z & \dots & -B_{1,n-1}z & -B_{1n}z \\ \vdots & & & & \vdots \\ -B_{n0}z & -B_{n1}z & \dots & 1-B_{n,n-1}z & -B_{nn}z \\ 0 & 0 & & -1 & 1 \end{pmatrix}$$

and we can add all columns to the first column, then factor out $(1 - z)$. Consequently $g_Q(z)$ has the form $h_Q(z)/(1-z)$, and $\alpha^{(Q)} = h_Q(1)$ because $h_Q(1) \neq 0$ and $\det(I - A) \neq 0$ for $|z| < 1$.

SECTION 5.4.7

1. Sort from least significant digit to most significant digit in the number system whose radices are alternately P and $T - P$. (If pairs of digits are grouped, we have

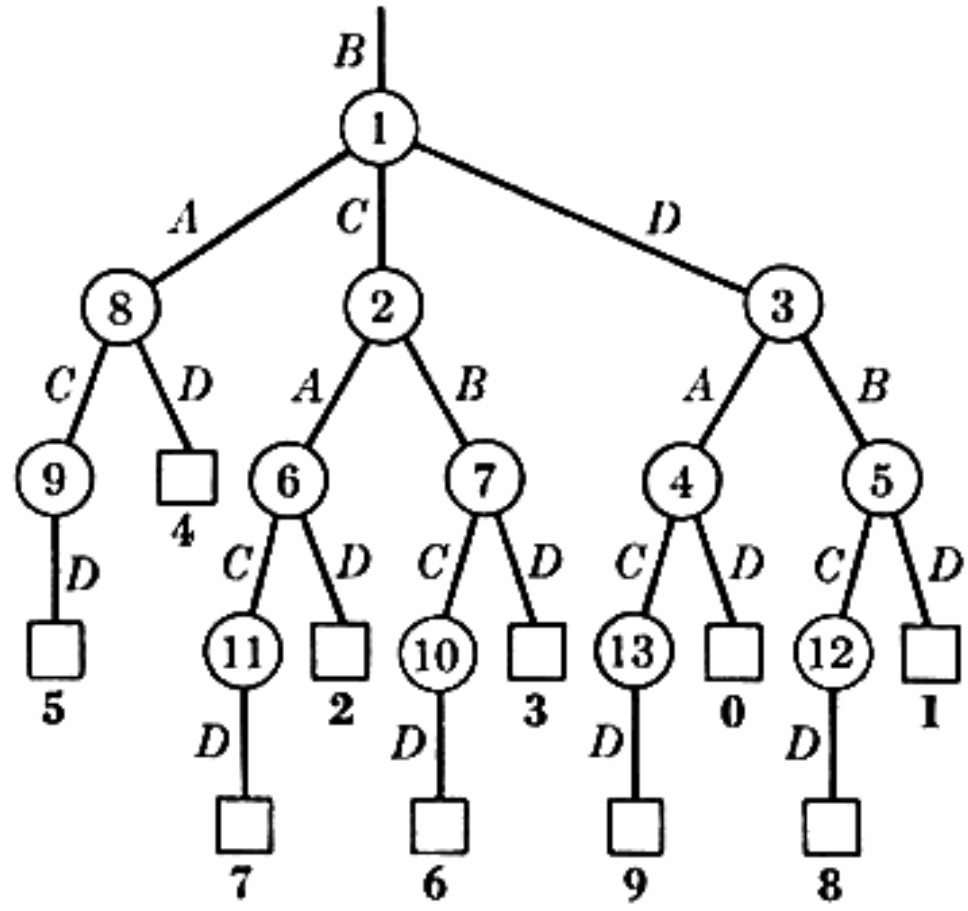
essentially a pure radix of $P \cdot (T - P)$. Thus, if $P = 2$ and $T = 7$, the number system is "biquinary," related to decimal notation in a simple way.)

2. If K is a key between 0 and $F_n - 1$, let the Fibonacci representation of $F_n - 1 - K$ be $a_{n-2}F_{n-1} + \cdots + a_1F_2$, where the a_j are 0 or 1, and no two consecutive 1's appear. After phase j, tape $j + 1$ (modulo 3) contains those keys with $a_j = 0$ and tape $j - 1$ (modulo 3) contains those with $a_j = 1$, in decreasing order of $a_{j-1} \ldots a_1$.

[Imagine a card sorter with two pockets "0" and "1," and consider the procedure of sorting F_n cards that have been punched with the keys $a_{n-2} \ldots a_1$ in $n - 2$ columns. The conventional procedure for sorting these into decreasing order, starting at the least significant digit, can be simplified since we know that everything in the "1" pocket at the end of one pass will go into the "0" pocket on the following pass.]

4. If there were an external node on level 2 we could not construct such a good tree. Otherwise there are at most three external nodes on level 3, six on level 4, since each external node is supposed to appear on the same tape.

5.



6. 09, 08, . . . , 00, 19, . . . , 10, 29, . . . , 20, 39, . . . , 30, 40, 41, . . . , 49, 59, . . . , 50, 60, 61, . . . , 99.

7. Yes; first distribute the records into smaller and smaller subfiles until obtaining one-reel files which can be individually sorted. This is dual to the process of sorting one-reel files and then merging them into larger and larger multireel files.

SECTION 5.4.8

1. Yes. The ordering of the file and the selection tree alternates between ascending and descending, and we have in effect an order-P cocktail shaker sort; cf. exercise 9.

2. Let $Z_N = Y_N - X_N$, and solve the recurrence for Z_N by noting that $(N+1)NZ_{N+1} = N(N-1)Z_N + N^2 + N$; hence

$$Z_N = \tfrac{1}{3}(N+1) + \binom{M+2}{3} \Big/ N(N-1), \qquad \text{for} \qquad N > M.$$

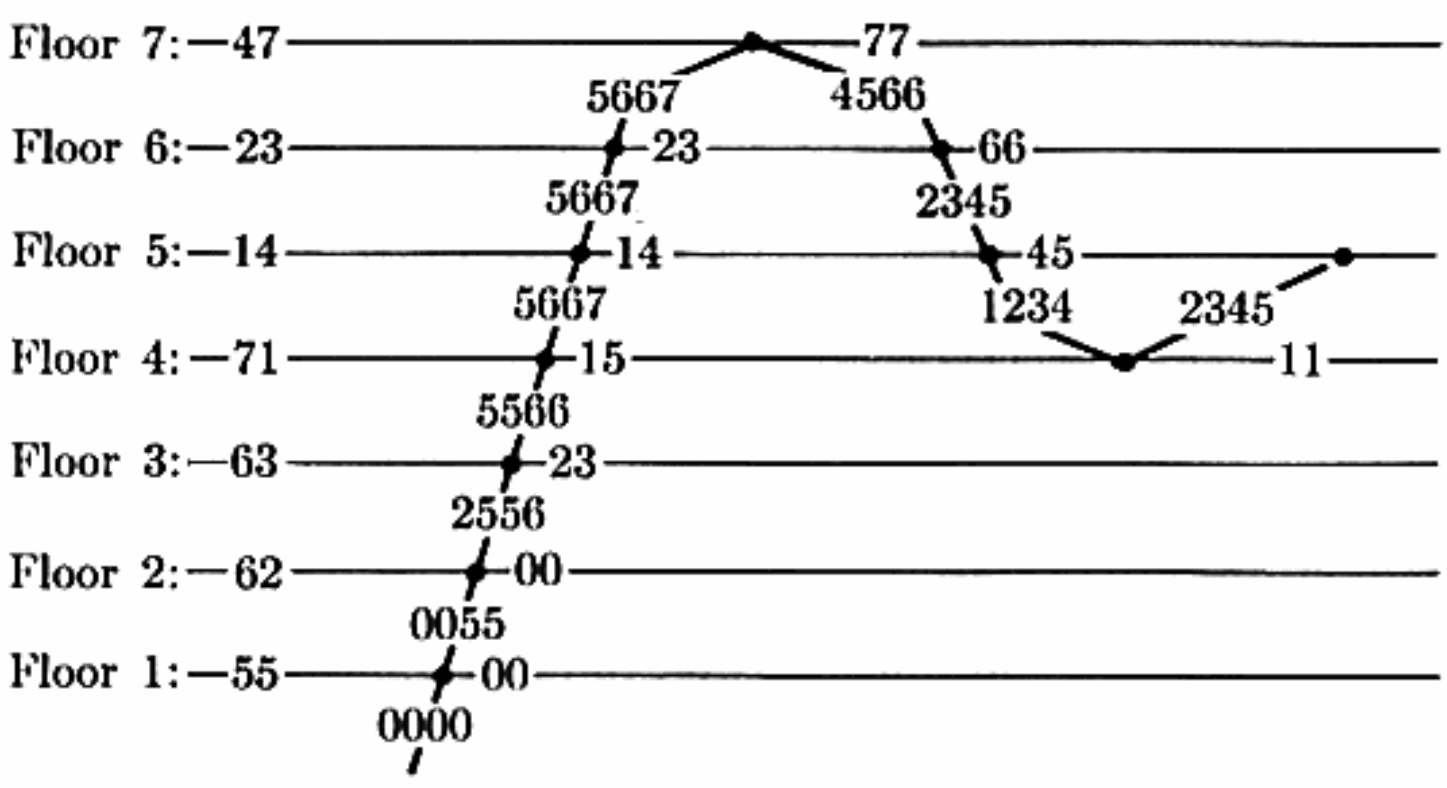
Now eliminate Y_N and obtain

$$\frac{X_N}{N+1} = 6\tfrac{2}{3}(H_{N+1} - H_{M+2}) + 2\left(\frac{1}{N+1} - \frac{1}{M+2}\right)$$
$$-\frac{2}{3}\binom{M+2}{3}\left(\frac{1}{(N+1)N(N-1)} - \frac{1}{(M+2)(M+1)M}\right) + \frac{3M+4}{M+2}, \qquad N > M.$$

3. Yes; find a median element in $O(N)$ steps, using a construction like that of Theorem 5.3.3, and use it to partition the file. Another interesting approach, due to R. W. Floyd and A. J. Smith, is to merge two runs of N items in $O(N)$ units of time as follows: Spread the items out on the tapes, with spaces between them, then successively fill each space with a number specifying the final position of the item just preceding that space.

4. It is possible to piece together a schedule for floors $1, \ldots, p+1$ with a schedule for floors $q, \ldots, n$: When the former schedule first reaches floor $p+1$, go up to floor q and carry out the latter schedule (using the current elevator contents as if they were the extra "0" men in the algorithm of Theorem K). After finishing that schedule, go back to floor $p+1$ and resume the previous schedule.

5. Consider $b = 4$, $c = 2$ and the following behavior of the algorithm:



Now 2 (in the elevator) is less than 3 (on floor 3).

[After constructing an example such as this, the reader should be able to see how to demonstrate the weaker property required in the proof of Theorem K.]

6. Let i, j be minimal with $c_i < c_i'$ and $c_j > c_j'$. Introduce a new man who wants to go from i to j. This doesn't increase $\max(u_k, d_{k+1}, 1)$ or $\max(c_k, c_k')$ for any k. Continue this until $c_j = c_j'$ for all j. Now observe that the algorithm in the text works also with c replaced by c_k in steps K1 and K3.

8. Let the number be P_n, and let Q_n be the number of permutations such that $u_k = 1$ for $1 \le k < n$. Then $P_n = Q_1P_{n-1} + Q_2P_{n-2} + \cdots + Q_nP_0$, $P_0 = 1$. It can be shown that $Q_n = 3^{n-2}$ for $n \ge 2$ (see below), hence a generating function argument yields

$$\sum P_n z^n = (1 - 3z)/(1 - 4z + 2z^2) = 1 + z + 2z^2 + 6z^3 + 20z^4 + \cdots;$$
$$2P_n = (2+\sqrt{2})^{n-1} + (2-\sqrt{2})^{n-1}.$$

To prove that $Q_n = 3^{n-2}$, consider a ternary sequence $x_1x_2 \ldots x_n$ such that $x_1 = 2, x_n = 0$, and $0 \leq x_k \leq 2$ for $1 < k < n$. The following rule defines a one-to-one correspondence between such sequences and the desired permutations $a_1a_2 \ldots a_n$:

$$a_k = \begin{cases} \max \{j \mid (j < k \quad \text{and} \quad x_j = 0) \quad \text{or} \quad j = 1\}, & \text{if} \quad x_k = 0; \\ k \qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad , & \text{if} \quad x_k = 1; \\ \min \{j \mid (j > k \quad \text{and} \quad x_j = 2) \quad \text{or} \quad j = n\}, & \text{if} \quad x_k = 2. \end{cases}$$

(This correspondence was obtained by the author jointly with E. A. Bender.)

9. The number of passes of the cocktail shaker sort is $2 \max (u_1, \ldots, u_n)$ — (0 or 1), since each pair of passes (left-right-left) reduces each of the nonzero u's by 1.

10. Begin with a distribution method (quicksort or radix exchange) until one-reel files are obtained. And be patient.

SECTION 5.4.9

1. $\frac{1}{4} - (x \bmod \frac{1}{2})^2$ revolutions.

2. The probability that $k = a_{iq}$ and $k+1 = a_{i'r}$ for fixed k, q, r, and $i \neq i'$ is $f(q, r, k)L!L!(PL - 2L)!/(PL)!$, where

$$f(q,r,k) = \binom{k-1}{q-1}\binom{k-q}{r-1}\binom{PL-k-1}{L-q}\binom{PL-k-1-L+q}{L-r}$$
$$= \binom{k-1}{q+r-2}\binom{q+r-2}{q-1}\binom{PL-k-1}{2L-q-r}\binom{2L-q-r}{L-q};$$

and

$$\sum_{\substack{1\le k<PL\\ 1\le q,r\le L}} |q-r|\, f(q,r,k) = \sum_{q,r} |q-r| \binom{PL-1}{2L-1}\binom{q+r-2}{q-1}\binom{2L-q-r}{L-q}$$
$$= \binom{PL-1}{2L-1} A_{2L-1}.$$

The probability that $k = a_{iq}$ and $k+1 = a_{i,q+1}$ for fixed k, q, and i is

$$g(k,q) \Big/ \binom{PL}{L}, \quad \text{where} \quad g(k,q) = \binom{k-1}{q-1}\binom{PL-k-1}{L-q-1};$$

and

$$\sum_{\substack{1\le k<PL\\ 1\le q<L}} g(k,q) = \sum_{1\le q<L} \binom{PL-1}{L-1} = (L-1)\binom{PL-1}{L-1}.$$

[*SIAM J. Computing* **1** (1972), 161–166.]

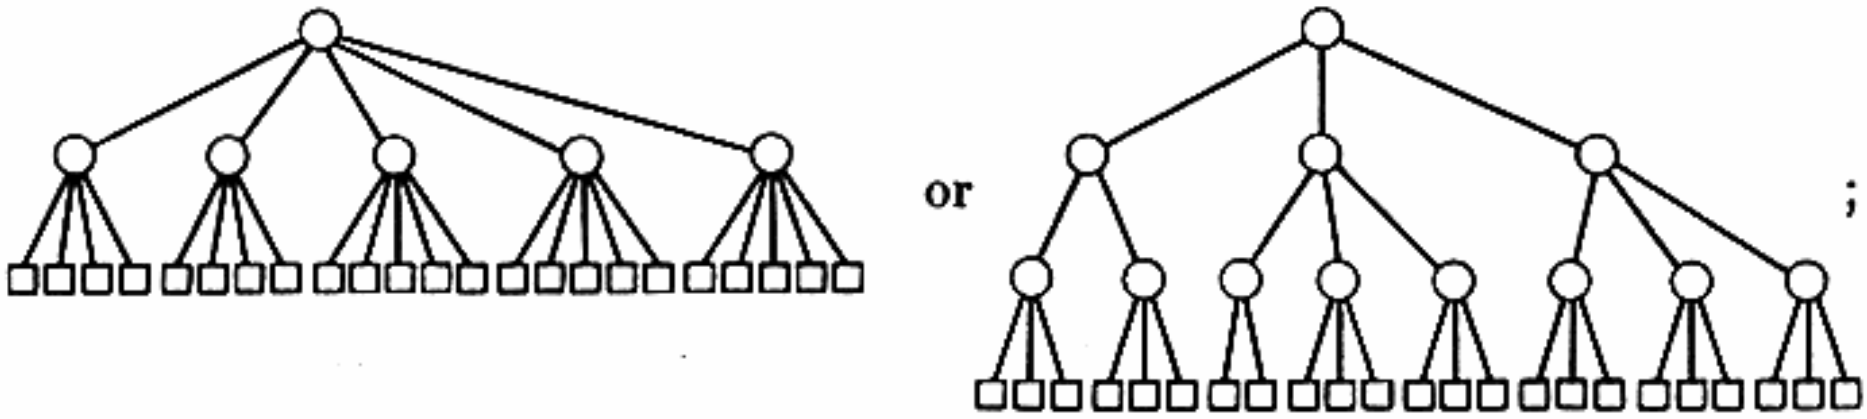
3. Take the minimum in (5) over the range $2 \le m \le \min(9, n)$.

4. (a) $(0.000725(\sqrt{P}+1)^2 + 0.014)L$. (b) Change "$\alpha mn + \beta n$" in formula (5) to "$(0.000725(\sqrt{m}+1)^2 + 0.014)n$." [Computer experiments show that the nature of the optimal trees defined by this new recurrence is very much the same as those

defined by Theorem K with $\alpha = 0.00145$, $\beta = 0.01545$; in fact, trees exist which are optimal for both recurrences, when $30 \le n \le 100$. The change suggested in this exercise saves about 10 percent of the merging time, when $n = 64$ or 100 as in the text's example. This style of buffer allocation was considered already in 1954 by H. Seward, who found that four-way merging minimizes the seek time.]

5. Let $A_m(n)$, $B_m(n)$ represent sets of m trees all of whose leaves are at (even, odd) levels, respectively. Then $A_1(1) = 0$, $B_1(1) = \alpha + \beta$; $A_m(n)$ and $B_m(n)$ are defined as in (4) when $m \ge 2$; $A_1(n) = \min_{1 \le m \le n} (\alpha mn + \beta n + B_m(n))$, $B_1(n) = \min_{1 \le m \le n} (\alpha mn + \beta n + A_m(n))$. The latter equations are well-defined in spite of the fact that $A_1(n)$ and $B_1(n)$ are defined in terms of each other!

6.



$A_1(23) = B_1(23) = 268$. [Curiously, $n = 23$ is the only value ≤ 50 for which no equal-parity tree with n leaves is optimal in the unrestricted-parity case. Perhaps it is the *only* such value, when $\alpha = \beta$.]

7. Consider the quantities $\alpha d_1 + \beta e_1, \ldots, \alpha d_n + \beta e_n$ in any tree, where (d_j, e_j) are the (degree sum, path length) for the jth leaf. An optimum tree for weights $w_1 \le \cdots \le w_n$ will have $\alpha d_1 + \beta e_1 \ge \cdots \ge \alpha d_n + \beta e_n$. It is always possible to reorder these so that $\alpha d_1 + \beta e_1 = \cdots = \alpha d_1 + \beta e_k$ where the first k leaves are merged together.

11. Using exercise 1.2.4–38, $f_m(n) = 3qn + 2(n - 3^q m)$, when $2 \cdot 3^{q-1} \le n/m \le 3^q$; $3qn + 4(n - 3^q m)$, when $3^q \le n/m \le 2 \cdot 3^q$. Thus $f_2(n) + 2n \ge f(n)$, with equality iff $4 \cdot 3^{q-1} \le n \le 2 \cdot 3^q$; $f_3(n) + 3n = f(n)$; $f_4(n) + 4n \ge f(n)$, with equality iff $n = 4 \cdot 3^q$; and $f_m(n) + mn > f(n)$ for all $m \ge 5$.

12. Use the specifications —, 1:1, 1:1:1, 1:1:1:1 or 2:2, 2:3, 2:2:2, . . . ,$\lfloor n/3 \rfloor$: $\lfloor (n+1)/3 \rfloor$:$\lfloor (n+2)/3 \rfloor$, . . . ; this gives trees with all leaves at level $q + 2$, for $4 \cdot 3^q \le n \le 4 \cdot 3^{q+1}$. (When $n = 4 \cdot 3^q$, two such trees are formed.)

14. The following tree specifications were found for $n = 1, 2, 3, \ldots$, by exhaustively examining all partitions of n. —, 1:1, 1:1:1, 1:1:1:1, 1:1:1:1:1, 1:1:1:1:1:1, 1:1:1:1:3, 1:1:3:3, 3:3:3, 1:3:3:3, 3:4:4, 3:3:3:3, 3:3:3:4, 3:3:4:4, 3:4:4:4, 4:4:4:4, . . . , 5:6:6:6:12, 6:6:6:6:12, 6:6:6:6:13, ... (The degrees seem to be always ≤ 6, but such a result appears to be quite difficult to prove.)

15. If a people initially got on the elevator, the togetherness rating increases by at most $a + c$ at the first stop. When it next stops at the initial floor, the rating increases by at most $b + c - a$. Hence the rating increases at most $(k - 1)b + kc$ after k stops.

16. 123456 → floor 2; 112334 → floor 3; 224456 → floor 4; 135566 → floor 5; 112334 → floor 6; 224456 → floor 2; 222444 → floor 4; 222222 → floor 2; 555666 → floor 5; 666666 → floor 6; 111333 → floor 3; 111111 → floor 1. [Is there a shorter solution? Exercise 15 implies that at least nine stops are needed.]

17. Consider doing step (g) backwards, distributing the records into bin 1, then bin 2, bin 3. This operation is precisely what step (d) is simulating on the key file.

18. The internal sort must be carefully chosen, with paging in mind; methods such as

Shell's diminishing increment sort, address calculation, heapsort, and list sorting would be disastrous, since they require a large "working set" of pages. Quicksort, radix exchange, and sequentially-allocated merge or radix sorting are much better suited to a paging environment.

Some things the designer of an external sort can do, which are "virtually impossible" to include in an automatically paged method, are: (a) Forecasting the input file which should be read next, so that the data is available when it is required; (b) choosing the buffer sizes and the order of merge according to hardware and data characteristics.

On the other hand a virtual machine is considerably easier to program, and it can give results that aren't bad, if the programmer is careful and knows the properties of the underlying actual machine. See the study made by Brawn, Gustavson, and Mankin [*CACM* **13** (1970), 483–494].

SECTION 5.5

1. *It is difficult to decide which sorting algorithm is best in a given situation.* ▮

2. For small N, list insertion; for medium N, e.g. $N = 64$, list merge; for large N, radix list sort.

SECTION 6.1

1. $\sqrt{(N^2 - 1)/12}$.

2. **S1′.** [Initialize.] Set P ← FIRST.

   S2′. [Compare.] If K = KEY(P), the algorithm terminates successfully.

   S3′. [Advance.] Set P ← LINK(P).

   S4′. [End of file?] If P ≠ Λ, go back to S2′. Otherwise the algorithm terminates unsuccessfully. ▮

3.

```

4. Yes, if we have a way to set "KEY(Λ)" equal to K. [But the technique of loop duplication used in Program Q′ has no effect in this case.]

5. No, Program Q always does at least as many operations as Program Q′.

6. Replace line 08 by

```
          JE    *+4
          CMPA  KEY+N+2,1
          JNE   3B
          INC1  1
```

and change lines 03–04 to `ENT1 -2-N; 3H INC1 3`.

7. Note that $\overline{C}_N = \frac{1}{2}\overline{C}_{N-1} + 1$.

8. Euler's summation formula gives

$$H_n^{(x)} \sim \text{const} + n^{1-x}/(1-x) + \tfrac{1}{2}n^{-x} - B_2 x n^{-1-x}/2! + B_3 x(x+1)n^{-2-x}/3! - \cdots.$$

[The constant is $\zeta(x)$; complex variable theory tells us that

$$\zeta(x) = 2^x \pi^{x-1} \sin(\tfrac{1}{2}\pi x)\Gamma(1-x)\zeta(1-x),$$

a formula which is particularly useful when $x < 0$.]

9. Yes; in fact, $\overline{C}_N = N - N^{-\theta}H_{N-1}^{(-\theta)} = \theta N/(1+\theta) + \frac{1}{2} + O(N^{-\theta})$.

10. $p_1 \le \cdots \le p_N$; maximum $\overline{C}_N = (N+1) - (\text{minimum } \overline{C}_N)$. [Similarly in the unequal-length case, the maximum average search time is $L_1(1+p_1) + \cdots + L_N(1+p_N)$ minus the minimum average search time.]

11. (a) The terms of $f_{m-1}(x_{i_1}, \ldots, x_{i_{m-1}})p_i$ are just the probabilities of the possible sequences of requests that could have preceded, leaving R_i in position m. (b) The second identity comes from summing $\binom{n}{m}$ cases of the first, noting the number of times each P_{nk} occurs. The third identity is a consequence of the second, by inversion. [Alternatively, the principle of inclusion and exclusion could be used.] (c) $\sum_{m\ge 0} mP_{nm} = nQ_{nn} - Q_{n,n-1}$; hence

$$d_i = 1 + (N-1) - p_i \sum_{j\ne i} 1/(p_i + p_j);$$

$$\sum p_i d_i = N - \sum_{i<j} (p_i^2 + p_j^2)/(p_i + p_j)$$

$$= N - \sum_{i<j} (p_i + p_j - 2p_ip_j/(p_i + p_j)) = (17).$$

12. $\overline{C}_N = 2^{1-N} + 2\sum_{0\le n\le N-2} 1/(2^n+1)$, which converges rapidly to $2\alpha' \approx 2.5290$; exercise 5.2.4–13 gives α' to 40 decimal places.

13. After evaluating the rather tedious sum

$$\sum_{1\le i\le n} i^2 H_{n+i} = \tfrac{1}{6}n(n+1)(2n+1)(2H_{2n} - H_n) - \tfrac{1}{36}n(10n^2 + 9n - 1),$$

we obtain the answer

$$\overline{C}_N = \tfrac{4}{3}N - \tfrac{2}{3}(2N+1)(H_{2N} - H_N) + \tfrac{5}{6} - \tfrac{1}{3}(N+1)^{-1} \approx .409N.$$

[It would be very interesting to know the maximum factor by which (17) can exceed the optimum result (3).]

14. We may assume that $x_1 \le x_2 \le \cdots \le x_n$; then the maximum value occurs when $y_{a_1} \le y_{a_2} \le \cdots \le y_{a_n}$, and the minimum when $y_{a_1} \ge \cdots \ge y_{a_n}$, by an argument like that of Theorem S.

15. Arguing as in Theorem S, the arrangement $R_1R_2 \ldots R_N$ is optimum iff

$$P_1/L_1(1-P_1) \ge \cdots \ge P_N/L_N(1-P_N).$$

16. The expected time $T_1 + p_1T_2 + p_1p_2T_3 + \cdots + p_1p_2 \ldots p_{N-1}T_N$ is minimized iff $T_1/(1-p_1) \le \cdots \le T_N/(1-p_N)$. [*BIT* **3** (1963), 255–256.]

17. Do the jobs in order of increasing deadlines, independent of the respective times T_i! [Of course in practice some jobs are more important than others, and we may want to minimize the maximum *weighted* tardiness. Or we may wish to minimize the sum $\sum_{1\le i\le n} \max(T_{a_1} + \cdots + T_{a_i} - D_{a_i}, 0)$. Neither of these problems appears to have a simple solution.]

18. Let $h = 1$ if s is present, 0 if s is absent. Let $A = \{i \mid q_i < r_i\}$, $B = \{i \mid q_i = r_i\}$, $C = \{i \mid q_i > r_i\}$, $D = \{j \mid t_j > 0\}$; then the sum $\sum_{1\le i,j\le N} p_i p_j d_{|i-j|}$ for the (q, r) arrangement minus the corresponding sum for the (q', r') arrangement is equal to

$$2 \sum_{i\in A, j\in C} (q_i - r_i)(q_j - r_j)(d_{|i-j|} - d_{h+1+2k-i-j}) + 2 \sum_{i\in C, j\in D} (q_i - r_i)t_j(d_{h+2k-i+j} - d_{i-1+j}).$$

This is positive unless $C = \emptyset$ or $A \cup D = \emptyset$. The desired result now follows because the organ pipe arrangements are the only permutations which are not improved by this construction and its left-right dual when $m = 0, 1$.

[This result is essentially due to G. H. Hardy, J. E. Littlewood, and G. Pólya, *Proc. London Math. Soc.* (2), **25** (1926), 265–282, who showed, in fact, that the minimum of $\sum p_i q_j d_{|i-j|}$ is achieved, under all independent rearrangements of the p's and q's, when both p's and q's are in a consistent organ-pipe order. For further commentary and generalizations, see their book *Inequalities* (Cambridge University Press, 1934), Chapter 10).]

19. All arrangements are equally good. We have

$$\sum p_i p_j\, d(i, j) = \tfrac{1}{2} \sum p_i p_j (d(i, j) + d(j, i)) = \tfrac{1}{2}c.$$

[The special case $d(i, j) = 1 + (j - i) \bmod N$ is due to K. E. Iverson, *A Programming Language* (New York: Wiley, 1962), 138. R. L. Baber, *JACM* **10** (1963), 478–486, has studied some other problems associated with tape searching when a tape can read forward, rewind, or backspace k blocks without reading. W. D. Frazer observes that it would be possible to make significant reductions in the search time if we were allowed to *replicate* some of the information in the file; cf. E. B. Eichelberger et. al., *IBM J. Research & Development* **12** (1968), 130–139, for an empirical solution to a similar problem.]

20. Going from (q, r) to (q', r') as in exercise 18, with $m = 0$ or $m = h = 1$, gives a net change of

$$\sum_{i\in A, j\in C} (q_i - r_i)(q_j - r_j)\big(d_{|i-j|} - \min(d_{h+1+2k-i-j}, d_{i+j-1})\big),$$

which is positive unless A or C is $\emptyset$. By circular symmetry it follows that the only optimal arrangements are cyclic shifts of the organ pipe configurations. [For a different problem with the same answer, see Alfred Lehman, *Israel J. Math* **1** (1963), 22–28.]

21. This problem was essentially first solved by L. H. Harper, *J. SIAM* **12** (1964), 131–135. For generalizations and references to other work, see *J. Applied Probability* **4** (1967), 397–401.

22. A priority queue of size 1000 (represented as, say, a heap, see Section 5.2.3).

Enter the first 1000 records into this queue, with the element of *greatest* $d(K_i, K)$ at the front. For each subsequent K_i with $d(K_i, K) < d$(front of queue, K), replace the front element by R_i.

SECTION 6.2.1

1. Prove inductively that $K_{l-1} < K < K_{u+1}$ whenever we reach step B2; and that $l \le i \le u$ whenever we reach B3.

2. (a, c) No, it loops if $l = u$ and $K > K_u$. (b) Yes, it would!

3. This is Algorithm 6.1T with $N = 3$. In a successful search, that algorithm makes $(N+1)/2$ comparisons, on the average; in a unsuccessful search it makes $N/2 + 1 - 1/(N+1)$.

4. It must be an unsuccessful search with $N = 127$; hence by Theorem B the answer is $138u$.

5. Program 6.1Q′ has an average running time of $1.75N + 8.5 - (N \bmod 2)/4N$; this beats Program B iff $N \le 44$. [It beats Program C only for $N \le 11$.]

7. (a) Certainly not. (b) The parenthesized remarks in Algorithm U will hold true, so it will work, but only if $K_0 = -\infty$ and $K_{N+1} = +\infty$ are both present when N is odd.

8. (a) N. It is interesting to prove this by induction, observing that exactly one of the DELTA's increases if we replace N by $N+1$. [See *AMM* 77 (1970), 884 for a generalization.] (b) Maximum $= \sum$DELTA$[j] = N$; minimum $=$ 2DELTA[1] $- \sum$DELTA$[j] = N \bmod 2$.

9. Consider the corresponding tree (e.g. Fig. 6): When N is odd, the left subtree of the root is a mirror image of the right subtree, so $K < K_i$ occurs just as often as $K > K_i$; on the average, $C1 = \frac{1}{2}(C+S)$ and $C2 = \frac{1}{2}(C-S)$, $A = \frac{1}{2}(1-S)$. When N is even, the tree is the same as the tree for $N+1$ with all labels decreased by 1, except that (0) becomes redundant; on the average,

$$C1 = \tfrac{1}{2}(C+1) - \tfrac{1}{2}\lfloor \log_2 N \rfloor / N,$$
$$C2 = \tfrac{1}{2}(C-1) + \tfrac{1}{2}\lfloor \log_2 N \rfloor / N, \qquad A = 0 \quad \text{for} \quad S = 1;$$

$$C1 = \frac{1}{2}\,\frac{N}{N+1}\,(\lfloor \log_2 N \rfloor + 1),$$

$$C2 = \frac{1}{2}\,\frac{N+2}{N+1}\,(\lfloor \log_2 N \rfloor + 1), \qquad A = \frac{1}{2}\,\frac{N}{N+1} \quad \text{for} \quad S = 0.$$

(The average value of C is stated in the text.)

10. Iff $N = 2^k - 1$.

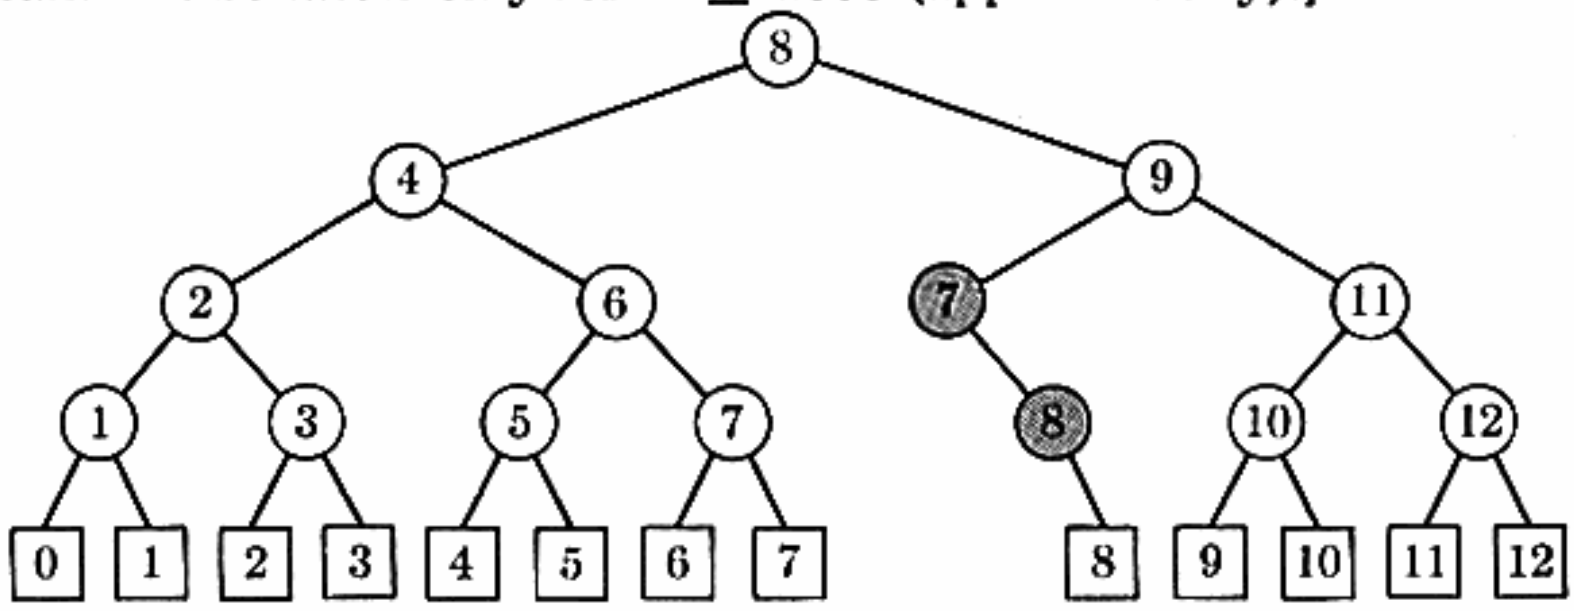
11. Use a "macro-expanded" program with the DELTA's included; e.g., for $N = 10$:

```
START   ENT1   5
        LDA    K
        CMPA   KEY,1
        JL     C3A
```

```
C4A     JE      SUCCESS         C3A     EQU     *
        INC1    3                       DEC1    3
        CMPA    KEY,1                   CMPA    KEY,1
        JL      C3B                     JGE     C4B
C4B     JE      SUCCESS         C3B     EQU     *
        INC1    1                       DEC1    1
        CMPA    KEY,1                   CMPA    KEY,1
        JL      C3C                     JGE     C4C
C4C     JE      SUCCESS         C3C     EQU     *
        INC1    1                       DEC1    1
        CMPA    KEY,1                   CMPA    KEY,1
        JE      SUCCESS                 JE      SUCCESS
        JMP     FAILURE                 JMP     FAILURE
```

[Exercise 23 shows that most of the "JE" instructions may be eliminated, yielding a program about $6 \log_2 N$ lines long which takes only about $4 \log_2 N$ units of time; but that program will be faster only for $N \geq 1000$ (approximately).]

12.



13.

$N =$	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16
$C_N =$	1	$1\frac{1}{2}$	$1\frac{2}{3}$	$2\frac{1}{4}$	$2\frac{1}{5}$	$2\frac{2}{6}$	$2\frac{3}{7}$	$3\frac{1}{8}$	3	3	3	$3\frac{2}{12}$	$3\frac{3}{13}$	$3\frac{3}{14}$	$3\frac{4}{15}$	$4\frac{1}{16}$
$C'_N =$	1	$1\frac{2}{3}$	2	$2\frac{3}{5}$	$2\frac{4}{6}$	3	3	$3\frac{6}{9}$	$3\frac{6}{10}$	$3\frac{8}{11}$	$3\frac{8}{12}$	4	4	4	4	$4\frac{13}{17}$

14. One idea is to find the least $M \geq 0$ such that $N + M$ has the form $F_{k+1} - 1$, then to start with $i \leftarrow F_k - M$ in step F1, and to insert "If $i \leq 0$, go to F4" at the beginning of F2. A better solution would be to adapt Shar's idea to the Fibonaccian case: If the result of the very first comparison is $K > K_{F_k}$, set $i \leftarrow i - M$ and go to F4 (proceeding normally from then on). This avoids extra time in the inner loop.

15. The Fibonacci tree of order k, with left and right reversed, is the binary tree corresponding to the lineal chart up to the kth month, under the "natural correspondence" of Section 2.3.2, if we remove the topmost node of the lineal chart.

16. The external nodes appear on levels $\lfloor k/2 \rfloor$ through $k - 1$; the difference between these levels is greater than unity except when $k = 0, 1, 2, 3, 4$.

17. Let the path length be $k - A(n)$; then $A(F_j) = j$ and $A(F_j + m) = 1 + A(m)$ when $0 < m < F_{j-1}$.

18. Successful search: $A_k = 0$, $C_k = (3kF_{k+1} + (k-4)F_k)/5(F_{k+1} - 1) - 1$, $C1_k = C_{k-1}$. Unsuccessful search: $A'_k = F_k/F_{k+1}$, $C'_k = (3kF_{k+1} + (k-4)F_k)/5F_{k+1}$, $C1'_k = C'_{k-1} + F_{k-1}/F_{k+1}$. $C2 = C - C1$. (Cf. exercise 1.2.8–12.)

20. (a) $p^{-p}q^{-q}$. (b) There are at least *two* errors. The first blunder is that division

is not a linear function, so it can't be simply "averaged over." Actually with probability p we get pN elements remaining, and with probability q we get qN, so we can expect to get $(p^2+q^2)N$; thus the average "reduction factor" is really $1/(p^2+q^2)$. Now the reduction factor after k iterations is $1/(p^2+q^2)^k$, but we cannot conclude that $b = 1/(p^2+q^2)$ since the number of iterations needed to locate some of the items is much more than to locate others. This is a second fallacy. [It is very easy to make plausible but fallacious probability arguments, and we must always be on our guard against such pitfalls!]

21. It's impossible, since the method depends on the key values.

23. Go to the right on $\geq$, to the left on $<$; when reaching node $\boxed{i}$ it follows from (1) that $K_i \leq K < K_{i+1}$, so a final test for equality will distinguish between success or failure. (The key $K_0 = -\infty$ should always be present.)

Algorithm C would be changed to go to C4 if $K = K_i$ in step C2. In C3 if DELTA[j] = 0, set $i \leftarrow i - 1$ and go to C5. In C4 if DELTA[j] = 0, go directly to C5. Add a new step C5: "If $K = K_i$, the algorithm terminates successfully, otherwise it terminates unsuccessfully." [This would not speed up Program C unless N were extremely large.]

24. The keys can be arranged so that we first set $i \leftarrow 1$, then $i \leftarrow 2i$ or $2i+1$ according as $K < K_i$ or $K > K_i$; the search is unsuccessful when $i > N$. For example when $N = 12$ the necessary key arrangement is

$$K_8 < K_4 < K_9 < K_2 < K_{10} < K_5 < K_{11} < K_1 < K_{12} < K_6 < K_3 < K_7.$$

When programmed for MIX this method will take only about $6 \log_2 N$ units of time, so it is faster than Program C. The only disadvantage is that it is a little tricky to set up the table in the first place.

25. (a) Since $a_0 = 1 - b_0$, $a_1 = 2a_0 - b_1$, $a_2 = 2a_1 - b_2$, etc., we have $A(z) + B(z) = 1 + 2zA(z)$. Several of the formulas derived in Section 2.3.4.5 follow immediately from this relation by considering $A(1)$, $B(1)$, $B(\frac{1}{2})$, $A'(1)$, $B'(1)$. If we use two variables to distinguish left and right steps of a path we obtain the more general result $A(x, y) + B(x, y) = 1 + (x+y)A(x, y)$, a special case of a formula which holds in t-ary trees [cf. R. M. Karp, *IRE Trans.* **IT–7** (1961), 27–38]. (b) var $(g) = ((N+1)/N)$ var $(h) - ((N+1)/N^2)$ mean $(h)^2 + 2$.

26. The merge tree for the three-tape polyphase merge with a perfect level k distribution is the Fibonacci tree of order $k+1$ if we permute left and right appropriately. (Redraw the Polyphase $T = 3$, $S = 13$ picture of Section 5.4.4, with the left and right subtrees of A, C reversed, obtaining Fig. 8.)

27. At most $k+1$ of the 2^k outcomes will ever occur, since we may order the indices such that $K_{i_1} < K_{i_2} < \cdots < K_{i_k}$. Thus the search can be described by a tree with at most $(k+1)$-way branching at each node. The number of items which can be found on the mth step is at most $k(k+1)^{m-1}$; hence the average number of comparisons is at least N^{-1} times the sum of the smallest N elements of the multiset $\{k \cdot 1, k(k+1) \cdot 2, k(k+1)^2 \cdot 3, \ldots\}$. When $N \geq (k+1)^n - 1$, the average number of comparisons is $\geq N^{-1} \sum_{1 \leq m \leq n} k(k+1)^{m-1} m > n - 1/k$.

1. Use a header node, with say ROOT ≡ RLINK(HEAD); start the algorithm at step T4 with P ← HEAD. Step T5 is to act as if $K >$ KEY(HEAD). [Thus change lines 04 and 05 of Program T to "ENT1 ROOT; CMPA K".]

2. In step T5, set RTAG ← —. Also, when inserting to the left, set RLINK(Q) ← P; when inserting to the right, set RLINK(Q) ← RLINK(P). [If nodes are inserted into successively increasing locations Q, and if all deletions are last-in-first-out, the RTAG fields can be eliminated since RTAG(P) will be — if and only if RLINK(P) $<$ P.]

3. We could replace Λ by a valid address, and set KEY(Λ) ← K at the beginning of the algorithm; then the tests for LLINK or RLINK = Λ could be removed from the inner loop. However, in order to do a proper insertion we need to introduce another pointer variable which follows P; this can be done without losing the stated speed advantage, by duplicating the code as in Program 6.2.1F. Thus the MIX time would be reduced to about $5.5C$.

4. $C_N = 1 + (0\cdot 1 + 1\cdot 2 + \cdots + (n-1)2^{n-1} + C'_{2^n} + \cdots + C'_{N-1})/N = (1 + 1/N)C'_N - 1$, for $N \geq 2^n - 1$. The solution to these equations is $C'_N = 2(H_{N+1} - H_{2^n}) + n$ for $N \geq 2^n - 1$, a savings of $2H_{2^n} - n - 2 \approx n(\ln 4 - 1)$ comparisons. The actual improvement for $n = 1, 2, 3, 4$ is, respectively, 0, $\frac{1}{6}$, $\frac{61}{140}$, $\frac{274399}{360360}$; thus comparatively little is gained for small fixed n. [See Frazer and McKellar, *JACM* **17** (1970), 502, for a more detailed derivation related to an equivalent sorting problem.]

5. (a) The first element must be CAPRICORN; then we multiply the number of ways to produce the left subtree by the number of ways to produce the right subtree, times $\binom{10}{3}$, the number of ways to shuffle those two sequences together. Thus the answer comes to

$$\binom{10}{3}\binom{2}{0}\binom{1}{0}\binom{0}{0}\binom{6}{3}\binom{2}{0}\binom{1}{0}\binom{0}{0}\binom{2}{1}\binom{0}{0}\binom{0}{0} = 4800.$$

[In general, the answer is the product, over all nodes, of $\binom{l+r}{r}$, where l and r stand for the sizes of the left and right subtrees of the node. This is equal to $N!$ divided by the product of the subtree sizes. It is same formula as in exercise 5.1.4-20; indeed, there is an obvious one-to-one correspondence between the permutations which yield a particular search tree and the "topological" permutations counted in that exercise, if we replace a_k in the search tree by k (using the notation of exercise 6).] (b) $2^{N-1} = 1024$; at each step but the last, insert either the smallest or largest remaining key.

6. (a) For each of the P_{nk} permutations $a_1 \ldots a_{n-1}a_n$ whose "score" is k, construct $n+1$ permutations $a'_1 \ldots a'_{n-1} m\, a'_n$, where $a'_j = a_j$ or $a_j + 1$, according as $a_j < m$ or $a_j \geq m$. [Cf. Section 1.2.5, Method 2.] If $m = a_n$ or $a_n + 1$, this permutation has a "score" of $k+1$, otherwise it has a score of k. (b) $G_n(z) = (2z + n - 2)(2z + n - 3) \ldots (2z)$. Hence

$$P_{nk} = \begin{bmatrix} n-1 \\ k \end{bmatrix} 2^k.$$

This generating function was, in essence, obtained by W. C. Lynch, *Comp. J.* **7** (1965), 299–302. (c) The generating function for probabilities is $g_n(z) = G_n(z)/n!$.

This is a product of simple probability generating functions, so

$$\begin{aligned}\operatorname{var}(g_n) &= \sum_{0\le k\le n-2} \operatorname{var}\left((2z+k)/(2+k)\right)\\ &= \sum_{0\le k\le n-2} \left(2/(k+2) - 4/(k+2)^2\right) = 2H_n - 4H_n^{(2)} + 2.\end{aligned}$$

[From exercise 6.2.1–25b we can therefore compute the variance of C_n, which is $(2+10/n)H_n - 4(1+1/n)(H_n^{(2)}/n + H_n^2) + 2$; this formula is due to G. D. Knott (unpublished).]

7. Set up a recurrence like that in the answer to exercise 5.2.2–32, but with $C_{nm} = 1 + (A_{nm} + B_{nm})/n$. The solution is $C_{nm} = H_m + H_{n+1-m} - 1$. [*CACM* **12** (1969), 77–80].

8. (a) $g_n(z) = z^{n-1}\sum_{1\le i\le n} g_{i-1}(z)g_{n-i}(z)/n$, $g_0(z) = 1$. (b) $7n^2 - 4(n+1)^2H_n^{(2)} - 2(n+1)H_n + 13n$. [P. F. Windley, *Comp. J.* **3** (1960), 86, gave recurrence relations from which this variance could be computed numerically, but he did not obtain the solution. Note that this result is *not* simply related to the variance of C_n stated in the answer to exercise 6.]

10. For example, each word x of the key could be replaced by $(ax) \bmod m$, where m is the computer word size and a is a random multiplier relatively prime to m. A value near to $(\phi - 1)m$ can be recommended, see Section 6.4. The flexible storage allocation of tree methods may make them more attractive than other hash coding schemes.

11. $N - 2$, but this occurs with probability $1/(N \cdot N!)$, only in the deletion (1) N $(N-1)\ldots 2$.

12. $\frac{1}{2}(n+1)(n+2)$ of the deletions in the proof of Theorem H belong to Case 1, so the answer is $(N+1)/2N$.

13. Yes, in fact the proof of Theorem H shows that if we delete the ith element inserted, for any fixed i, the result is random. [Conjecture: After an arbitrary sequence of random insertions and *first-in-first-out* deletions, the result is random.]

14. Let `NODE(T)` be on level k, and let `LLINK(T)` $= \Lambda$, `RLINK(T)` $=$ `R`$_1$, `LLINK(R`$_1$`)` $=$ `R`$_2$, $\ldots$, `LLINK(R`$_d$`)` $= \Lambda$, where `R`$_d \neq \Lambda$ and $d \ge 1$. Let `NODE(R`$_i$`)` have n_i nodes in its right subtree, for $1 \le i \le d$. With step $D1\frac{1}{2}$ the internal path length decreases by $k + d + n_1 + \cdots + n_d$; without that step it decreases by $k + d + n_d$.

16. Yes; even the deletion operation on permutations, as defined in the proof of Theorem H, is commutative (if we omit the renumbering aspect). If there is an element between X and Y, deletion is obviously commutative since the operation is affected only by the relative positions of X, Y, and their successors and there is no interaction between the deletion of X and the deletion of Y. On the other hand, if Y is the successor of X, and Y is the largest element, both orders of deletion have the effect of simply removing X and Y. If Y is the successor of X and Z the successor of Y, both orders of deletion have the effect of replacing the *first* occurrence of X, Y, or Z by Z and deleting the second and third occurrences of these elements within the permutation.

18. Use exercise 1.2.7–14.

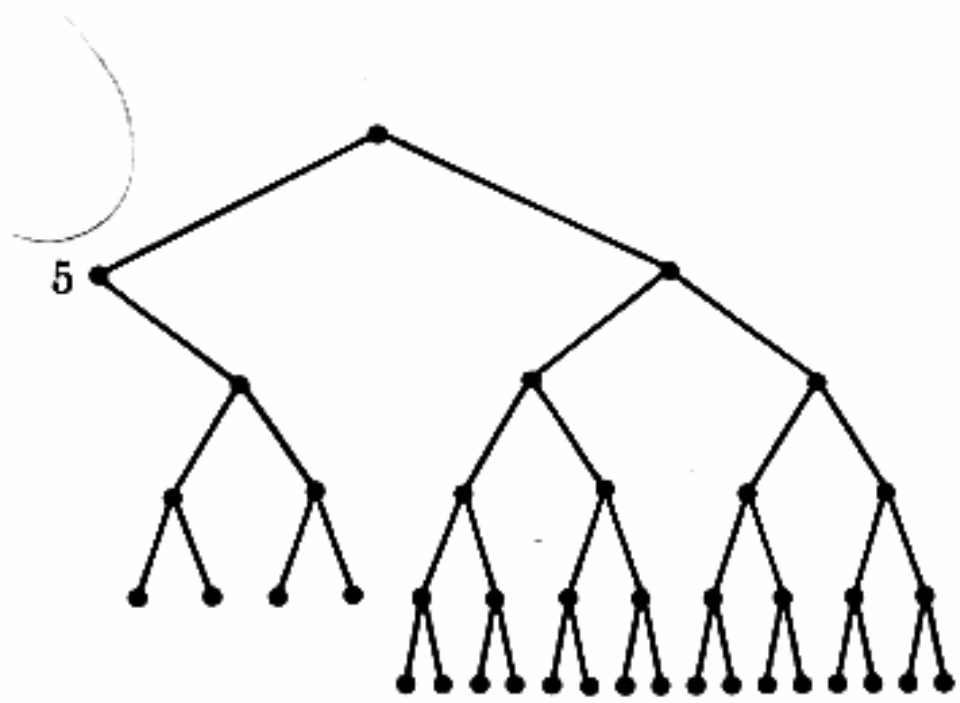
19. $2H_N - 1 - 2\sum_{1\le k\le N}(k-1)^\theta/kN^\theta = 2H_N - 1 - 2/\theta + O(N^{-\theta})$.

20. Yes indeed. Assume that $K_1 < \cdots < K_N$, so that the tree built by Algorithm T is degenerate; if, say, $p_k = (1 + ((N+1)/2 - k)\epsilon)/N$, the average number of comparisons is $(N+1)/2 - (N^2-1)\epsilon/12$, while the optimum tree requires less than $\lceil \log_2 N \rceil$ comparisons.

21. $\frac{1}{8}, \frac{3}{20}, \frac{9}{20}, \frac{3}{20}, \frac{1}{8}$. (Most of the angles are 30°, 60°, or 90°.)

22. This is obvious when $d = 2$, and for $d > 2$ we had $r[i, j-1] \le r[i+1, j-1] \le r[i+1, j]$.

23.



[Increasing the weight of the first node will eventually make it move to the root position; this suggests that dynamically maintaining a perfectly optimum tree is hard.]

24. Let c be the cost of a tree obtained by deleting the nth node of an optimum tree. Then $c(0, n-1) \le c \le c(0, n) - q_{n-1}$, since the deletion operation always moves $\boxed{n-1}$ up one level. Also $c(0, n) \le c(0, n-1) + q_{n-1}$, since the stated replacement yields a tree of the latter cost. It follows that $c(0, n-1) = c = c(0, n) - q_{n-1}$.

25. (a) Assume that $A \le B$ and $B \le C$, and let $a \in A$, $b \in B$, $c \in C$, $c < a$. If $c \le b$ then $c \in B$; hence $c \in A$ and $a \in B$; hence $a \in C$. If $c > b$, then $a \in B$; hence $a \in C$ and $c \in B$; hence $c \in A$. (b) Not hard to prove.

26. The cost of every tree has the form $y + lx$ for some real $y \ge 0$ and integer $l > 0$. The minimum of a finite number of such functions (taken over all trees) always has the form described.

27. (a) The answer to exercise 24 (especially the fact that $c = c(0, n-1)$) implies that $R(0, n-1) = R(0, n)\backslash\{n\}$. (b) If $l = l'$ the result in the hint is trivial. Otherwise let the respective paths to $\boxed{n}$ be

$$\textcircled{r_1}, \textcircled{r_2}, \ldots, \boxed{r_l} \qquad \text{and} \qquad \textcircled{s_1}, \textcircled{s_2}, \ldots, \boxed{s_{l'}}.$$

Since $r = r_1 > s_1 = s$ and $r_{l'} < s_{l'} = n$, we can find a level $k \ge 1$ such that $r_k > s_k$ and $r_{k+1} \le s_{k+1}$. We have $r_{k+1} \in R(r_k, n)$, $s_{k+1} \in R(s_k, n)$, and $R(s_k, n) \le R(r_k, n)$ by induction, hence $r_{k+1} \in R(s_k, n)$ and $s_{k+1} \in R(r_k, n)$; the right subtrees of $\textcircled{r_k}$ and $\textcircled{s_k}$ can be interchanged, and the result in the hint follows.

Now to show that $R'_h \le R_h$, let $r \in R'_h$, $s \in R_h$, $s < r$, and consider the optimum trees shown when $x = x_h$; we must have $l \ge l_h$ and we may assume that $l' = l_h$. To show that $R_h \le R'_{h+1}$, let $r \in R_h$, $s \in R'_{h+1}$, $s < r$, and consider the optimum trees shown when $x = x_{h+1}$; we must have $l' \le l_h$ and we may assume that $l = l_h$.

29. It is a degenerate tree with YOU at the top, THE at the bottom, needing 19.158 comparisons on the average.

Douglas A. Hamilton has proved that some degenerate tree is always worst. Therefore an $O(n^2)$ algorithm exists to find pessimal binary search trees.

31. (a) 30; (b) 31. Thus there are trees built up according to rule (i) which have less cost than trees for which Phase 3 will succeed.

32. Suppose that we form $q_i + q_j$ at one step, and $q_{i'} + q_{j'} < q_i + q_j$ at the next step. Then the combination $q_{i'} + q_{j'}$ must have been blocked at the first step by having external node $\boxed{q_i}$ or $\boxed{q_j}$ (or both) between $q_{i'}$ and $q_{j'}$. If both, we must have $q_{i'} > q_i$, $q_{j'} \geq q_j$; otherwise we must have $q_{i'} > q_j$, $q_{j'} > q_i$.

35. Let $i < j$; C_i is the leading $e_i + 1$ bits of x_i and C_j is the leading $e_j + 1$ bits of $x_j \geq x_i + 2^{-e_i-1} + 2^{-e_j-1}$. Therefore if $e_i \leq e_j$, C_i cannot be a prefix of C_j; if $e_i > e_j$, C_j cannot be a prefix of C_i.

36. In fact it is less than $2S + \sum_{0\leq i\leq n} (q_i + x_i + y_i) \log_2 \big(S/(q_i + x_i + y_i)\big)$, where the x_i and y_i are *any* nonnegative values such that $p_i = x_i + y_{i-1}$ and $x_0 = y_n = 0$. For if $\textcircled{i}$ appears at level l_i and $\boxed{j}$ at level l'_j, we have $l'_i > l_i$ and $l'_{i-1} > l_i$ in any tree. Hence, constructing the tree of Theorem G with weights $q_i + x_i + y_i$, we have $\sum p_i(l_i + 1) + \sum q_j l'_j \leq \sum (q_j + x_j + y_j) l'_j$. [The best bound is obtained when the $q_j + x_j + y_j$ are farthest from uniformity.]

38. Let $a_r = \sum_{i\in S(r)} c_i$; then $a_{r+1} - a_r \geq a_r - a_{r-1}$ for $1 \leq r < \lceil n/2 \rceil$. (Cf. exercise 32.) Hence $a_r \leq r/\lceil n/2 \rceil$, for all r; this follows since the relations $a_r > r/\lceil n/2 \rceil$ and $a_{r-1} \leq (r-1)/\lceil n/2 \rceil$ imply $1 \geq a_{\lceil n/2 \rceil} = a_r + \sum_{r\leq k<\lceil n/2 \rceil} (a_{k+1} - a_k) \geq a_r + (\lceil n/2 \rceil - r)(a_r - a_{r-1}) > r/\lceil n/2 \rceil + (\lceil n/2 \rceil - r)/\lceil n/2 \rceil = 1$. The proof is completed by using the Hu-Tucker algorithm on the given "worst" probabilities: the resulting tree has $n + 1 - 2^q$ pairs of external nodes on level $q + 1$, and all other external nodes on level q, so $f(n) = q(n + 1 - 2^q)/\lceil n/2 \rceil + (q-1)\big(1 - (n+1-2^q)/\lceil n/2 \rceil\big)$. This is at least as great as the cost of T, which has a weight of $a_{n+1-2^q} \leq (n + 1 - 2^q)/\lceil n/2 \rceil$ on level q. [*Acta Informatica* 2 (1972), to appear.]

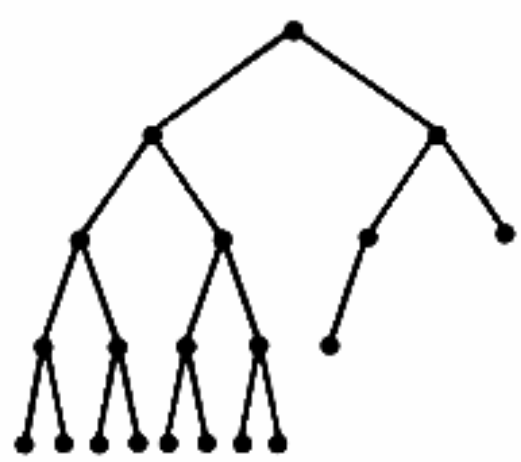
SECTION 6.2.3

1. The symmetric order of nodes must be preserved by the transformation, otherwise we wouldn't have a binary search tree.

2. B(S) = 0 can happen only when S points to the root of the tree (it has never been changed in steps A3 or A4), and all nodes from S to the point of insertion were balanced.

3. Let ρ_h be the largest possible ratio of unbalanced nodes in balanced trees of height h. Thus $\rho_1 = 0$, $\rho_2 = \frac{1}{2}$, $\rho_3 = \frac{1}{2}$. We will prove that $\rho_h = (F_{h+1} - 1)/(F_{h+2} - 1)$. Let T_h be a tree which maximizes ρ_h; then we may assume that its left subtree has height $h - 1$ and its right subtree has height $h - 2$, for if both subtrees had height $h - 1$ the ratio would be less than ρ_{h-1}. Thus the ratio for T_h is at most $(\rho_{h-1}N_l + \rho_{h-2}N_r + 1)/(N_l + N_r + 1)$, where there are (N_l, N_r) nodes in the (left, right) subtree. This formula takes its maximum value when (N_l, N_r) take their minimum values; hence we may assume that T_h is a Fibonacci tree.

4. When $n = 7$,



has greater path length. [Note: C. C. Foster, *Proc. ACM Nat. Conf.* **20** (1965), 197–198, gave an incorrect procedure for constructing N-node balanced trees of maximum path length; Edward Logg has observed that Foster's Fig. 3 gives a nonoptimal result after 24 steps (node number 22 can be removed in favor of number 25).]

5. This can be proved by induction; if T_N denotes the tree constructed, we have

$T_N =$  , if $2^n \le N < 2^n + 2^{n-1}$;

$T_N =$ $T_{2^{n-1}-1}$ $T_{N-2^{n-1}}$  T_{2^n-1} T_{N-2^n} , if $2^n + 2^{n-1} \le N < 2^{n+1}$.

6. The coefficient of z^n in $zB_i(z)B_j(z)$ is the number of n-node binary trees whose left subtree is a balanced binary tree of height i and whose right subtree is a balanced binary tree of height j.

7. $C_{n+1} = C_n^2 + 2B_{n-1}B_{n-2}$; hence if we let $\alpha_0 = \ln 2$, $\alpha_1 = 0$, and $\alpha_{n+2} = \ln(1 + 2B_{n+1}B_n/C_{n+2}^2) = O(1/B_nC_{n+2})$, and $\theta = \exp(\alpha_0/2 + \alpha_1/4 + \alpha_2/8 + \cdots)$, we find that $0 < \theta^{2^n} - C_n = C_n(\exp(\alpha_n/2 + \alpha_{n+1}/4 + \cdots) - 1) < 1$, i.e., $C_n = \lfloor \theta^{2^n} \rfloor$.

8. Let $b_h = B_h'(1)/B_h(1) + 1$, and let ϵ_h be the very small quantity $2B_hB_{h-1}(b_h - b_{h-1})/B_{h+1}$. Then $b_h = 2b_{h-1} - \epsilon_h$; hence $b_h = 2^h(1 - \epsilon_1/2 - \epsilon_2/4 - \cdots) + r_h$, where $r_h = \epsilon_{h+1}/2 + \epsilon_{h+2}/4 + \cdots$ is extremely small for large h. [*Zh. vychisl. matem. i matem. fiziki* **6**,2 (1966), 389–394.]

11. Good reason: A balanced tree with more than one internal node has precisely as many −A external nodes as it has −+B and ++B, and as many +A's as +−B's and −−B's.

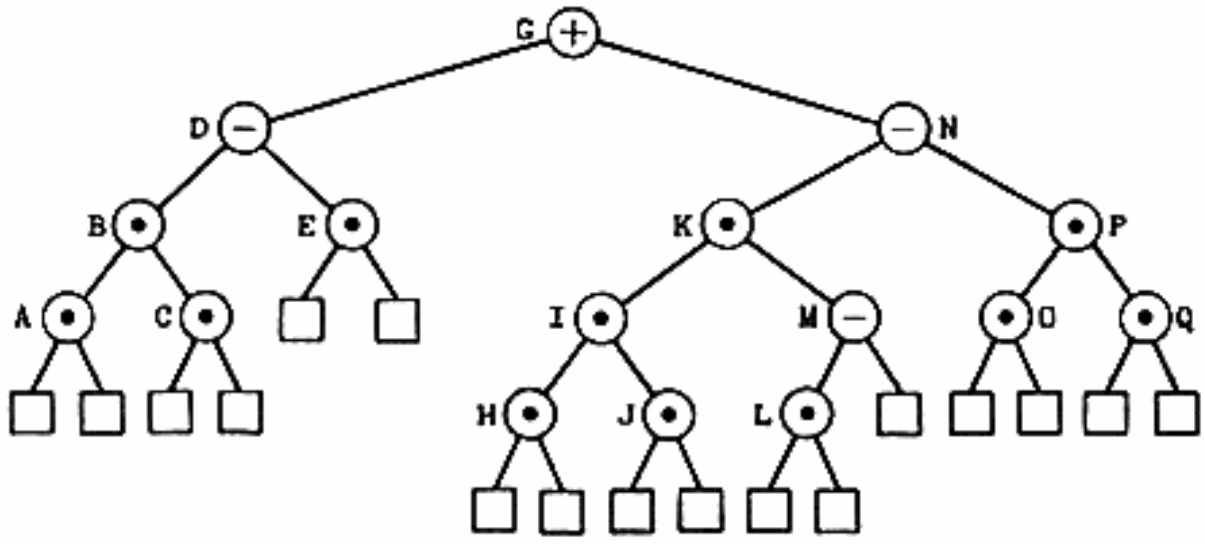
12. The maximum occurs when inserting into the second external node of (12); $C = 4$, $C1 = 3$, $D = 3$, $A = 1$, $F = G = H = 1$, $E = J = 0$, and the `JMP` in line 67 is taken, for a total time of $132u$. The minimum occurs when inserting into the third-last external node of (13); $C = 2$, $C1 = 1$, $D = 2$, $A = E = F = G = H = J = 0$, for a total time of $61u$. [The corresponding figures for Program 6.2.2T are $74u$ and $26u$.]

13. When the tree changes, only $O(\log N)$ `RANK` values need to be updated; the "simple" system might require very extensive changes.

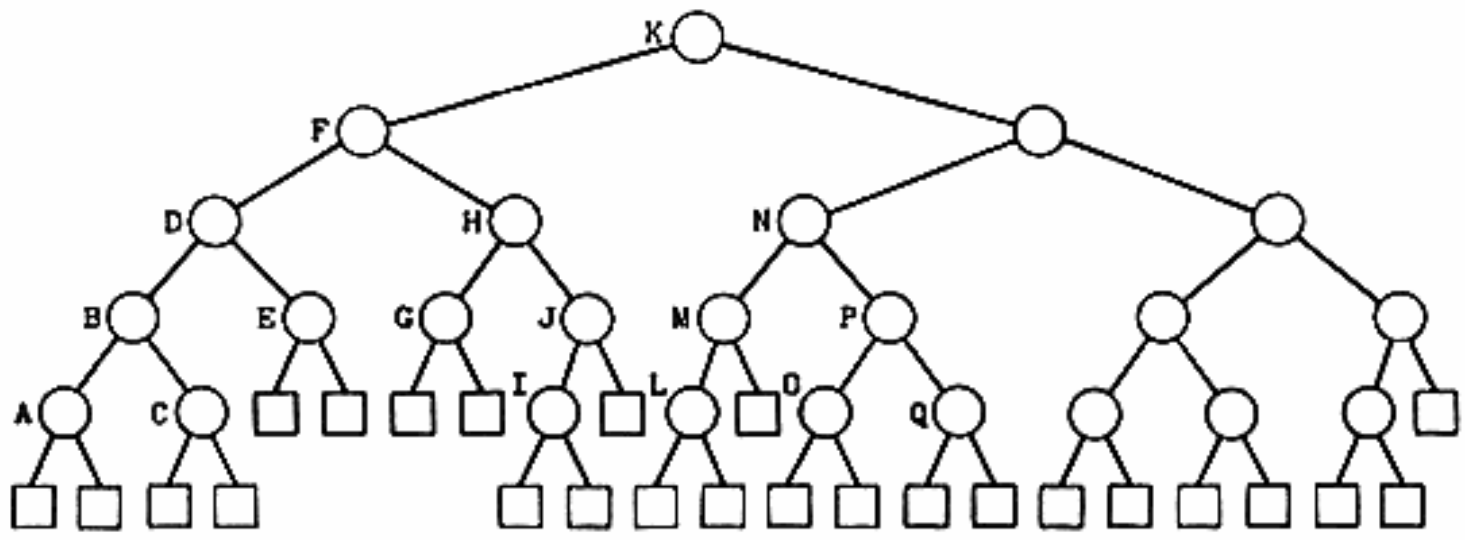
14. Yes. (But typical operations on lists are sufficiently nonrandom that degenerate trees would probably occur.)

15. Use Algorithm 6.2.2T with `M` set to zero in step T1, and `M` ← `M` + `RANK(P)` whenever $K \ge$ `KEY(P)` in step T2.

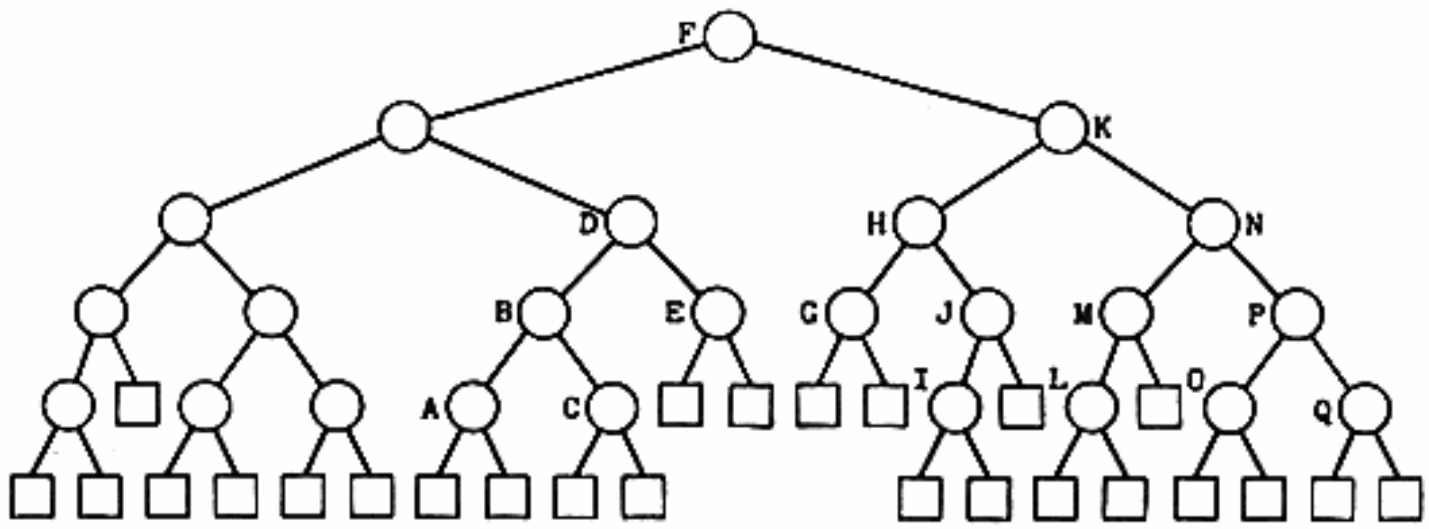
16. Delete G; replace F by G; Case 2 rebalancing at H; Case 3 rebalancing at K.



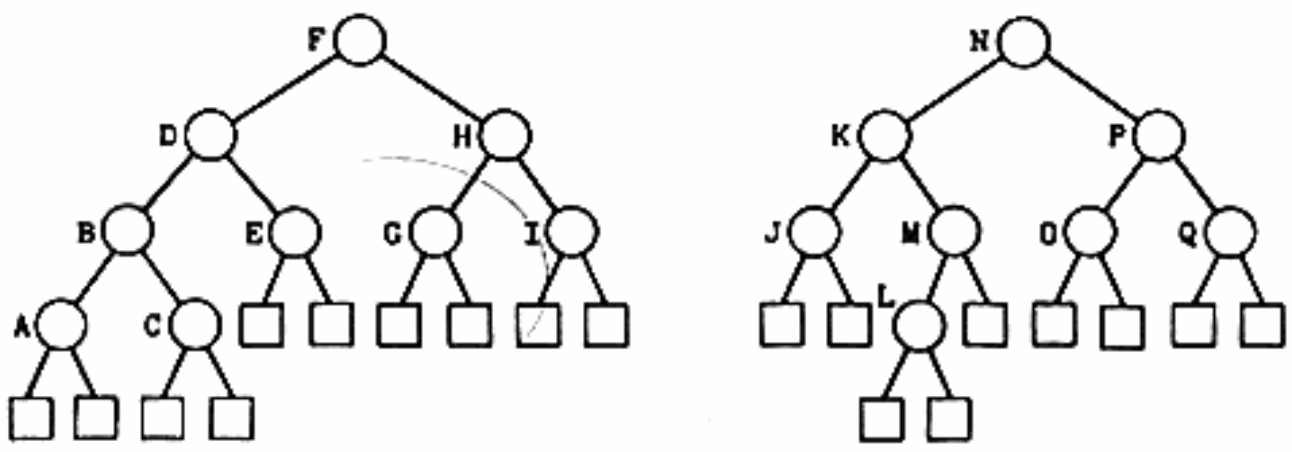
17. (a)



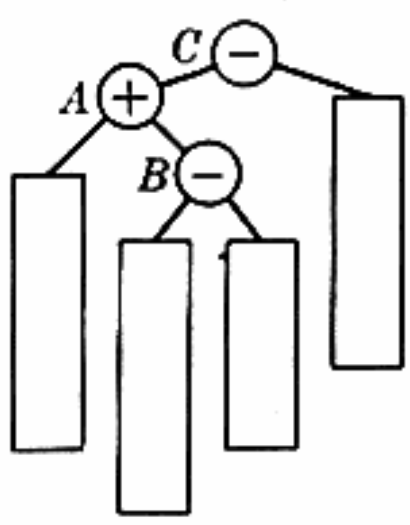
(b)



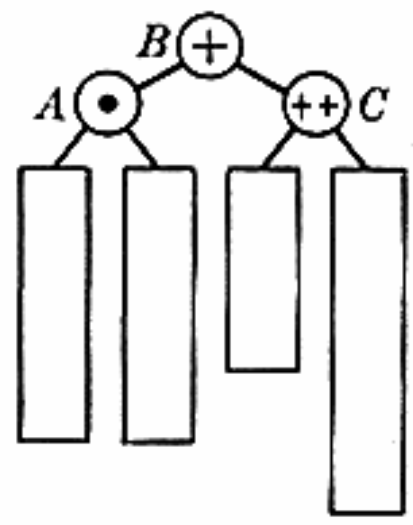
18.



19. (Solution by Clark Crane.) There is one case which can't be handled by a single or double rotation at the root, namely

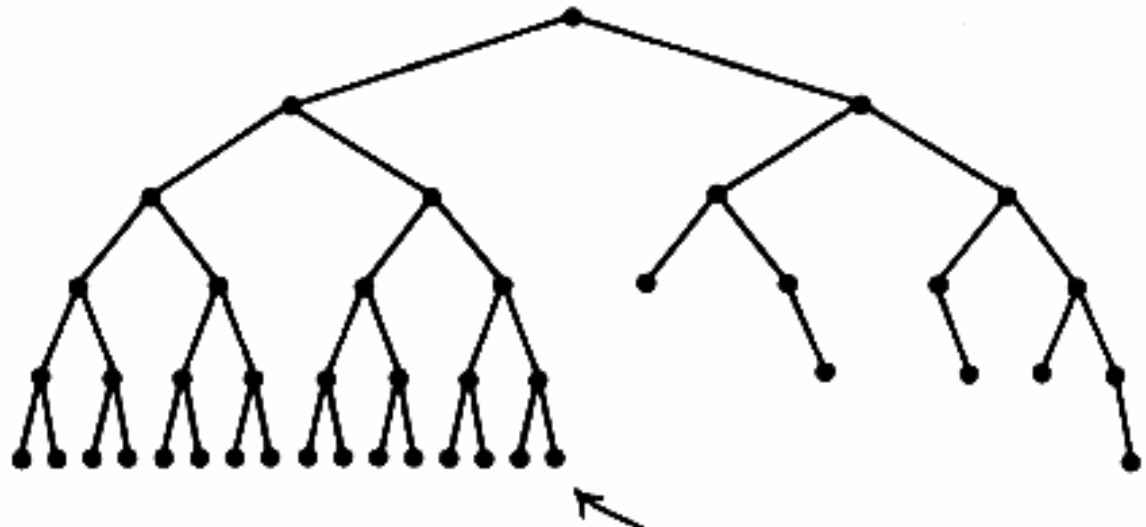


. Change it to



and then resolve the imbalance by applying a single or double rotation at *C*.

20.



It may be difficult to insert a new node here ↖ .

21. Algorithm A does the job in order $N \log N$ steps (see exercise 5); the following algorithm creates the same trees in $O(N)$ steps, using an interesting iterative rendition of a recursive method. We use three auxiliary lists:

$\mathtt{D}_1, \ldots, \mathtt{D}_l$ (a binary counter that essentially controls the recursion);

$\mathtt{J}_1, \ldots, \mathtt{J}_l$ (a list of pointers to "juncture nodes");

$\mathtt{T}_1, \ldots, \mathtt{T}_l$ (a list of pointers to trees).

Here $l = \lceil \log_2 (N+1) \rceil$. For convenience the algorithm also sets $\mathtt{D}_0 \leftarrow 1$, $\mathtt{J}_0 \leftarrow \mathtt{J}_{l+1} \leftarrow \Lambda$.

G1. [Initialize.] Set $l \leftarrow 0$, $\mathtt{J}_0 \leftarrow \mathtt{J}_1 \leftarrow \Lambda$, $\mathtt{D}_0 \leftarrow 1$.

G2. [Get next item.] Let P point to the next input node. (We may invoke another coroutine in order to obtain P.) If there is no more input, go to G5. Otherwise, set $k \leftarrow 1$, $\mathtt{Q} \leftarrow \Lambda$, and interchange $\mathtt{P} \leftrightarrow \mathtt{J}_1$.

G3. [Carry.] If $k > l$ (equivalently if $\mathtt{P} = \Lambda$), set $l \leftarrow l+1$, $\mathtt{D}_k \leftarrow 1$, $\mathtt{T}_k \leftarrow \mathtt{Q}$, $\mathtt{J}_{k+1} \leftarrow \Lambda$, and return to G2. Otherwise set $\mathtt{D}_k \leftarrow 1 - \mathtt{D}_k$, interchange $\mathtt{Q} \leftrightarrow \mathtt{T}_k$, $\mathtt{P} \leftrightarrow \mathtt{J}_{k+1}$, and increase k by 1. If now $\mathtt{D}_{k-1} = 0$, repeat this step.

G4. [Concatenate.] Set $\mathtt{LLINK(P)} \leftarrow \mathtt{T}_k$, $\mathtt{RLINK(P)} \leftarrow \mathtt{Q}$, $\mathtt{B(P)} \leftarrow 0$, $\mathtt{T}_k \leftarrow \mathtt{P}$, and return to G2.

G5. [Finish up.] Set $\mathtt{LLINK}(\mathtt{J}_k) \leftarrow \mathtt{T}_k$, $\mathtt{RLINK}(\mathtt{J}_k) \leftarrow \mathtt{J}_{k-1}$, $\mathtt{B}(\mathtt{J}_k) \leftarrow 1 - \mathtt{D}_{k-1}$, for $1 \le k \le l$. Then terminate the algorithm ($\mathtt{J}_l$ points to the root of the desired tree). ▮

Step G3 is executed $2N - \nu(N)$ times, where $\nu(N)$ is the number of 1's in the binary representation of N.

22. The height of a weight-balanced tree with N internal nodes always lies between $\log_2 (N+1)$ and $2 \log_2 (N+1)$. To get this upper bound, note that the heavier subtree of the root has at most $(N+1)/\sqrt{2}$ external nodes.

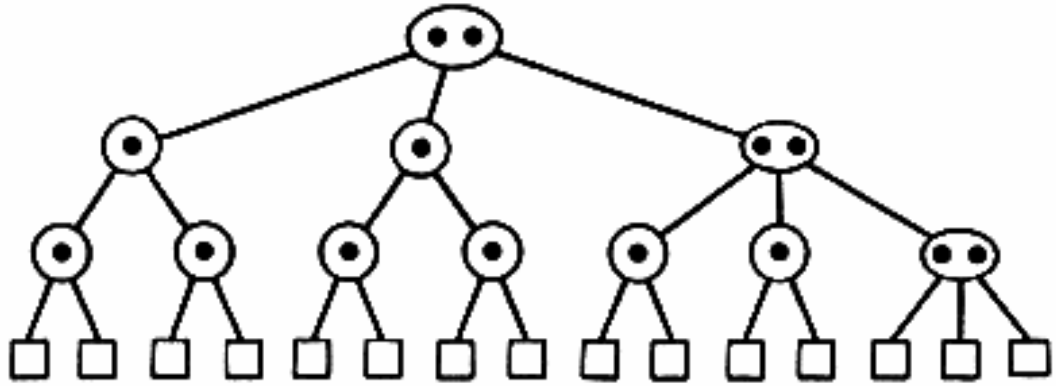
23. (a) Form a tree whose right subtree is a complete binary tree with $2^n - 1$ nodes, and whose left subtree is a Fibonacci tree with $F_{n+1} - 1$ nodes. (b) Form a weight balanced tree whose right subtree is about $2 \log_2 N$ levels high and whose left subtree is about $\log_2 N$ levels high (cf. exercise 22).

24. Consider a smallest tree which satisfies the condition but is not perfectly balanced. Then its left and right subtrees are perfectly balanced, so they have 2^l and 2^r external nodes, respectively, where $l \neq r$. But this contradicts the stated condition.

25. After inserting a node at the bottom of the tree, we work up from the bottom to check the weight balance at each node on the search path. Suppose imbalance occurs at node A in (1), after having inserted a new node in the right subtree, where B and its subtrees are weight-balanced. Then a single rotation will restore the balance unless

$(|\alpha| + |\beta|)/|\gamma| > \sqrt{2} + 1$, where $|x|$ denotes the number of external nodes in a tree x. But in this case it can be shown that a double rotation will suffice.

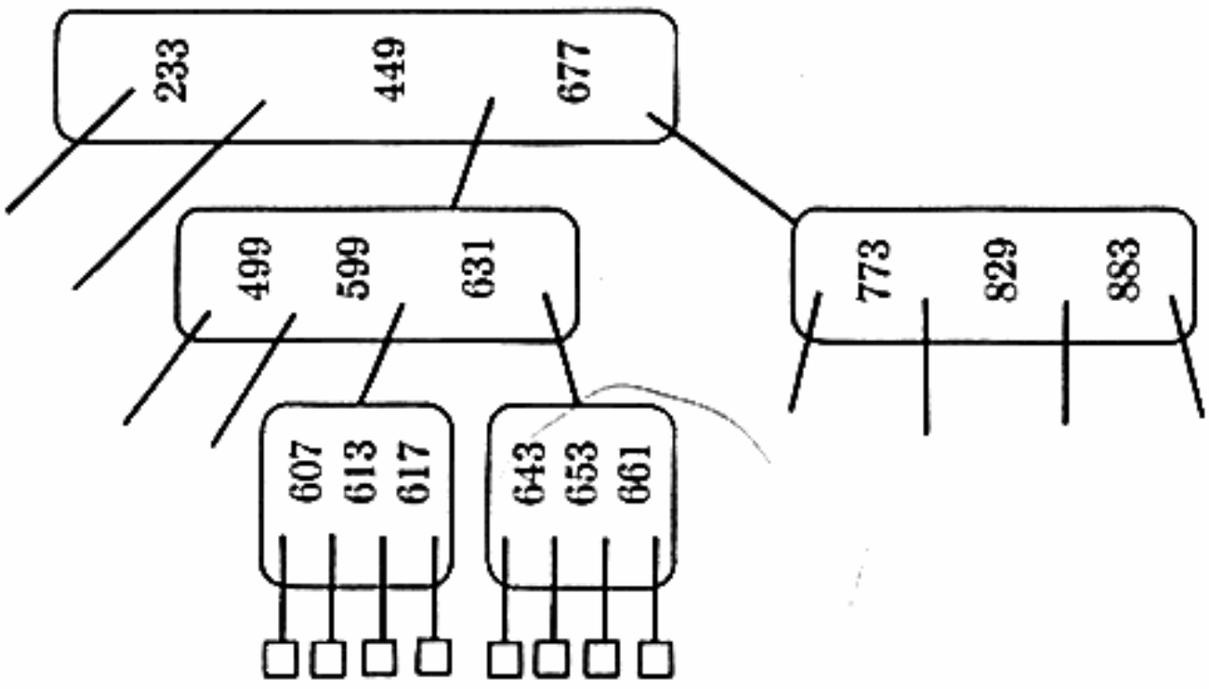
27. It is sometimes necessary to make two comparisons in nodes that contain two keys. The worst case occurs in a tree like the following, which sometimes needs $2 \log_2 (N + 2) - 2$ comparisons:



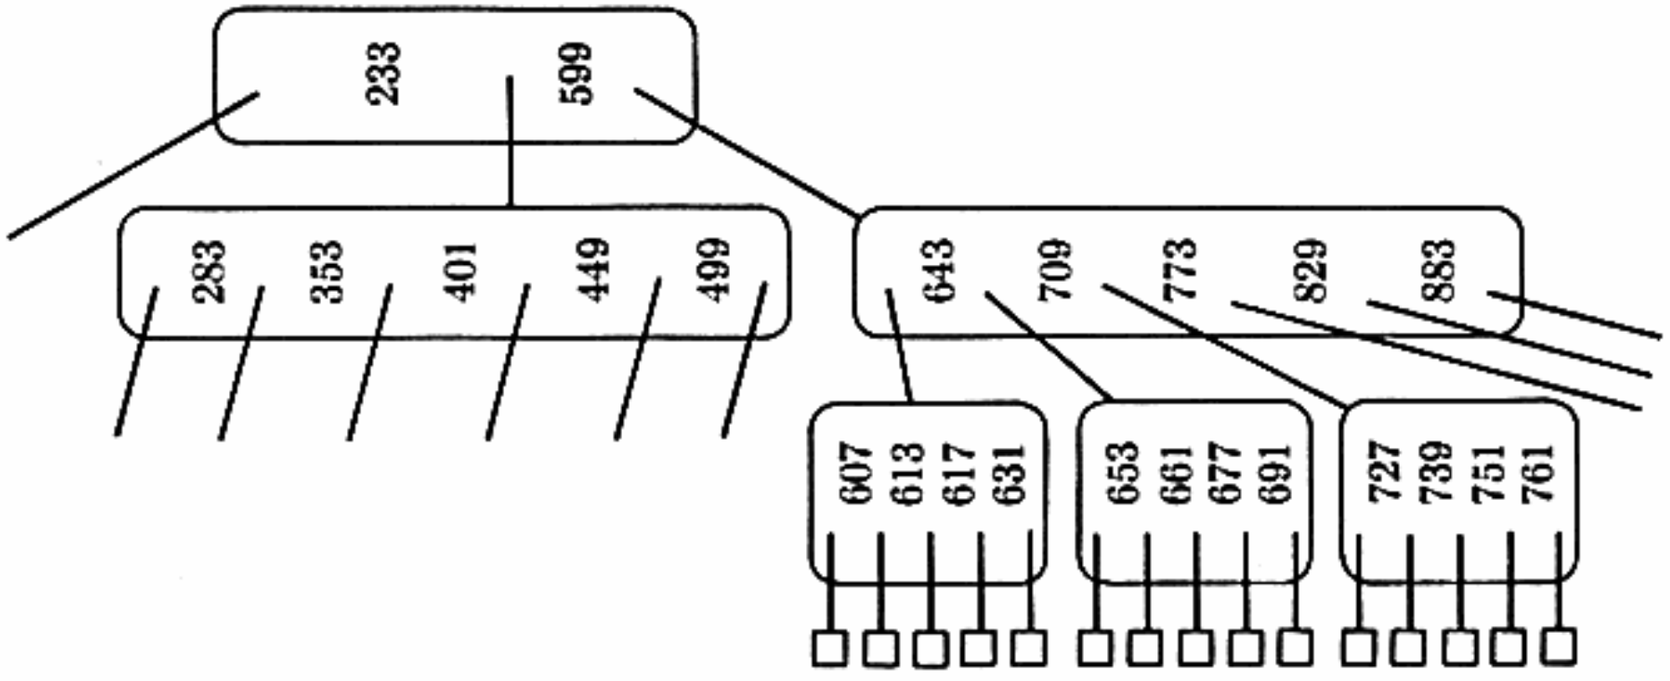
30. For best-fit, arrange the records in order of size, with an arbitrary rule to break ties in case of equality. (Cf. exercise 2.5–9.) For first fit, arrange the records in order of location, with an extra field in each node telling the size of the largest area in the left subtree of that node. This extra field can be maintained under insertions and deletions. (Although the running time is $O(\log n)$, it probably still doesn't beat the "ROVER" method of exercise 2.5–6 in practice.)

SECTION 6.2.4

1. Two nodes split:



2. Altered nodes:



(Of course a B^*-tree would have no 3-key nodes, although Fig. 30 does.)

3. (a) $1 + 2 \cdot 50 + 2 \cdot 51 \cdot 50 + 2 \cdot 51 \cdot 51 \cdot 50 = 2 \cdot 51^3 - 1 = 265301$. (b) $1 + 2 \cdot 50 + (2 \cdot 51 \cdot 100 - 100) + ((2 \cdot 51 \cdot 101 - 100) \cdot 100 - 100) = 101^3 = 1030301$. (c) $1 + 2 \cdot 66 + (2 \cdot 67 \cdot 66 + 2) + (2 \cdot 67 \cdot 67 \cdot 66 + 2 \cdot 67) = 601661$. (Less than (b)!)

4. Before splitting a non-root node, make sure that it has two full brothers, then split these three nodes into four. The root should split only when it has more than $3\lfloor(3m - 3)/4\rfloor$ keys.

5. 450. The worst case occurs if we have 1005 characters and the key to be passed to Father must be 50 characters long: 445 chars + ptr + 50-char key + ptr + 50-char key + ptr + 445 chars.

6. Yes, for example we could replace each K_i in (1) by i plus the number of keys in subtrees $P_0, \ldots, P_{i-1}$. The search, insertion, and deletion algorithms can be modified appropriately.

7. If the key to be deleted is not on level $l - 1$, replace it by its successor and delete the successor. To delete a key on level $l - 1$, we simply erase it; if this makes the node too empty, we look at its right (or left) brother, and "underflow," i.e., move keys in from the brother so that both nodes have approximately the same amount of data. This underflow operation will fail only if the brother was minimally full, but in that case the two nodes can be collapsed into one (together with one key from their father); such a collapsing may cause the father in turn to underflow, etc.

9. Brief sketch: Extend the paging scheme so that exclusive access to buffers is given to one user at a time; the search, insertion, and deletion algorithms must be carefully modified so that such exclusive access is granted only for a limited time when absolutely necessary, and such that no deadlocks can occur. When a particular user needs to update a father page, it will be necessary for him to see if it has changed or moved since he last observed it.

10. Given a tree $\mathfrak{I}$ with N internal nodes, let there be $a_k^{(j)}$ external nodes that require k accesses and whose father node belongs to a page containing j keys; and let $A^{(j)}(z)$ be the corresponding generating function. Thus $A^{(1)}(1) + \cdots + A^{(M)}(1) = N + 1$. (Note that $a_k^{(j)}$ is a multiple of $j + 1$, for $1 \le j < M$.) The next random insertion leads to $N + 1$ equally probable trees, whose generating functions are obtained by decreasing some coefficient $a_k^{(j)}$ by $j + 1$ and adding $j + 2$ to $a_k^{(j+1)}$; or (if $j = M$) by decreasing some $a_k^{(M)}$ by 1 and adding 2 to $a_{k+1}^{(1)}$. Now $B_N^{(j)}(z)$ is $(N + 1)^{-1}$ times the sum, over all $\mathfrak{I}$, of the generating function $A^{(j)}(z)$ for $\mathfrak{I}$ times the probability that $\mathfrak{I}$ occurs; the stated recurrence relations follow.

The recurrence has the form

$$\begin{aligned}(B_N^{(1)}(z), \ldots, B_N^{(M)}(z))^T &= (I + (N + 1)^{-1}\mathbf{W}(z))(B_{N-1}^{(1)}(z), \ldots, B_{N-1}^{(M)}(z))^T \\ &= \cdots = g_N(\mathbf{W}(z))(0, \ldots, 0, 1)^T,\end{aligned}$$

where

$$g_n(x) = (1 + x/(n + 1)) \cdots (1 + x/2) = \binom{x+n+1}{n+1}/(x + 1).$$

It follows that $C'_N = (1, \ldots, 1)(B_N^{(1)\prime}(1), \ldots, B_N^{(M)\prime}(1))^T = 2B_{N-1}^{(M)}(1)/(N + 1) + C'_{N-1} = 2f_N(\mathbf{W})_{MM}$, where $f_n(x) = g_{n-1}(x)/(n + 1) + \cdots + g_0(x)/2 = (g_n(x) - 1)/x$, and $\mathbf{W} = \mathbf{W}(1)$. (The subscript MM denotes the lower right corner element of the matrix.) Now $\mathbf{W} = \mathbf{S}^{-1}\,\mathbf{diag}\,(\lambda_1, \ldots, \lambda_M)\mathbf{S}$, for some matrix $\mathbf{S}$, where $\mathbf{diag}(\lambda_1, \ldots, \lambda_M)$ denotes the diagonal matrix whose entries are the roots of $\chi(\lambda) = (\lambda + 2) \ldots$

$(\lambda+M+1)-(M+1)!$. (These roots are distinct, since $\chi(\lambda)=\chi'(\lambda)=0$ implies $1/(\lambda+2)+\cdots+1/(\lambda+M+1)=0$; the latter can hold only when λ is real, and $-M-1<\lambda<-2$, which implies that $|\lambda+2|\ldots|\lambda+M+1|<(M+1)!$, a contradiction.) If $p(x)$ is any polynomial, $p(\mathbf{W})=p(\mathbf{S}^{-1}\,\mathbf{diag}\,(\lambda_1,\ldots,\lambda_M)\mathbf{S})=\mathbf{S}^{-1}\,\mathbf{diag}\,(p(\lambda_1),\ldots,p(\lambda_M))\mathbf{S}$; hence the lower right corner element of $p(\mathbf{W})$ has the form $c_1p(\lambda_1)+\cdots+c_Mp(\lambda_M)$ for some constants $c_1,\ldots,c_M$ independent of p. These constants may be evaluated by setting $p(\lambda)=\chi(\lambda)/(\lambda-\lambda_i)$; since $(\mathbf{W}^k)_{MM}=(-2)^k$ for $0\le k\le M-1$, we have $p(\mathbf{W})_{MM}=p(-2)=(M+1)!/(\lambda_i+2)=c_ip(\lambda_i)=c_i\chi'(\lambda_i)=c_i(M+1)!\big(1/(\lambda_i+2)+\cdots+1/(\lambda_i+M+1)\big)$; hence $c_i=(\lambda_i+2)^{-1}\big((1/(\lambda_i+2)+\cdots+1/(\lambda_i+M+1)\big)^{-1}$. This yields an "explicit" formula $C'_N=\sum_{1\le i\le M}2c_if_N(\lambda_i)$; and it remains to study the roots λ_i. Note that $|\lambda_i+M+1|\le M+1$ for all i, otherwise we would have $|\lambda_i+2|\ldots|\lambda_i+M+1|>(M+1)!$. Taking $\lambda_1=0$, this implies that $\Re(\lambda_i)<0$ for $2\le i\le M$. By Eq. 1.2.5–15, $g_n(x)\sim(n+1)^x/\Gamma(x+2)$ as $n\to\infty$; hence $g_n(\lambda_i)\to0$ for $2\le i\le M$. Consequently $C'_N=2c_1f_N(0)+O(1)=H_N/(H_{M+1}-1)+O(1)$.

Notes: The above analysis is relevant also to the "samplesort" algorithm discussed briefly in Section 5.2.2. The calculations may readily be extended to show that $B_N^{(j)}(1)\sim(H_{M+1}-1)^{-1}/(j+2)$ for $1\le j<M$, $B_N^{(M)}(1)\sim(H_{M+1}-1)^{-1}/2$. Hence the total number of interior nodes on unfilled pages is approximately $N\big(1/(3\times2)+2/(4\times3)+\cdots+(M-1)/((M+1)\times M)\big)/(H_{M+1}-1)=N\big(1-M/(M+1)(H_{M+1}-1)\big)$; and the total number of pages used is approximately

$$N\big(1/(3\times2)+1/(4\times3)+\cdots+1/((M+1)\times M)+1/(M+1)\big)/(H_{M+1}-1)$$
$$=N/2(H_{M+1}-1),$$

yielding an asymptotic storage utilization of $2(H_{M+1}-1)/M$.

SECTION 6.3

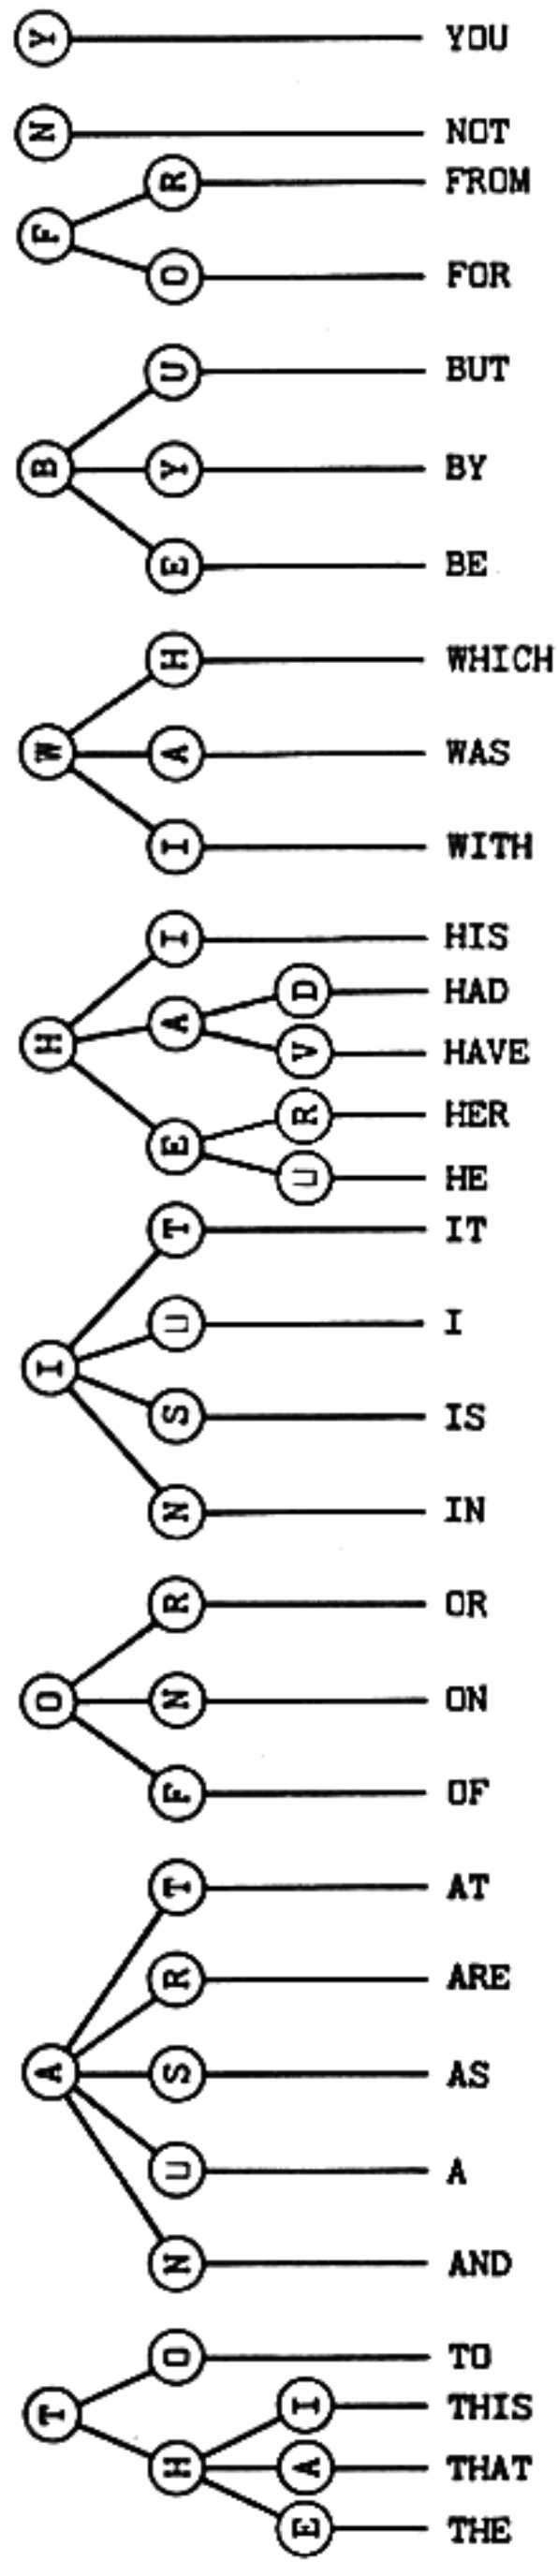
1. Lieves (pl. of "lief").

2. Perform Algorithm T using the new key as argument; it will terminate unsuccessfully in either step T3 or T4. If in T3, simply set table entry k of NODE(P) to K and terminate the insertion algorithm. Otherwise set this table entry to the address of a new node Q $\Leftarrow$ AVAIL, containing only null links, then set P $\leftarrow$ Q. Now set k and k' to the respective next characters of K and X; if $k \neq k'$, store K in position k of NODE(P) and store X in position k', but if $k = k'$ again make the k position point to a new node Q $\Leftarrow$ AVAIL, set P $\leftarrow$ Q, and repeat the process until eventually $k \neq k'$. (We must assume that no key is a prefix of another.)

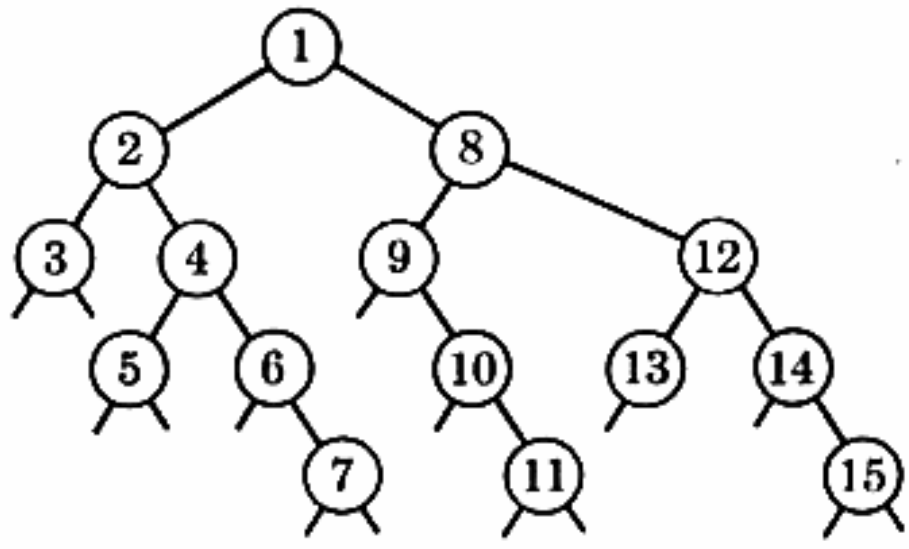
3. Replace the key by a null link, in the node where it appears. If this node is now "useless," i.e. if all its entries are null except one which is a key X, delete the node and replace the corresponding pointer in its father by X. If the father node is now useless, delete it in the same way.

4. Successful searches take place exactly as with the full table, but unsuccessful searches in the compressed table may go through several additional iterations. For example, an input argument such as IONIC will make Program T take *seven* iterations (more than five!); this is the worst case. It is necessary to verify that no infinite looping on blank sequences is possible.

5. In each family, test for the most probable outcome first, by arranging the letters from left to right in decreasing order of probability. The optimality of this arrangement can be proved as in Theorem 6.1S. [Cf. *CACM* **12** (1969), 72–76.]



6.



7. For example, 8, 4, 12, 1, 2, 3, 5, 6, 7, 9, 10, 11, 13, 14, 15. (No matter what sequence is used, the left subtree cannot contain more than two nodes on level 4, nor can the right subtree.) Even this "worst" tree is within 4 of the best possible tree, so we see that digital search trees aren't very sensitive to the order of insertion.

8. Yes. The KEY fields now contain only a truncated key; leading bits implied by the node position are chopped off. (A similar modification of Algorithm T is possible.)

9.

START	LDX	K	1	*D1. Initialize.* (rX ≡ K)
	LD1	ROOT	1	P ← ROOT. (rI1 ≡ P)
	JMP	2F	1	
4H	LD2	0,1(RLINK)	$C2$	*D4. Move right.* Q ← RLINK(P).
	J2Z	5F	$C2$	To D5 if Q = Λ.
1H	ENT1	0,2	$C - 1$	P ← Q.
2H	CMPX	1,1	C	*D2. Compare.*
	JE	SUCCESS	C	Exit if K = KEY(P).
	SLB	1	$C - S$	Shift K left one bit.
	JAO	4B	$C - S$	To D4 if the detached bit was 1.
	LD2	0,1(LLINK)	$C1$	*D3. Move left.* Q ← LLINK(P).
	J2NZ	1B	$C1$	To D2 with P ← Q if Q ≠ Λ.
5H	Continue as in Program 6.2.2T, interchanging the roles of rA, rX.			

The running time for the searching phase of this program is $(10C - 3S + 4)u$, where $C - S$ is the number of bit inspections. For random data, the approximate average running times are therefore:

	Successful	Unsuccessful
Program 6.2.2T	$15 \ln N - 12.34$	$15 \ln N - 2.34$
This program	$14.4 \ln N - 6.17$	$14.4 \ln N + 1.26$

(Consequently Program 6.2.2T is a shade faster unless N is very large.)

10. Let $\oplus$ denote the "exclusive or" operation on n-bit numbers, and let $f(x) = n - \lceil \log_2 (x + 1) \rceil$, the number of leading zero bits of x. One solution: (b) If a search via Algorithm T ends unsuccessfully in step T3, k is one less than the number of bit inspections made so far; otherwise if the search ends in step T4, $k = f(K \oplus X)$. (a, c) Do a regular search, but also keep track of the minimum value, x, of $K \oplus$ KEY(P) over all KEY(P) compared with K during the search. Then $k = f(x)$. (Prove that no other key can have more bits in common with K than those compared to K. In case (a), the maximum k occurs for either the largest key $\leq K$ or the smallest key $> K$.)

11. Yes, since the keys of all nodes in the subtree of NODE(Q) begin with the appropriate sequence of bits. But major changes to the tree would be necessary if keys are

truncated as in exercises 8 and 9, so truncation should not be used together with deletion.

12. Insert three random numbers α, β, γ between 0 and 1 into an initially empty tree; then delete α with probability p, β with probability q, γ with probability r, using Algorithm 6.2.2D. The tree

is obtained with probability $\frac{3}{8}p + \frac{1}{2}q + \frac{1}{2}r$, and this is $\frac{1}{2}$ only if $p = 0$.

13. Add a KEY field to each node, and compare K with this key before looking at the vector element in step T2. Table 1 would change as follows: Nodes (1), . . . , (12) would contain the respective keys THE, AND, BE, FOR, HIS, IN, OF, TO, WITH, HAVE, HE, THAT (if we inserted them in order of decreasing frequency), and these keys would be deleted from their previous positions. [The corresponding program would be slower and more complicated than Program T, in this case. A more direct M-ary generalization of Algorithm D would create a tree with N nodes, having one key and M links per node.]

14. If $j \leq n$, there is only one place, namely KEY(P). But if $j > n$, the set of all occurrences is found by traversing the subtree of node P: If there are r occurrences, this subtree contains $r - 1$ nodes (including node P), and so it has r link fields with TAG = 1; these link fields point to all the nodes that reference TEXT, positions matching K. (It isn't necessary to check the TEXT again at all.)

15. To begin forming the tree, set KEY(HEAD) to the first TEXT reference, and LLINK(HEAD) $\leftarrow$ HEAD, LTAG(HEAD) $\leftarrow 1$. Further TEXT references can be entered into the tree using the following insertion algorithm:

Set K to the new key which we wish to enter. (This is the first reference the insertion algorithm makes to the TEXT array.) Perform Algorithm P; it must terminate unsuccessfully, since no key is allowed to be a prefix of another. (Step P6 makes the second reference to the TEXT; no more references will be needed!) Now suppose that the key located in step P6 agrees with the argument K in the first l bits, but differs from it in position $l + 1$, where K has the digit b and the key has $1 - b$. (Even though the search in Algorithm P might have let j get much greater than l, it is possible to prove that the procedure specified here will find the longest match between K and *any* existing key. Thus, *all* keys of the text which start with the first l bits of K have $1 - b$ as their $(l + 1)$st bit.) Now repeat Algorithm P with K replaced by these leading l bits (i.e., $n \leftarrow l$). This time the search will be successful, so we needn't perform step P6. Now set R $\Leftarrow$ AVAIL, KEY(R) $\leftarrow$ position of the new key in TEXT. If LLINK(Q) = P, set LLINK(Q) $\leftarrow$ R, $l \leftarrow$ LTAG(Q), LTAG(Q) $\leftarrow 0$; otherwise set RLINK(Q) $\leftarrow$ R, $l \leftarrow$ RTAG(Q), RTAG(Q) $\leftarrow 0$. If $b = 0$, set LTAG(R) $\leftarrow 1$, LLINK(R) $\leftarrow$ R, RTAG(R) $\leftarrow l$, RLINK(R) $\leftarrow$ P; otherwise set RTAG(R) $\leftarrow 1$, RLINK(R) $\leftarrow$ R, LTAG(R) $\leftarrow l$, LLINK(R) $\leftarrow$ P. If $l = 1$, set SKIP(R) $\leftarrow 1 + l - j$; otherwise set SKIP(R) $\leftarrow 1 + l - j +$ SKIP(P) and SKIP(P) $\leftarrow j - l - 1$.

16. The tree setup requires precisely one dotted link coming from below a node to that node; it comes from that part of the tree where this key first differs from all others. If there is no such part of the tree, the algorithms break down. We could simply drop keys that are prefixes of others, but then the algorithm of exercise 14 wouldn't have enough data to find *all* occurrences of the argument.

17. If we define $a_0 = a_1 = 0$, then

$$x_n = a_n + \sum_{k\geq 2} \binom{n}{k} (-1)^k \hat{a}_k/(m^{k-1} - 1) = \sum_{k\geq 2} \binom{n}{k} (-1)^k \hat{a}_k m^{k-1}/(m^{k-1} - 1).$$

18. To solve (4) we need the transform of $a_n = 1 - \delta_{n0} - \delta_{n1}$, namely $\hat{a}_n = \delta_{n0} - 1 + n$; hence for $N \geq 2$ we obtain $A_N = 1 - U_N + V_N$, where $U_N = K(N, 0, M)$ and $V_N = K(N, 1, M)$ in the notation of exercise 19. Similarly to solve (5), take $a_n = n - \delta_{n1} = \hat{a}_n$ and obtain $C_N = N + V_N$ for $N \geq 2$.

19. For $s = 1$, we have $V_n = K(n, 1, m) = n\big((\ln n + \gamma)/(\ln m) - \frac{1}{2} - f_0(n-1)\big) + O(1)$, and for $s \geq 2$ we have $K(n, s, m) = (-1)^s n\big(1/(\ln m) + f_{s-1}(n-s)\big)/s(s-1) + O(1)$, where

$$f_s(n) = \frac{2}{\ln m} \sum_{k\geq 1} \Re\left(\Gamma(s - 2\pi i k/(\ln m)) \exp(2\pi i k \log_m n)\right)$$

is a periodic function of $\log n$. [In this derivation we have

$$K(n+s, s, m)/(-1)^s \binom{n+s}{s} = (n^{-s+1}/2\pi i) \int_{1/2-i\infty}^{1/2+i\infty} \Gamma(z) n^{s-1-z}\, dz/(m^{s-1-z} - 1) + O(n^{-s}).$$

For small m and s, the f's will be negligibly small; cf. exercise 5.2.2–46. Note that $f_s(n-a) = f_s(n) + O(n^{-1})$ for fixed a.]

20. For (a), let $a_n = 1 - \delta_{n0} - \delta_{n1} - \cdots - \delta_{ns}$; for (b), let $a_n = n - \delta_{n1} - 2\delta_{n2} - \cdots - s\delta_{ns}$; and for (c), we want to solve the recurrence

$$y_n = m^{1-n} \sum_k \binom{n}{k} (m-1)^{n-k} y_k \qquad \text{for} \qquad n > s,$$

$$y_n = \binom{n+1}{2} \qquad \text{for} \qquad n \leq s.$$

Setting $x_n = y_n - n$ yields a recurrence of the form of exercise 17, with

$$a_n = (1 - M^{-1}) \sum_{0\leq k\leq s} \binom{k}{2} \delta_{nk}.$$

Therefore, in the notation of previous exercises, the answers are (a) $1 - K(N, 0, M) + K(N, 1, M) - \cdots + (-1)^{s-1} K(N, s, M) = N/(s \ln M) - N\big(f_{-1}(N) + f_0(n-1) + f_1(N-2)/2\cdot 1 + \cdots + f_{s-1}(N-s)/s(s-1)\big) + O(1)$; (b) $N^{-1}\big(N + K(N, 1, M) - 2K(N, 2, M) + \cdots + (-1)^{s-1} sK(N, s, M)\big) = (\ln N + \gamma - H_{s-1})/(\ln M) + \frac{1}{2} - \big(f_0(N-1) + f_1(N-2)/1 + \cdots + f_{s-1}(N-s)/(s-1)\big) + O(N^{-1})$; (c) $N^{-1}\big(N + (1 - M^{-1})\sum_{2\leq k\leq s} (-1)^k \binom{k}{2} K(N, k, M)\big) = 1 + \frac{1}{2}(1 - M^{-1})\big((s-1)/(\ln M) + f_1(N-2) + \cdots + f_{s-1}(N-s)\big) + O(N^{-1})$.

21. Let there be A_N nodes in all. The number of nonnull pointers is $A_N - 1$, and the number of nonpointers is N, so the total number of null pointers is $MA_N - A_N +$

$1 - N$. To get the average number of these in any fixed position, divide by M. [The average value of A_N appears in exercise 20(a).]

22. There is a node for each of the M^l sequences of leading bits such that at least two keys have this bit pattern. The probability that exactly k keys have a particular bit pattern is

$$\binom{N}{k} M^{-lk}(1 - M^{-l})^{N-k},$$

so the average number of trie nodes on level l is $M^l(1 - (1 - M^{-l})^N) - N(1 - M^{-l})^{N-1}$.

23. More generally, consider the case of arbitrary s as in exercise 20. If there are a_l nodes on level l, they contain a_{l+1} links and $Ma_l - a_{l+1}$ places where the search might be unsuccessful. The average number of digit inspections will therefore be $\sum_{l\geq 0}(l+1)M^{-l-1}(Ma_l - a_{l+1}) = \sum_{l\geq 0} M^{-l}a_l$. Using the formula for a_l in a random trie, this equals $1 + (N+1)^{-1}\big(K(N+1, 1, M) - 2K(N+1, 2, M) + \cdots + (-1)^s (s+1)K(N+1, s+1, M)\big) = (\ln N + \gamma - H_s)/(\ln M) + \frac{1}{2} - f_0(N) - f_1(N-1)/1 - \cdots - f_s(N-s)/s + O(N^{-1})$.

24. We must solve the recurrences $x_0 = x_1 = y_0 = y_1 = 0$,

$$x_n = m^{-n} \sum_{n_1+\cdots+n_m=n} \binom{n}{n_1, \ldots, n_m}\Big(x_{n_1} + \cdots + x_{n_m} + \sum_{1\leq j\leq m}(1 - \delta_{n_j 0})\Big)$$

$$= a_n + m^{1-n}\sum_k \binom{n}{k} x_k,$$

$$y_n = m^{-n} \sum_{n_1+\cdots+n_m=n} \binom{n}{n_1, \ldots, n_m}\Big(y_{n_1} + \cdots + y_{n_m} + \sum_{1\leq i<j\leq m}(1 - \delta_{n_i 0})n_j\Big)$$

$$= b_n + m^{1-n}\sum_k \binom{n}{k} y_k,$$

for $n \geq 2$, where $a_n = m(1 - (1 - 1/m)^n)$ and $b_n = \frac{1}{2}(m-1)n(1 - (1 - 1/m)^{n-1})$. By exercises 17, 18 the answers are (a) $x_N = N + V_N - U_N - \delta_{N1} = A_N + N - 1$ [a result which could have been obtained directly, since the number of nodes in the forest is always $N - 1$ more than the number in the corresponding trie!]; and (b) $y_N/N = \frac{1}{2}(M-1)V_N/N = \frac{1}{2}(M-1)\big((\ln N + \gamma)/(\ln M) - \frac{1}{2} - f_0(N-1)\big) + O(N^{-1})$.

25. (a) Let $A_N = M(N-1)/(M-1) - E_N$; then for $N \geq 2$, we have $(1 - M^{1-N})E_N = M - 1 - M(1 - 1/M)^{N-1} + M^{1-N}\sum_{0<k<N}\binom{N}{k}(M-1)^{N-k}E_k$. Since $M - 1 - M(1 - 1/M)^{N-1} \geq 0$, we have $E_N \geq 0$ by induction. (b) By Theorem 1.2.7A with $x = 1/(M-1)$, $n = N - 1$, we find $D_N = a_N + M^{1-N}\sum_k \binom{N}{k}(M-1)^{N-k}D_k$, where $a_1 = 0$ and $0 < a_N < M(1 - 1/M)^N/\ln M \leq (M-1)^2/M \ln M$ for $N \geq 2$. Hence $0 \leq D_N \leq (M-1)^2 A_N/M \ln M \leq (M-1)(N-1)/\ln M$.

26. Taking $q = \frac{1}{2}$, $z = -\frac{1}{2}$ in the second identity of exercise 5.1.1–16, we get $1/3 - 1/(3\cdot 7) + 1/(3\cdot 7\cdot 15) - \cdots = 0.28879$; it's slightly faster to use $z = -\frac{1}{4}$ and take half of the result. Alternatively, Euler's formula from exercise 5.1.1–14 can be used,

involving only negative powers of 2. (John Wrench has computed the 40D value 0.28878 80950 86602 42127 88997 21929 23078 00889+.)

27. (For fun, the following derivation goes to $O(N^{-1})$.) In the notation of exercises 5.2.2–38, 48, we have $\overline{C}_N = U_N + N - 1 + V_{N+1}/(N+1) - \alpha N - \beta + \sum_{n\geq 2} (-1)^n 2^{-n(n+1)/2} \big(\prod_{1\leq r\leq n} (1-2^{-r})^{-1}\big) \big(\sum_{m\geq 0} (2^{1-n})^m (1-2^{-m})^N\big)$, where $\alpha = 2/(1\cdot 1) - 4/(3\cdot 3\cdot 1) + 8/(7\cdot 7\cdot 3\cdot 1) - \cdots \approx$ 1.60669 51524 15291 76378 33015 23190 92458 04806— and $\beta = 2/(1\cdot 3\cdot 1) - 4/(3\cdot 7\cdot 3\cdot 1) + 8/(7\cdot 15\cdot 7\cdot 3\cdot 1) - \cdots \approx 0.60670$. This numerical evaluation suggests that $\alpha = \beta + 1$, a fact which is not hard to prove. The value of $\sum_{m\geq 0} (2^{1-n})^m (1-2^{-m})^N$ is $O(N^{1-n})$, by exercise 5.2.2–46; and $V_{N+1}/(N+1) = U_{N+1} - U_N$. Hence $\overline{C}_N = U_{N+1} - (\alpha-1)N - \alpha + O(N^{-1}) = (N+1)\log_2(N+1) + N\big((\gamma-1)/\ln 2 + \frac{1}{2} - \alpha + f_{-1}(N)\big) + \frac{1}{2} - 1/\ln 4 - \alpha - \frac{1}{2}f_1(N) + O(N^{-1})$, by exercise 5.2.2–50.

28. The derivations in the text and exercise 27 apply to general $M \geq 2$, if we substitute M for 2 in the obvious places. Hence the average number of digit inspections in a random successful search is $\overline{C}_N/N = U_{N+1} - \alpha_M + 1 + O(N^{-1}) = \log_M N + (\gamma-1)/\ln M + \frac{1}{2} - \alpha_M + f_{-1}(N) + (\log_M N)/N + O(N^{-1})$; and for the unsuccessful case it is $\overline{C}_{N+1} - \overline{C}_N = V_{N+2}/(N+2) - \alpha_M + 1 + O(N^{-1}) = \log_M N + \gamma/\ln M + \frac{1}{2} - \alpha_M - f_0(N+1) + O(N^{-1})$. Here $f_s(n)$ is defined in exercise 19, and $\alpha_M = \sum_{j\geq 0} (-1)^j M^{j+1}/(M^{j+1}-1)^2(M^j-1)\cdots(M-1)$.

30. By iterating the recurrence, $h_n(z)$ is the sum of all possible terms of the form

$$\binom{n}{p_1}(z/(2^{p_1}-1))\binom{p_1}{p_2}(z/(2^{p_2}-1))\cdots(z/(2^{p_m}-1))\binom{p_m}{1},$$

for $n > p_1 > \cdots > p_m > 1$.

31. $h_n'(1) = V_n$ (cf. exercise 5.2.2–36b).

32. The sum of the SKIP fields is the number of nodes in the corresponding binary trie, so the answer is A_N (cf. exercise 20).

33. Here's how (18) was discovered: $A(2z) - 2A(z) = e^{2z} - 2e^z + 1 + A(z)(e^z - 1)$ can be transformed into $A(2z)/(e^{2z}-1) = (e^z-1)/(e^z+1) + A(z)/(e^z-1)$. Hence $A(z) = (e^z-1)\sum_{j\geq 1} (e^{z/2^j}-1)/(e^{z/2^j}+1)$. Now if $f(z) = \sum c_n z^n$, $\sum_{j\geq 1} f(z/2^j) = \sum c_n z^n/(2^n-1)$. In this case $f(z) = (e^z-1)/(e^z+1) = \tanh(z/2) = 1 - 2z^{-1}\times \big(z/(e^z-1) - 2z/(e^{2z}-1)\big) = \sum_{n\geq 1} B_{n+1}\, z^n(2^{n+1}-1)/(n+1)!$. From this formula the route is apparent.

34. (a) Consider $\sum_{j\geq 1}\sum_{2\leq k<n} \binom{n}{k} B_k 2^{j(k-1)}$; $1^{n-1} + \cdots + (m-1)^{n-1} = (B_n(m) - B_n)/n$ by exercise 1.2.11.2–4. (b) Consider $(B_n(m) - B_n)/nm^{n-1}$. (c) Argue as in Section 5.2.2 when $|x| < 2\pi$, then use analytic continuation. (d) $\frac{1}{2}\log_2(n/\pi) + \gamma/(2\ln 2) - \frac{3}{4} + f(n)$, where $f(n) = (2/\ln 2)\sum_{k\geq 1} \Re\big(\zeta(-2\pi ik/\ln 2)\, \Gamma(-2\pi ik/\ln 2)\, \exp(2\pi ik \log_2 n)\big) = (1/\ln 2)\sum_{k\geq 1} \Re\big(\zeta(1 + 2\pi ik/\ln 2)\times \exp(2\pi ik \log_2(n/\pi))/\cosh(\pi^2 k/\ln 2)\big)$.

35. The keys must be $\{\alpha 0\beta 0\omega_1, \alpha 0\beta 1\omega_2, \alpha 1\gamma 0\omega_3, \alpha 1\gamma 1\delta 0\omega_4, \alpha 1\gamma 1\delta 1\omega_5\}$, where $\alpha, \beta, \ldots$ are strings of 0's and 1's with $|\alpha| = a-1$, $|\beta| = b-1$, etc. The probability that five random keys have this form is $5!2^{a-1+b-1+c-1+d-1}/2^{a+b+a+b+a+c+a+c+d+a+c+d} = 5!/2^{4a+b+2c+d+4}$.

36. Let n be the number of internal nodes. (a) $(n!/2^I)\prod\big(1/s(x)\big) = n!\prod\big(1/2^{s(x)-1}s(x)\big)$, where I is the internal path length of the tree.

(b) $((n+1)!/2^n)\prod(1/(2^{s(x)}-1))$. (Consider summing the answer of exercise 35 over all $a, b, c, d \geq 1$.)

37. The smallest modified external path length is actually $2 - 1/2^{N-2}$, and it occurs only in a degenerate tree (whose external path length is *maximal*). [One can prove that the *largest* modified external path length occurs iff the external nodes appear on at most two adjacent levels! But it is not always true that a tree whose external path length is smaller than another has a larger modified external path length.]

38. Consider as subproblems the finding of k-node trees with parameters (α, β), $(\alpha, \frac{1}{2}\beta)$, . . . , $(\alpha, 2^{k-n}\beta)$.

40. Let N/r be the true period length of the sequence. Form a Patricia-like tree, with $a_0a_1\ldots$ as the TEXT and with N/r keys starting at positions 0, 1, . . . , $N/r - 1$. (No key is a prefix of another, because of our choice of r.) Also include in each node a SIZE field, containing the number of tagged link fields in the subtree below that node. To do the specified operation, use Algorithm P; if the search is unsuccessful, the answer is 0, but if it is successful and $j \leq n$ the answer is r. Finally if it is successful and $j > n$, the answer is $r \cdot$ SIZE(P).

SECTION 6.4

1. $-38 \leq$ rI1 ≤ 46. Therefore the locations preceding and following TABLE must be guaranteed to contain no data that matches any given argument, e.g. their first byte could be zero. It would certainly be bad to store K in this range! [In a sense we could say that the method in exercise 6.3–4 uses less space, since the boundaries of that table are never exceeded.]

2. TOW. [Can the reader find ten "common" words of ≤ 5 letters that fill all the remaining gaps between -10 and 30?]

3. The alphabetic codes A + T = I + N and B − E = O − R, so we would have either f(AT) = f(IN) or f(BE) = f(OR). Note that instructions 4 and 5 of Table 1 resolve this dilemma rather well, while keeping rI1 from having too wide a range.

4. The smallest m such that

$$n^{-m} m! \sum_{0 \leq k \leq m} \binom{n}{m-k} \binom{m-k}{k} 2^{-k} < \frac{1}{2}$$

is 88. If you invite 88 people, the chance of a birthday trio is .5111, but if only 87 people come it is lowered to .4995.

5. The hash function is bad since it assumes at most 26 different values, and some of them occur much more often than the others. Even with double hashing (letting $h_2(K) = 1$ plus the second byte of K, say, and $M = 101$) the search will be slowed down more than the time saved by faster hashing. Also $M = 100$ is too small, since FORTRAN programs often have more than 100 distinct variables.

6. Not on MIX, since arithmetic overflow will almost always occur (dividend too large). [It would be nice to be able to compute (wK) mod M, especially if linear probing were being used with $c = 1$, but unfortunately most computers disallow this since the quotient overflows.]

7. If $R(x)$ is a multiple of $P(x)$, then $R(\alpha^j) = 0$ in $GF(2^k)$ for all $j \in S$. Let $R(x) = x^{a_1} + \cdots + x^{a_s}$, where $a_1 > \cdots > a_s \geq 0$ and $s \leq t$, and select $t - s$ further values $a_{s+1}, \ldots, a_t$ such that $a_1, \ldots, a_t$ are distinct nonnegative integers less than n. The Vandermonde matrix

$$\begin{pmatrix} \alpha^{a_1} & \ldots & \alpha^{a_t} \\ \alpha^{2a_1} & \ldots & \alpha^{2a_t} \\ \vdots & & \vdots \\ \alpha^{ta_1} & \ldots & \alpha^{ta_t} \end{pmatrix}$$

is singular, since the sum of its first s columns is zero. But this contradicts the fact that $\alpha^{a_1}, \ldots, \alpha^{a_t}$ are distinct elements of $GF(2^k)$. (See exercise 1.2.3–37.)

[The idea of polynomial hashing originated with M. Hanan, S. Muroga, F. P. Palermo, N. Raver, and G. Schay; see *IBM J. Research & Development* 7 (1963), 121–129; *U.S. Patent* 3311888 (March 28, 1967).]

8. By induction. The strong induction hypotheses can be supplemented by the fact that $\{(-1)^k(rq_k + q_{k-1})\theta\} = (-1)^k\big(r(q_k\theta - p_k) + (q_{k-1}\theta - p_{k-1})\big)$ for $0 \leq r \leq a_k$. The "record low" values of $\{n\theta\}$ occur for $n = q_1, q_2 + q_1, 2q_2 + q_1, \ldots, a_2q_2 + q_1 = 0q_4 + q_3,\ q_4 + q_3, \ldots, a_4q_4 + q_3 = 0q_6 + q_5, \ldots$; the "record high" values occur for $n = q_0,\ q_1 + q_0, \ldots, a_1q_1 + q_0 = 0q_3 + q_2, \ldots$. These are the steps when interval number 0 of a new length is formed.

9. We have $\phi^{-1} = /1, 1, 1, \ldots/$ and $\phi^{-2} = /2, 1, 1, \ldots/$. Let $\theta = /a_1, a_2, \ldots/$, and $\theta_k = /a_{k+1}, a_{k+2}, \ldots/$, and $Q_k = q_k + q_{k-1}\theta_{k-2}$ in the notation of exercise 8. If $a_1 > 2$, the very first break is bad. The three sizes of intervals in exercise 8 are, respectively, $(1 - r\theta_{k-1})/Q_k$, θ_{k-1}/Q_k, and $\big(1 - (r-1)\theta_{k-1}\big)/Q_k$, so the ratio of the first length to the second is $(a_k - r) + \theta_k$. This will be less than $\frac{1}{2}$ when $r = a_k$ and $a_{k+1} \geq 2$; hence $\{a_2, a_3, \ldots\}$ must all equal 1 if there are to be no bad breaks. [For related theorems, cf. R. L. Graham and J. H. van Lint, *Canadian J. Math.* **20** (1968), 1020–1024, and the references cited there.]

11. There would be a problem if $K = 0$. If keys were required to be nonzero as in Program L, this change would be worth while, and we could also represent empty positions by 0.

12. We can store K in KEY[0], replacing lines 14–19 by

```
        STA   TABLE(KEY)          A - S1
        CMPA  TABLE,2(KEY)        A - S1
        JE    3F                  A - S1
2H      ENT1  0,2                 C - 1 - S2
        LD2   TABLE,1(LINK)       C - 1 - S2
        CMPA  TABLE,2(KEY)        C - 1 - S2
        JNE   2B                  C - 1 - S2
3H      J2Z   5F                  A - S1
        ENT1  0,2                   S2
        JMP   SUCCESS               S2
```

The "savings" in time is $C - 1 - 5A + S + 4S1$, which is actually a net *loss* because C is rarely more than 5. (An inner loop shouldn't always be optimized!)

13. Let the table entries be of two distinguishable types, as in Algorithm C, with an additional one-bit TAG[i] field in each entry. This solution uses circular lists, with TAG[i] = 1 in the first word of each list.

A1. [Initialize.] Set $i \leftarrow j \leftarrow h(K) + 1$, $Q \leftarrow q(K)$.

A2. [Is there a list?] If TABLE[i] is empty, set TAG[i] $\leftarrow$ 1 and go to A8. Otherwise if TAG[i] = 0, go to A7.

A3. [Compare.] If Q = KEY[i], the algorithm terminates successfully.

A4. [Advance to next.] If LINK[i] $\neq j$, set $i \leftarrow$ LINK[i] and go back to A3.

A5. [Find empty node.] Decrease R one or more times until finding a value such that TABLE[R] is empty. If $R = 0$, the algorithm terminates with overflow; otherwise set LINK[i] $\leftarrow R$.

A6. [Prepare to insert.] Set $i \leftarrow R$, TAG[R] $\leftarrow$ 0, and go to A8.

A7. [Displace a record.] Repeatedly set $i \leftarrow$ LINK[i] one or more times until LINK[i] = j. Then do step A5. Then set TABLE[R] $\leftarrow$ TABLE[j], $i \leftarrow j$, TAG[j] $\leftarrow$ 1.

A8. [Insert new key.] Mark TABLE[i] as an occupied node, with KEY[i] $\leftarrow Q$, LINK[i] $\leftarrow j$. ∎

(Note that if TABLE[i] is occupied it is possible to determine the corresponding full key K, given only the value of i. We have $q(K)$ = KEY[i], and then if we set $i \leftarrow$ LINK[i] zero or more times until TAG[i] = 1 we will have $h(K) = i - 1$.)

14. To insert a new key K: Set Q $\Leftarrow$ AVAIL, TAG(Q) $\leftarrow$ 1, and store K in this word. [Alternatively, if keys are short, omit this and substitute K for Q in what follows.] Then set R $\Leftarrow$ AVAIL, TAG(R) $\leftarrow$ 1, AUX(R) $\leftarrow$ Q, LINK(R) $\leftarrow \Lambda$. Set P $\leftarrow h(K)$, and then:

If TAG(P) = 0, set TAG(P) $\leftarrow$ 2, AUX(P) $\leftarrow$ R.

If TAG(P) = 1, set S $\Leftarrow$ AVAIL, CONTENTS(S) $\leftarrow$ CONTENTS(P), TAG(P) $\leftarrow$ 2, AUX(P) $\leftarrow$ R, LINK(P) $\leftarrow$ S.

If TAG(P) = 2, set LINK(R) $\leftarrow$ AUX(P), AUX(P) $\leftarrow$ R.

To retrieve a key K: Set P $\leftarrow h(K)$, and then:

If TAG(P) $\neq$ 2, K is not present.

If TAG(P) = 2, set P $\leftarrow$ AUX(P). Then set P $\leftarrow$ LINK(P) zero or more times until either AUX(P) points to a word containing K [or if keys are short, AUX(P) = K] or LINK(P) = Λ.

(Elcock's original scheme, *Comp. J.* **8** (1965), 242–243, actually used TAG = 2 and TAG = 3 to distinguish between lists of length one (when we can save one word of space) and longer lists. This would be a worthwhile improvement, since we presumably have such a large scatter table that almost all lists have length one.)

15. Knowing that there is always an empty node makes the inner search loop faster, since we need not maintain a counter to determine how many times step L2 is performed. The shorter program amply compensates for this one wasted cell. [On the other hand, there is a neat way to avoid the variable N and to allow the table to become completely full, in Algorithm L, without slowing down the method appreci-

ably except when the table actually does overflow: Simply check whether $i < 0$ happens twice! This trick does not apply to Algorithm D.]

16. No; 0 always leads to SUCCESS, whether it has been inserted or not, and SUCCESS occurs with different values of i at different times.

17. The second probe would then always be to position 0.

18. The code in (31) costs about $3(A - S1)$ units, compared to (30), and it saves $4u$ times the difference between (26), (27) and (28), (29). For a successful search, (31) is advantageous only when the table is more than about 94 percent full, and it never saves more than about $\frac{1}{2}u$ of time. For an unsuccessful search, (31) is advantageous when the table is more than about 71 percent full.

20. We want to show that

$$\binom{j}{2} \equiv \binom{k}{2} \text{ (modulo } 2^m\text{)} \qquad \text{and} \qquad 1 \le j \le k \le 2^m$$

implies $j = k$. Observe that $j(j-1) \equiv k(k-1)$(modulo 2^{m+1}) implies $(k-j) \times (k+j-1) \equiv 0$. If $k-j$ is odd, $k+j-1$ must be a multiple of 2^{m+1}, but that's impossible since $2 \le k+j-1 \le 2^{m+1}-2$. Hence $k-j$ is even, so $k+j-1$ is odd, so $k-j$ is a multiple of 2^{m+1}, so $k = j$. [Conversely, if M is not a power of 2, this probe sequence does not work.]

The probe sequence has secondary clustering, and it increases the running time of Program D (as modified in (30)) by about $\frac{1}{2}(C-1) - (A - S1)$ units since $B \approx \binom{C+1}{3}/M$ will now be negligible. This is a small improvement, until the table gets about 60 percent full.

21. If N is decreased, Algorithm D may fail since it may reach a state with no empty spaces and it will loop indefinitely. On the other hand, if N isn't decreased, Algorithm D may signal overflow when there still is room. The latter alternative is the lesser of the two evils, because rehashing can be used to get rid of deleted cells. (Note that in this case Algorithm D should increase N and test for overflow *only* when inserting an item into a previously *empty* position, since N represents the number of nonempty positions.) We could also have two counters.

22. Suppose that positions $j-1, j-2, \ldots, j-k$ are occupied and $j-k-1$ is empty (modulo M). The keys which probe position j and find it occupied before being inserted are precisely those keys in positions $j-1$ through $j-k$ whose hash address does not lie between $j-1$ and $j-k$; these "problematical keys" appear in order of insertion. Algorithm R moves the first such key into position j, and repeats the process on a smaller range of problematical positions until no problematical keys remain.

23. If possible, replace KEY[i] by a later key on the list that starts at LINK[i], by recomputing the hash addresses and searching down the list for each such key. (Recall that the lists are almost always short.) Algorithm C should also be changed to use a doubly-linked list of available space instead of R.

24. $P(P-1)(P-2)P(P-1)P(P-1)/MP(MP-1)\ldots(MP-6) = M^{-7} \times \big(1 - (5 - 21/M)P^{-1} + O(P^{-2})\big)$. In general, the probability of a hash sequence $a_1 \ldots a_N$ is $(\prod_{0 \le j < M} P^{\underline{b_j}})/(MP)^{\underline{N}} = M^{-N} + O(P^{-1})$, where b_j is the number of a_i that equal j.

25. Let the $(N+1)$st key hash to location a; P_k is M^{-N} times the number of hash sequences that leave the k locations $a, a-1, \ldots, a-k+1$ (modulo M) occupied and $a-k$ empty. The number of such sequences with $a+1, \ldots, a+t$ occupied and $a+t+1$ empty is $g(M, N, t+k)$, by circular symmetry of the algorithm.

26. $\dfrac{9!}{2!2!4!1!} f(3,2)f(3,2)f(5,4)f(2,1) = 2^2 3^5 5^4 7 = 4252500.$

27. Following the hint,

$$s(n,x,y) = \sum_{k\ge 0} \binom{n}{k} x(x+k)^k (y-k)^{n-k-1}(y-n) + n\sum_{k\ge 0}\binom{n-1}{k-1}(x+k)^k(y-k)^{n-k-1}(y-n).$$

In the first sum, replace k by $n-k$ and apply Abel's formula; in the second, replace k by $k+1$. Now

$$g(M,N,k) = \binom{N}{k}(k+1)^{k-1}(M-k-1)^{N-k-1}(M-N-1),$$

and

$$M^N \sum (k+1)P_k = \sum_{k\ge 0}\binom{k+2}{2} g(M,N,k)$$

$$= \frac{1}{2}\left(\sum_{k\ge 0}(k+1)g(M,N,k) + \sum_{k\ge 0}(k+1)^2 g(M,N,k)\right).$$

The first sum is $M^N \sum P_k = M^N$, and the second is $s(N,1,M-1) = M^N + N\big(2M^{N-1} + (N-1)(3M^{N-2}+\cdots)\big) = M^N Q_1(M,N)$. [See J. Riordan, *Combinatorial Identities* (New York: Wiley, 1968), 18–23, for further study of sums like $s(n,x,y)$.]

28. Let $t(n,x,y) = \sum_{k\ge 0}\binom{n}{k}(x+k)^{k+2}(y-k)^{n-k-1}(y-n)$; then as in exercise 27 we find $t(n,x,y) = xs(n,x,y) + nt(n-1,x+1,y-1)$, $t(N,1,M-1) = M^N\big(3Q_3(M,N) - 2Q_2(M,N)\big)$. Thus $\sum(k+1)^2 P_k = M^{-N}\sum\big(\frac{1}{3}(k+1)^3 + \frac{1}{2}(k+1)^2 + \frac{1}{6}(k+1)\big)g(M,N,k) = Q_3(M,N) - \frac{2}{3}Q_2(M,N) + \frac{1}{2}Q_1(M,N) + \frac{1}{6}$. Subtracting $(C'_N)^2$ gives the variance, which is approximately $\frac{3}{4}(1-\alpha)^{-4} - \frac{2}{3}(1-\alpha)^{-3} - \frac{1}{12}$. The standard deviation is often larger than the mean; for example, when $\alpha = .9$ the mean is 50.5 and the standard deviation is $\frac{1}{2}\sqrt{27333} \approx 83$.

29. Let $M = m+1$, $N = n$; the safe parking sequences are precisely those in which location 0 is empty when Algorithm L is applied to the hash sequence $(M-a_1)\ldots(M-a_n)$. Hence the answer is $f(m+1,n) = (m+1)^n - n(m+1)^{n-1}$. [This parking problem originated with A. G. Konheim and B. Weiss, *SIAM J. Applied Math.* **14** (1966), 1266–1274, who were the first to publish a correct analysis of Algorithm L.]

30. Obviously if the cars get parked they define such a permutation. Conversely, if $p_1 p_2 \ldots p_n$ exists, let $q_1 q_2 \ldots q_n$ be the inverse permutation ($q_i = j$ iff $p_j = i$), and let b_i be the number of a_j that equal i. Every car will be parked if we can prove that

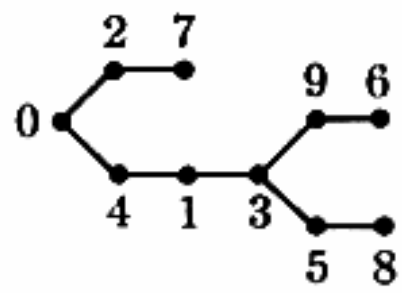
$b_n \le 1$, $b_{n-1} + b_n \le 2$, etc.; equivalently $b_1 \ge 1$, $b_1 + b_2 \ge 2$, etc. But this is clearly true, since the k elements $a_{q_1}, \ldots, a_{q_k}$ are all $\le k$.

[Let r_j be the "left influence" of q_j, namely $r_j = k$ iff $q_{j-1} < q_j, \ldots, q_{j-k+1} < q_j$ and either $j = k$ or $q_{j-k} > q_j$. Of all permutations $p_1 \ldots p_n$ that dominate a given wakeup sequence $a_1 \ldots a_n$, the "park immediately" algorithm finds the smallest one (in lexicographic order). Konheim and Weiss observed that the number of wakeup sequences leading to a given permutation $p_1 \ldots p_n$ is $\prod_{1 \le j \le n} r_j$; it is remarkable that the sum of these products, taken over all permutations $q_1 \ldots q_n$, is $(n+1)^{n-1}$.]

31. Many interesting connections are possible, and the following two are the author's favorites:

a) In the notation of the previous answer, the counts $b_1, b_2, \ldots, b_n$ correspond to a full parking sequence iff $(b_1, b_2, \ldots, b_n, 0)$ is a valid sequence of *degrees* of tree nodes in preorder. (Cf. 2.3.3–9, which illustrates postorder.) Each such tree corresponds to $n!/b_1! \ldots b_n!$ distinct labeled free trees on $\{0, \ldots, n\}$, since we can let 0 be the label of the root, and for $k = 1, 2, \ldots, n$ we can successively choose the labels of the sons of the kth node in preorder in $(b_k + \cdots + b_n)!/b_k!(b_{k+1} + \cdots + b_n)!$ ways from the remaining unused labels, attaching labels from left to right in increasing order. And each such sequence of counts corresponds to $n!/b_1! \ldots b_n!$ wakeup sequences.

b) Dominique Foata has given the following pretty one-to-one correspondence: Let $a_1 \ldots a_n$ be a safe parking sequence, which leaves car q_j parked in space j. A labeled free tree on $\{0, 1, \ldots, n\}$ is constructed by drawing a line from j to 0 when $a_j = 1$, and from j to $q_{a_j - 1}$ otherwise, for $1 \le j \le n$. (Think of the tree nodes as cars; car j is connected to the car that eventually winds up parked just before where wife j woke up.) Thus the example shown in exercise 29 corresponds to the free tree



The sequence of parked cars may be obtained from the tree by topological sorting, assuming that arrows emanate from the root 0, choosing the smallest "source" at each step. From this sequence, $a_1 \ldots a_n$ can be reconstructed.

Actually the two constructions in (a) and (b) are strongly related. For further information, see Dominique Foata and John Riordan, "Mappings of acyclic and parking functions" (to appear).

32. Let subscripts be treated cyclically, so that $c_M = c_0$, $c_{M+1} = c_1$, etc. There is no solution with $c_j = b_j + c_{j+1} - 1$ for all j, since the sum over all j would give $\sum c_j = \sum b_j + \sum c_j - M < \sum c_j$. Hence every solution has $M - \sum b_j$ values of j such that $b_j = c_{j+1} = 0$. If $(c'_0, \ldots, c'_{M-1})$ is a different solution we must have $c'_{j+1} > 0$ for all such j; but this implies $c'_{j+2} > c_{j+2}$, $c'_{j+3} > c_{j+3}, \ldots$, a contradiction. The solution can be found by defining $c_{M-1}, c_{M-2}, \ldots$ on the assumption that $c_0 = 0$; then if c_0 turns out to be greater than 0, it suffices to redefine $c_{M-1}, c_{M-2}, \ldots$ until no more changes are made. [A slightly more efficient algorithm, for computing $\sum c_j$ from the b's, has been given by T. C. Lowe and D. C. Roberts (to appear).]

33. The individual probabilities are not independent, since the condition $b_0 + b_1 + \cdots + b_{M-1} = N$ was not taken into account; the derivation allows a nonzero probability that $\sum b_j$ has any given nonnegative value. Equations (46) are not strictly correct; they imply, for example, that q_k is positive for all k, contradicting the fact that c_j can never exceed $N - 1$.

34. (a) There are $\binom{N}{k}$ ways to choose the set of j such that a_j has a particular value, and $(M-1)^{N-k}$ ways to assign values to the other a's. Therefore

$$P_{Nk} = \binom{N}{k} (M-1)^{N-k}/M^N.$$

(b) $P_N(z) = B(z)$ in (50). (c) $C'_N = \sum(k + \delta_{k0})P_{Nk} = P'_N(1) + P_N(0)$. For C_N, consider the total number of probes to find all keys. A list of length k contributes $\binom{k+1}{2}$ to the total; hence

$$C_N = M \sum \binom{k+1}{2} P_{Nk}/N = (M/N)\left(\tfrac{1}{2}P''_N(1) + P'_N(1)\right).$$

Thus we obtain (18), (19).

35. $\sum(1 + \frac{1}{2}k - (k+1)^{-1} + \delta_{k0})P_{Nk} = 1 + N/2M - M(1 - (1-1/M)^{N+1})/(N+1) + (1-1/M)^N \approx 1 + \frac{1}{2}\alpha - (1 - e^{-\alpha})/\alpha + e^{-\alpha}$.

36. $\sum(\delta_{k0} + k)^2 P_{Nk} = \sum(\delta_{k0} + k^2)P_{Nk} = P(0) + P''(1) + P'(1)$. Subtracting C'^2_N gives the answer, $(M-1)N/M^2 + (1-1/M)^N(1 - 2N/M - (1-1/M)^N) \approx \alpha + e^{-\alpha}(1 - 2\alpha - e^{-\alpha}) \leq 1 - e^{-1} - e^{-2} = 0.4968$.

37. Let S_N be the average value of $(C_N - 1)^2$; then

$$\begin{aligned}
M^N N^2 S_N &= \sum \binom{N}{k_1, \ldots, k_M} \left(\binom{k_1}{2} + \cdots + \binom{k_M}{2} \right)^2 \\
&= M(M-1) \sum \binom{N}{k_1, \ldots, k_M} \binom{k_1}{2}\binom{k_2}{2} + M \sum \binom{N}{k_1, \ldots, k_M} \binom{k_1}{2}^2 \\
&= M(M-1) \sum \binom{N}{k}\binom{N-k}{j}\binom{k}{2}\binom{j}{2} (M-2)^{N-k-j} \\
&\quad + M \sum \binom{N}{k}\binom{k}{2}^2 (M-1)^{N-k} \\
&= M(M-1)(\tfrac{1}{4}M^{N-4}N^{\underline{4}}) + M(M^{N-4})(\tfrac{1}{4}N^{\underline{4}} + N^{\underline{3}} + \tfrac{1}{2}N^{\underline{2}}).
\end{aligned}$$

The variance is $S_N - ((N-1)/2M)^2 = (M-1)(N-1)/2NM^2$. (Hence the standard deviation is $O(M^{-1/2})$ as $M \to \infty$.)

38. The average number of probes is $\sum P_{Nk}(2H_{k+1} - 2 + \delta_{k0})$ in the unsuccessful case, $(M/N)\sum P_{Nk}k(2(1+1/k)H_k - 3)$ in the successful case, by Eqs. 6.2.2–5,6. These sums are respectively equal to $2f(N) + 2M(1 - (1-1/M)^{N+1})/(N+1) + (1-1/M)^N - 2$ and $2(M/N)f(N) + 2f(N-1) + 2M(1 - (1-1/M)^N)/N - 3$, where $f(N) = \sum P_{Nk}H_k$. Exercise 5.2.2–57 tells us that $f(N) = \ln\alpha + \gamma + E_1(\alpha) + O(M^{-1})$ when $N = \alpha M$, $M \to \infty$.

[Tree hashing was first proposed by P. F. Windley, *Comp. J.* **3** (1960), 84–88. The above analysis shows that tree hashing is not enough better than simple chaining

to justify the extra link fields (the lists are short anyway); and when M is small it is not enough better than pure tree search to justify the hashing time.]

39. $c(k_1, k_2, \ldots) = (M - N + 1)c(k_1 - 1, k_2, \ldots) + (k_1 + 1)c(k_1 + 1, k_2 - 1, k_3, \ldots) + 2(k_2 + 1)c(k_1, k_2 + 1, k_3 - 1, \ldots) + \cdots$. [This is similar to the recurrence in exercise 1.2.5–21, but it does not seem to have a simple solution.] Hence

$$\begin{aligned} S_{N+1} &= (M - N) \sum_{j\ge 1, k_1+2k_2+\cdots=N+1} \binom{j}{2} k_j\, c(k_1 - 1, k_2, \ldots) \\ &\quad + \sum_{j\ge 1, k_1+2k_2+\cdots=N+1} \binom{j}{2} k_j(k_1 + 1)c(k_1 + 1, k_2 - 1, \ldots) + \cdots \\ &= (M - N)S_N + \sum_{j\ge 1, k_1+2k_2+\cdots=N} c(k_1, k_2, \ldots) \times \\ &\qquad \left(\left(\binom{j}{2} k_j - \binom{1}{2} + \binom{2}{2}\right) k_1 + \left(\binom{j}{2} k_j - \binom{2}{2} + \binom{3}{2}\right) 2k_2 + \cdots\right) \\ &= MS_N + \sum_{j\ge 1, k_1+2k_2+\cdots=N} j^2 k_j\, c(k_1, k_2, \ldots) = MS_N + 2S_N + NM^N. \end{aligned}$$

Consequently $S_N = (N - 1)M^{N-1} + (N - 2)M^{N-2}(M + 2) + \cdots + M(M + 2)^{N-2} = \frac{1}{4}(M(M + 2)^N - M^{N+1} - 2NM^N)$.

Consider the total number of probes in unsuccessful searches, summed over all M values of $h(K)$; each list of length k contributes $k + \delta_{k0} + \binom{k}{2}$ to the total, hence $M^{N+1}C'_N = M^{N+1} + S_N$.

40. Define U_N to be like S_N in exercise 39, but with $\binom{j}{2}$ replaced by $\binom{j+1}{3}$. We find $U_{N+1} = (M + 3)U_N + S_N + NM^N$, hence $U_N = \frac{1}{36}(M^N(M - 6N) - 9M(M + 2)^N + 8M(M + 3)^N)$. The variance is $2U_N/M^{N+1} + C'_N - C'^2_N$, which approaches $\frac{35}{144} - \frac{1}{12}\alpha - \frac{1}{4}\alpha^2 + (\frac{1}{4}\alpha - \frac{5}{8})e^{2\alpha} + \frac{4}{9}e^{3\alpha} - \frac{1}{16}e^{4\alpha}$ for $N = \alpha M$, $M \to \infty$. When $\alpha = 1$ this is about 4.50, so the standard deviation is bounded by about 2.12.

41. Let V_N be the average length of the block of occupied cells at the "high" end of the table. The probability that this block has length k is $A_{Nk}(M - 1 - k)^{\underline{N-k}}/M^N$, where A_{Nk} is the number of hash sequences (35) such that Algorithm C leaves the first $N - k$ and the last k cells occupied and such that the subsequence $1, 2, \ldots, N - k$ appears in increasing order. Therefore

$$\begin{aligned} M^N V_N &= \sum kA_{Nk}(M - 1 - k)^{\underline{N-k}} = M^{N+1} - \sum (M - k)A_{Nk}(M - 1 - k)^{\underline{N-k}} \\ &= M^{N+1} - (M - N)\sum A_{Nk}(M - k)^{\underline{N-k}} = M^{N+1} - (M - N)(M + 1)^N. \end{aligned}$$

Now $T_N = (N/M)(1 + V_N - T_0 - \cdots - T_{N-1})$, since $T_0 + \cdots + T_{N-1}$ is the average number of times R has previously decreased and N/M is the probability that it decreases this time. The solution to this recurrence is $T_N = (N/M)(1 + 1/M)^N$. (Such a simple formula deserves a simpler proof!)

42. $S1_N$ is the number of items that were inserted with $A = 0$, divided by N.

44. Number the positions of the array from 1 to m, left to right. Considering the set of all $\binom{n}{k}$ sequences of operations with k "p-steps" and $n - k$ "q-steps" to be equally

likely, let $g(m, n+1, k, r)$ be $\binom{n}{k}$ times the probability that the first $r-1$ positions become occupied and the rth remains empty. Thus $g(m, l, k, r)$ is $(m-1)^{-(l-1-k)}$, times the sum over all configurations

$$1 \le a_1 < \cdots < a_k < l; \qquad (c_1, \ldots, c_{l-1-k}), \qquad 2 \le c_i \le m,$$

of the probability that the first empty location is r, when the a_jth operation is a p-step and the remaining $l-1-k$ operations are q-steps that begin by selecting positions $c_1, \ldots, c_{l-1-k}$, respectively. By summing over all configurations subject to the further condition that the a_jth operation occupies position b_j, for specified

$$1 \le b_1 < \cdots < b_k < r,$$

we obtain the recurrence

$$g(m, l, k+1, r) = \sum_{\substack{a<l \\ b<r \\ 1\le b\le a}} \frac{(l-b-1)!}{(l-r)!} \frac{(m-r)!}{(m-b)!} (m-l+1) g(m, a, k, b);$$

$$g(m, l, 0, r) = \frac{(l-1)!}{(l-r)!} \frac{(m-r)!}{m!} (m-l+1) \left(P_l + (1-\delta_{r1}) \frac{m}{l-1} (1-P_l) \right),$$

where $P_l = (m/(m-1))^{l-1}$. It follows that if $G(m, l, k) = \sum_{1\le r\le l} (m+1-r) \times g(m, l, k, r)$, we have

$$G(m, l, k+1) = \frac{m-l+1}{m-l+2} \sum_{1\le a<l} G(m, a, k); \qquad G(m, l, 0) = \frac{m-l+1}{m-l+2} (m+P_l).$$

The answer to the stated problem is $m - \sum_{0\le k\le n} p^k q^{n-k} G(m, n+1, k)$, which (after some maneuvering) equals $m - ((m-n)/(m-n+1))(Q_n + mR + pSR)$, where

$$Q_j = P_{j+1} q^j,$$

$$R = \left(1 - \frac{p}{m+1}\right)\left(1 - \frac{p}{m}\right) \cdots \left(1 - \frac{p}{m-n+2}\right) = \prod_{0\le j<n} \left(1 - \frac{p}{m+1-j}\right),$$

$$S = \frac{\left(1 - \frac{1}{m+1}\right) Q_0}{\left(1 - \frac{p}{m+1}\right)} + \frac{\left(1 - \frac{1}{m}\right) Q_1}{\left(1 - \frac{p}{m+1}\right)\left(1 - \frac{p}{m}\right)} + \cdots + \frac{\left(1 - \frac{1}{m-n+2}\right) Q_{n-1}}{R}$$

$$= \sum_{0\le j<n} \frac{(1 - 1/(m+1-j)) Q_j}{\prod_{0\le i\le j} (1 - p/(m+1-i))}.$$

When $p = 1/m$, $Q_j = 1$ for all j. Letting $w = m+1$, $n = \alpha w$, $w \to \infty$, we find $\ln R = -p(H_w - H_{w(1-\alpha)}) + O(p^2)$; hence $R = 1 + w^{-1} \ln(1-\alpha) + O(w^{-2})$; and similarly $S = \alpha w + O(1)$. Thus the answer is $(1-\alpha)^{-1} - 1 - \alpha - \ln(1-\alpha) + O(w^{-1})$.

Notes: The simpler problem "with probability p occupy the leftmost, otherwise occupy any randomly chosen empty position" is solved by taking $P_j = 1$ in the above, and the answer is $m - (m+1)(m-n)R/(m-n+1)$. To get C'_N for random probing with secondary clustering, set $n = N-1$, $m = M$ and add 1 to the above answer.

46. Define the numbers $\left[\!\left[{n \atop k}\right]\!\right]$ for $k \geq 0$ by the rule

$$\sum_k \binom{x+k}{k} \left[\!\left[{n \atop k}\right]\!\right] = (x+n+1)^n$$

for all x and all nonnegative integers n. Setting $x = -1, -2, \ldots, -n-1$ implies that

$$\left[\!\left[{n \atop k}\right]\!\right] = \sum_j \binom{k}{j} (-1)^j (n-j)^n \qquad \text{for} \qquad 0 \leq k \leq n;$$

then setting $x = 0$ implies that we may take $\left[\!\left[{n \atop k}\right]\!\right] = 0$ for all $k > n$, so the two sides of the defining equation are polynomials in x of degree n that agree on $n+1$ points. It follows that the numbers $\left[\!\left[{n \atop k}\right]\!\right]$ have the stated property.

Let $f(N, r)$ be the number of hash sequences $a_1 \ldots a_N$ that leave the first r locations occupied and the next one empty. There are $\binom{M-r-1}{N-r-1}$ possible patterns of occupied cells, and each pattern occurs as many times as there are sequences $a'_1 \ldots a'_N$, $1 \leq a'_i \leq N$, that contain each of the numbers $r+1, r+2, \ldots, N$ at least once. By inclusion-exclusion, there are $\left[\!\left[{N \atop N-r}\right]\!\right]$ such sequences; hence

$$f(N, r) = \binom{M-r-1}{N-r} \left[\!\left[{N \atop N-r}\right]\!\right].$$

Now $C'_N = 1 + M^{-N-1} \sum_{0 \leq r \leq N} f(N, r) \left(\sum_{0 \leq a < r} r + \sum_{r < a < M} ((N-r)/(M-r-1))(r+1) \right) = 1 + M^{-N-1} \sum_{0 \leq r \leq N} f(N, r)\,(N + (N-1)r)$. Let

$$S_n(x) = \sum_k k \binom{x+k}{k} \left[\!\left[{n \atop k}\right]\!\right];$$

we have

$$(x+1)^{-1} S_n(x) + \sum_k \binom{x+k}{k} \left[\!\left[{n \atop k}\right]\!\right] = \sum_k \binom{x+1+k}{k} \left[\!\left[{n \atop k}\right]\!\right];$$

hence $S_n(x) = (x+1)\big((x+n+2)^n - (x+n+1)^n\big)$. It follows that $C'_N = N(1+1/M) - (N-1)(1-N/M)(1+1/M)^N \approx N\big(1-(1-\alpha)e^{\alpha}\big)$; and $C_N = (N-1)\big((1+1/M)/2 + (1+1/M)^N\big) + (3M^2+6M+2)\big((1+1/M)^N - 1\big)/N - (3M+2)(1+1/M)^N$, which is $(e-2.5)M + O(1)$ when $N = M-1$.

For further properties of the numbers $\left[\!\left[{n \atop k}\right]\!\right]$, cf. John Riordan, *Combinatorial Identities* (New York: Wiley, 1968), 228.

47. The analysis of Algorithm L applies, almost word-for-word! Any probe sequence with cyclic symmetry, and which explores only positions adjacent to those previously examined, will have the same behavior.

48. $C'_N = 1 + p + p^2 + \cdots$, where $p = N/M$ is the probability that a random location is filled; hence $C'_N = M/(M-N)$, and $C_N = N^{-1} \sum_{0 \leq k < N} C'_k = N^{-1} M (H_M - H_{M-N})$. These values are approximately equal to those for uniform

probing, but slightly higher because of the chance of multiple probes in the same place. Indeed, for $4 = N < M \leq 16$, linear probing is better!

In practice we wouldn't use infinitely many hash functions, some other scheme like linear probing would ultimately be used as a last resort. This method is inferior to those described in the text, but it is of historical importance because it suggested Morris's method which led to Algorithm D. See *CACM* **6** (1963), 101, where M. D. McIlroy credits the idea to V. A. Vyssotsky; the same technique had been discovered as early as 1956 by A. W. Holt, who used it successfully in the GPX system for the UNIVAC.

49. $C'_N - 1 = \sum_{k>b} (k-b)P_{Nk} \approx \sum_{k>b} (k-b)e^{-\alpha b}(\alpha b)^k/k! = \alpha b t_b(\alpha)$. [*Note:* In general if $P(z)$ is any probability generating function,

$$\sum_{b\geq 0}\left(\sum_{k>b}(k-b)P_k\right)z^b = P'(1)/(1-z) + z(P(z)-1)/(1-z)^2.]$$

$$C_N - 1 = (M/N)\sum_{k>b}\binom{k-b+1}{2}P_{Nk}$$

$$= (M/2N)\sum_{k>b}\big(k(k-1) - 2k(b-1) + b(b-1)\big)P_{Nk}$$

$$\approx \tfrac{1}{2}e^{-b\alpha}(b\alpha)^b b!^{-1}\big(b + b\alpha - 2b + 2 + (b\alpha^2 - 2\alpha(b-1) + b - 1)R(\alpha, b)\big).$$

[The analysis of successful search with chaining was first carried out by W. P. Heising in 1957. The simple expressions in (57), (58) were found by J. A. van der Pool in 1971; he also considered how to minimize a function that represents the combined cost of storage space and number of accesses. Since $\sum_{k>b}(k-b)^2P_{Nk} = (2N/M) \times (C_N - 1) - (C'_N - 1)$, we can determine the variance of C'_N and of the number of overflows per bucket. The variance of the total number of overflows may be approximated by M times the variance in a single bucket, but this is actually too high because the total number of records is constrained to be N. The true variance may be found as in exercise 37. Cf. also the derivation of the chi-square test in Section 3.3.1C.]

50. And next that $Q_0(M, N-1) = (M/N)\big(Q_0(M, N) - 1\big)$.

51. $R(\alpha, n) = \alpha^{-1}\big(n!e^{\alpha n}(\alpha n)^{-n} - Q_0(\alpha n, n)\big)$.

52. Cf. Eq. 1.2.11.3–9 and exercise 3.1–14.

53. By Eq. 1.2.11.3–8, $\alpha(\alpha n)^n R(\alpha, n) = e^{\alpha n}\gamma(n+1, \alpha n)$; hence by the suggested exercise $R(\alpha, n) = (1-\alpha)^{-1} - (1-\alpha)^{-3}n^{-1} + O(n^{-2})$. [This asymptotic formula can be obtained more directly by the method of (43), by noting that the coefficient of α^k in $R(\alpha, n)$ is

$$1 - \binom{k+2}{2}n^{-1} + O(k^4 n^{-2}).$$

In fact, the coefficient of α^k is

$$\sum_{r\geq 0}(-1)^r n^{-r}\left\{{r+k+1 \atop k+1}\right\}$$

by Eq. 1.2.9–28.]

55. If $B(z)C(z) = \sum s_i z^i$, we have $c_0 = s_0 + \cdots + s_b$, $c_1 = s_{b+1}$, $c_2 = s_{b+2}, \ldots$; hence $B(z)C(z) = z^b C(z) + Q(z)$. Now $P(z) = z^b$ has $b - 1$ roots $|q_j| < 1$, determined as the solutions to $e^{\alpha(q_j - 1)} = \omega^{-j} q_j$, $\omega = e^{2\pi i/b}$. To solve $e^{\alpha(q-1)} = \omega^{-1} q$, let $t = \alpha q$ and $z = \alpha\omega e^{-\alpha}$ so that $t = ze^t$. By Lagrange's formula we get

$$\frac{1}{1-q} = 1 + \sum_{r\ge 0} r \sum_{n\ge r} \frac{n^{n-r-1}\omega^n \alpha^{n-r} e^{-n\alpha}}{(n-r)!}$$

$$= 1 + \sum_{r\ge 1} r \sum_{m\ge 0} \frac{\alpha^m}{m!} (-1)^m \sum_{n\ge r} \binom{m}{n-r} (-1)^{n-r} \omega^n n^{m-1}.$$

By Abel's limit theorem, letting $|\omega| \to 1$ from inside the unit circle, this can be rearranged to

$$\frac{1-\alpha\omega}{1-\omega} + \sum_{m\ge 2} \frac{\alpha^m}{m!} (-1)^m \sum_{n\ge 0} \binom{m-2}{n} (-1)^n \omega^{n+1} (n+1)^{m-1}.$$

Now replacing ω by ω^j and summing for $1 \le j < b$ reduces this to

$$\frac{b-1}{2} + \alpha\frac{b-1}{2} + \sum_{m\ge 2} \alpha^m \left(-\frac{1}{2} + \frac{(-1)^m}{m!} b \sum_{n\ge 1} \binom{m-2}{nb-1} (-1)^{nb-1} (nb)^{m-1} \right)$$

and the desired result follows after some more juggling since

$$t_n(\alpha) = (-1)^{n-1}(n!\alpha)^{-1} \sum_{m>n} (-n\alpha)^m / m(m-1)(m-n-1)!.$$

This analysis was first begun by M. Tainiter, *JACM* **10** (1963), 307–315.

58. 0 1 2 3 4 and 0 2 4 1 3, plus additive shifts of 1 1 1 1 1 mod 5, each with probability $\frac{1}{10}$. [For $M = 6$, we need 30 permutations, and a solution exists starting with $\frac{1}{20} \times$ 0 1 2 3 4 5, $\frac{1}{60} \times$ 0 1 3 2 5 4, $\frac{1}{60} \times$ 0 2 4 3 1 5, $\frac{1}{20} \times$ 0 2 3 4 5 1, $\frac{1}{30} \times$ 0 3 4 1 2 5. For $M = 7$, we need 49, and a solution is generated by $\frac{1}{35} \times$ 0 1 2 3 4 5 6, $\frac{2}{105} \times$ 0 1 5 3 2 4 6, $\frac{1}{35} \times$ 0 2 4 3 5 1 6, $\frac{2}{105} \times$ 0 2 6 3 1 4 5, $\frac{1}{35} \times$ 0 3 6 1 4 2 5, $\frac{1}{105} \times$ 0 3 2 6 4 1 5, $\frac{1}{105} \times$ 0 3 1 5 4 2 6.]

59. No permutation can have a probability larger than

$$1 \Big/ \binom{M}{\lfloor M/2 \rfloor},$$

so there must be at least

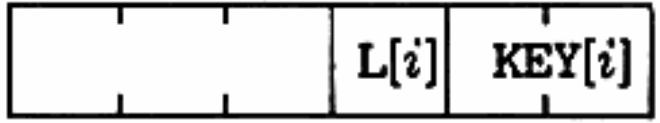
$$\binom{M}{\lfloor M/2 \rfloor} = \exp\left(M \ln 2 + O(\log M)\right)$$

permutations with nonzero probability.

63. MH_M, by exercise 3.3.2–8; the standard deviation is $\pi M/\sqrt{6}$. [This is the "mean time to failure" of the deletion method that simply marks cells "deleted."]

65. The keys can be stored in a separate table, allocated sequentially (assuming that deletions, if any, are LIFO). The scatter table entries point to this "names table",

e.g., TABLE[i] might have the form



,

where L[i] is the number of words in the key stored at locations KEY[i], KEY[i] + 1, ...

The rest of the scatter table entry might be used in any of several ways: (a) as a link for Algorithm C; (b) as part of the information associated with the key; or (c) as a "secondary hash code." The latter idea, suggested by Robert Morris, sometimes speeds up a search [we take a careful look at the key in KEY[i] only if $h_2(K)$ matches its secondary hash code, for some function $h_2(K)$].

SECTION 6.5

1. The path described in the hint can be converted by changing each downward step that runs from $(i-1, j)$ to a "new record low" value $(i, j-1)$ into an upward step. If c such changes are made, the path ends at $(n, n-2t+2c)$, where $c \geq 0$ and $c \geq 2t-n$; hence $n-2t+2c \geq n-2k$. In the permutation corresponding to the changed path, the smallest c elements of list B correspond to the downward steps that changed, and list A contains the $t-c$ elements corresponding to downward steps that didn't change.

When $t = k$ it is not difficult to see that the construction is reversible; hence exactly $\binom{n}{k}$ permutations are constructed. Note that, according to this proof, the contents of lists A and C may appear in arbitrary order.

Notes: We have counted these paths in another way in exercise 2.2.1–4. When $k = \lfloor n/2 \rfloor$ this construction proves *Sperner's Lemma*, which states that it is impossible to have more than $\binom{n}{\lfloor n/2 \rfloor}$ subsets of $\{1, 2, \ldots, n\}$ with no subset contained in another. [Emanuel Sperner, *Math. Zeitschrift* **27** (1928), 544–548.] For if we had such a collection of subsets, each of the $\binom{n}{k}$ permutations can have at most one of the subsets appearing in the initial positions, yet each subset appears in some permutation. The construction used here is a disguised form of a more general construction by which N. G. de Bruijn et al. [*Nieuw Archief voor Wiskunde* (2) **23** (1951), 191–193] proved the multiset generalization of Sperner's Lemma: "Let M be a multiset containing n elements (counting multiplicities). The collection of all $\lfloor n/2 \rfloor$-element submultisets of M is the largest possible collection such that no submultiset is contained in another." For example, the largest such collection when $M = \{a, a, b, b, c, c\}$ consists of the seven submultisets $\{a, a, b\}$, $\{a, a, c\}$, $\{a, b, b\}$, $\{a, b, c\}$, $\{a, c, c\}$, $\{b, b, c\}$, $\{b, c, c\}$. This would correspond to seven permutations of six attributes A_1, B_1, A_2, B_2, A_3, B_3 in which all queries involving A_i also involve B_i.

2. Let a_{ijk} be a list of all references to records having (i, j, k) as the respective values of the three attributes, and assume that a_{011} is the shortest of the three lists a_{011}, a_{101}, a_{110}. Then a minimum-length list is $a_{001}a_{011}a_{111}a_{101}a_{100}a_{110}a_{111}a_{011}a_{010}$. However, if a_{011} is empty and so is either of a_{001}, a_{010}, or a_{100}, the length can be shortened by deleting one of the two occurrences of a_{111}.

3. (a) Anise seed, possibly in combination with nutmeg and/or vanilla extract. (b) None.

4. Let p_t be the probability that the query involves exactly t bit positions, and let P_t be the probability that t given positions are all 1 in a random record. Then the

answer is $\sum_t p_t P_t$. By the principle of inclusion and exclusion,

$$P_t = \sum_{j\geq 0} (-1)^j \binom{t}{j} f(n-j, k, r)/f(n, k, r),$$

where $f(n, k, r)$ is the number of possible choices of r distinct k-bit attribute codes in an n-bit field, namely,

$$f(n, k, r) = \binom{\binom{n}{k}}{r}.$$

And (cf. exercise 1.3.3–26)

$$p_t = \sum_{i\geq 0} (-1)^i \binom{t+i}{t}\binom{n}{t+i} P_{t+i}|_{r=q} = \binom{n}{t} \sum_{j\geq 0} (-1)^j \binom{t}{j} f(t-j, k, q)/f(n, k, q).$$

Notes: The above calculations were first carried out, in more general form, by G. Orosz and L. Takács, *J. of Documentation* **12** (1956), 231–234. The mean $\sum t p_t$ is easily shown to be $n\big((1 - f(n-1, k, q)/f(n, k, q)\big)$. Another assumption, that the random attribute codes in records and queries are not necessarily distinct, as in the techniques of Harrison and Bloom, can be analyzed by the same method, setting $f(n, k, r) = \binom{n}{k}^r$. When the parameters are in appropriate ranges, we have $P_t \approx (1 - e^{-kr/n})^t$ and $\sum p_t P_t \approx P_{n(1-\exp(-kq/n))}$.

6. $L(k) = \sum_j \binom{m_1}{j}\binom{m_2}{k-j} L_1(j) L_2(k-j)/\binom{m_1+m_2}{k}$. [Hence if $L_1(k) \approx N_1\alpha^{-k}$ and $L_2(k) \approx N_2\alpha^{-k}$, then $L(k) \approx N_1 N_2 \alpha^{-k}$.]

7. (a) $L(1) = 3$, $L(2) = 1\frac{3}{4}$. (b) $L(1) = 3\frac{1}{4}$, $L(2) = 2\frac{1}{3}$, $L(3) = 1\frac{9}{16}$. [*Note:* Earl Sacerdoti has suggested the mapping

$$0\ 0\ *\ * \rightarrow 1$$
$$0\ 1\ *\ * \rightarrow 2$$
$$1\ 0\ *\ * \rightarrow 3$$
$$1\ 1\ *\ * \rightarrow 4$$

which has a worse "worst case" but a better average case: $L(1) = 3$, $L(2) = 2\frac{1}{6}$, $L(3) = 1\frac{1}{2}$. A similar mapping exists whenever $m = 2^n$.]

10. (a) There must be $\frac{1}{6}v(v-1)$ triples, and x_v must occur in $\frac{1}{2}v$ of them. (b) Since v is odd, there is a unique triple $\{x_i, y_j, z\}$ for each i, and so S' is readily shown to be a Steiner triple system. The pairs missing in K' are $\{z, x_2\}$, $\{x_2, y_2\}$, $\{y_2, x_3\}$, $\{x_3, y_3\}$, $\ldots$, $\{x_{v-1}, y_{v-1}\}$, $\{y_{v-1}, x_v\}$, $\{x_v, z\}$. (d) Starting with the case $v = 1$ and applying the operations $v \rightarrow 2v-2$, $v \rightarrow 2v+1$ yields all nonnegative numbers not of the form $3k+2$, because the cases $6k + (0, 1, 3, 4)$ come respectively from the smaller cases $3k + (1, 0, 1, 3)$.

11. Take a Steiner triple system on $2v+1$ objects. Call one of the objects z and name the other objects in such a way that the triples containing z are $\{z, x_i, \bar{x}_i\}$; delete these triples.

12. $\{k, (k+1) \bmod 14, (k+4) \bmod 14, (k+6) \bmod 14\}$, for $0 \leq k < 14$, where $(k+7) \bmod 14$ is the complement of k. [Complemented systems are a special case of so-called *group divisible* block designs; cf. Bose, Shrikhande, and Bhattacharya, *Ann. Math. Statistics* **24** (1953), 167–195.]

Tables 1 and 2 contain several hitherto unpublished 40-digit values which have been furnished to the author by Dr. John W. Wrench, Jr.

For high-precision values of constants not found in this list, see J. Peters, *Ten Place Logarithms of the Numbers from 1 to 100000*, Appendix to Volume 1 (New York: F. Ungar Publ. Co., 1957); and *Handbook of Mathematical Functions*, ed. by M. Abramowitz and I. A. Stegun (Washington, D.C.: U. S. Govt. Printing Office, 1964), Chapter 1.

Table 3

Values of harmonic numbers, Bernoulli numbers, and Fibonacci numbers for small values of n.

n	H_n	B_n	F_n	n
0	0	1	0	0
1	1	−1/2	1	1
2	3/2	1/6	1	2
3	11/6	0	2	3
4	25/12	−1/30	3	4
5	137/60	0	5	5
6	49/20	1/42	8	6
7	363/140	0	13	7
8	761/280	−1/30	21	8
9	7129/2520	0	34	9
10	7381/2520	5/66	55	10
11	83711/27720	0	89	11
12	86021/27720	−691/2730	144	12
13	1145993/360360	0	233	13
14	1171733/360360	7/6	377	14
15	1195757/360360	0	610	15
16	2436559/720720	−3617/510	987	16
17	42142223/12252240	0	1597	17
18	14274301/4084080	43867/798	2584	18
19	275295799/77597520	0	4181	19
20	55835135/15519504	−174611/330	6765	20
21	18858053/5173168	0	10946	21
22	19093197/5173168	854513/138	17711	22
23	444316699/118982864	0	28657	23
24	1347822955/356948592	−236364091/2730	46368	24
25	34052522467/8923714800	0	75025	25

For any x, let $H_x = \sum_{n\geq 1}\left(\frac{1}{n} - \frac{1}{n+x}\right)$. Then

$$H_{1/2} = 2 - 2\ln 2,$$
$$H_{1/3} = 3 - \tfrac{1}{2}\pi/\sqrt{3} - \tfrac{3}{2}\ln 3,$$
$$H_{2/3} = \tfrac{3}{2} + \tfrac{1}{2}\pi/\sqrt{3} - \tfrac{3}{2}\ln 3,$$
$$H_{1/4} = 4 - \tfrac{1}{2}\pi - 3\ln 2,$$
$$H_{3/4} = \tfrac{4}{3} + \tfrac{1}{2}\pi - 3\ln 2,$$
$$H_{1/5} = 5 - \tfrac{1}{2}\pi\phi\sqrt{\frac{2+\phi}{5}} - \tfrac{1}{2}(3-\phi)\ln 5 - (\phi - \tfrac{1}{2})\ln(2+\phi),$$
$$H_{2/5} = \tfrac{5}{2} - \tfrac{1}{2}\pi/\phi\sqrt{2+\phi} - \tfrac{1}{2}(2+\phi)\ln 5 + (\phi - \tfrac{1}{2})\ln(2+\phi),$$
$$H_{3/5} = \tfrac{5}{3} + \tfrac{1}{2}\pi/\phi\sqrt{2+\phi} - \tfrac{1}{2}(2+\phi)\ln 5 + (\phi - \tfrac{1}{2})\ln(2+\phi),$$
$$H_{4/5} = \tfrac{5}{4} + \tfrac{1}{2}\pi\phi\sqrt{\frac{2+\phi}{5}} - \tfrac{1}{2}(3-\phi)\ln 5 - (\phi - \tfrac{1}{2})\ln(2+\phi),$$
$$H_{1/6} = 6 - \tfrac{1}{2}\pi\sqrt{3} - 2\ln 2 - \tfrac{3}{2}\ln 3,$$
$$H_{5/6} = \tfrac{6}{5} + \tfrac{1}{2}\pi\sqrt{3} - 2\ln 2 - \tfrac{3}{2}\ln 3,$$

and, in general, when $0 < p < q$ (cf. exercise 1.2.9–19),

$$H_{p/q} = \frac{q}{p} - \tfrac{1}{2}\pi\cot\frac{p}{q}\pi - \ln 2q + 2\sum_{1\leq n<q/2}\cos\frac{2\pi np}{q}\ln\sin\frac{n}{q}\pi.$$

INDEX TO NOTATIONS

In the following formulas, letters which are not further qualified have the following significance:

j, k	integer-valued arithmetic expression
m, n	nonnegative integer-valued arithmetic expression
x, y, z	real-valued arithmetic expression
f	real-valued function
P	pointer-valued expression, i.e., either Λ or an address within a computer.
α	string of symbols

Formal symbolism	Meaning	Section reference
NODE(P)	the node (group of variables which are individually distinguished by their field names) whose address is P, P $\neq \Lambda$	2.1
F(P)	the variable in NODE(P) whose field name is F	2.1
CONTENTS(P)	contents of computer "word" whose address is P	2.1
LOC(V)	address of variable V within a computer	2.1
A_n or $A[n]$	the nth element of linear array A	1.1
A_{mn} or $A[m, n]$	the element in row m, column n of rectangular array A	1.1
$V \leftarrow E$	give variable V the value of expression E	1.1
$U \leftrightarrow V$	interchange the values of variables U and V	1.1
P $\Leftarrow$ AVAIL	set the value of pointer variable P to the address of a new node, or signal memory overflow if there is no room for a new node	2.2.3
AVAIL $\Leftarrow$ P	NODE(P) is returned to free storage; all its fields lose their identity	2.2.3

Formal symbolism	Meaning	Section reference
$\text{top}(S)$	node at the top of a nonempty stack S	2.2.1
$X \Leftarrow S$	pop up S to X: set $X \leftarrow \text{top}(S)$; delete $\text{top}(S)$ from nonempty stack S	2.2.1
$S \Leftarrow X$	push down X onto S: insert the value or group of values denoted by X as a new entry on the top of stack S	2.2.1
$(B \Rightarrow E_1; E_2)$	conditional expression: denotes E_1 if B is true, E_2 if B is false	8.1
δ_{jk}	Kronecker delta: $(j = k \Rightarrow 1;\ 0)$	1.2.6
$\sum_{R(k)} f(k)$	sum of all $f(k)$ such that k is an integer and relation $R(k)$ is true	1.2.3
$\prod_{R(k)} f(k)$	product of all $f(k)$ such that k is an integer and relation $R(k)$ is true	1.2.3
$\min_{R(k)} f(k)$	minimum value of all $f(k)$ such that k is an integer and relation $R(k)$ is true	1.2.3
$\max_{R(k)} f(k)$	maximum value of all $f(k)$ such that k is an integer and relation $R(k)$ is true	1.2.3
$j \backslash k$	j divides k: $k \bmod j = 0$	1.2.4
$U \backslash V$	set difference: $\{x \mid x \text{ is in } U \text{ but not in } V\}$	
$\gcd(j, k)$	greatest common divisor of j and k: $(j = k = 0 \Rightarrow 0;\quad \max_{d \backslash j, d \backslash k} d)$	1.1
$\det(A)$	determinant of square matrix A	1.2.3
A^T	transpose of rectangular array A: $A^T[j, k] = A[k, j]$	1.2.3
x^y	x to the y power, x positive	1.2.2
α^R	left-right reversal of α	
x^k	x to the kth power: $\left(k \geq 0 \Rightarrow \prod_{0 \leq j < k} x;\quad 1/x^{-k}\right)$	1.2.2
$x^{\overline{k}}$	x upper k: $\left(k \geq 0 \Rightarrow x(x+1)\cdots(x+k-1) = \prod_{0 \leq j < k} (x+j);\quad 1/(x+k)^{\overline{-k}}\right)$	1.2.6

Formal symbolism	Meaning	Section reference
$x^{\underline{k}}$	x lower k: $\left(k \geq 0 \Rightarrow x(x-1)\cdots(x-k+1) = \prod_{0 \leq j < k} (x-j);\right.$ $\left. 1/(x-k)^{\overline{-k}}\right) = (-1)^k(-x)^{\overline{k}}$	1.2.6
$n!$	n factorial: $1 \cdot 2 \cdot \cdots \cdot n = n^{\underline{n}}$	1.2.5
$\binom{x}{k}$	binomial coefficient: $(k < 0 \Rightarrow 0;\ x^{\underline{k}}/k!)$	1.2.6
$\binom{n}{n_1, n_2, \ldots, n_m}$	multinomial coefficient, $n = n_1 + n_2 + \cdots + n_m$	1.2.6
$\begin{bmatrix} n \\ m \end{bmatrix}$	Stirling number of first kind: $\sum_{0<k_1<k_2<\cdots<k_{n-m}<n} k_1 k_2 \cdots k_{n-m}$	1.2.6
$\left\{ {n \atop m} \right\}$	Stirling number of second kind: $\sum_{0 \leq k_1 \leq k_2 \leq \cdots \leq k_{n-m} \leq m} k_1 k_2 \cdots k_{n-m}$	1.2.6
$\left\langle {n \atop k} \right\rangle$	Eulerian number	5.1.3.
$\{a \mid R(a)\}$	set of all a for which the relation $R(a)$ is true	
$\{a_1, \ldots, a_n\}$	the set or multiset $\{a_k \mid 1 \leq k \leq n\}$	
$\{n_1 \cdot a_1, \ldots, n_m \cdot a_m\}$	the multiset containing n_k occurrences of a_k	5.1.2
$\|M\|$	cardinality: the number of elements in the multiset M	
$\|x\|$	absolute value of x: $(x < 0 \Rightarrow -x;\ x)$	
$\|\alpha\|$	length of α	
$\lfloor x \rfloor$	floor of x, greatest integer function: $\max_{k \leq x} k$	1.2.4
$\lceil x \rceil$	ceiling of x, least integer function: $\min_{k \geq x} k$	1.2.4
$x \bmod y$	mod function: $(y = 0 \Rightarrow x;\ x - y\lfloor x/y \rfloor)$	1.2.4
$x \equiv y \pmod z$	relation of congruence: $x \bmod z = y \bmod z$	1.2.4

Formal symbolism	Meaning	Section reference
$\log_b x$	logarithm, base b, of x (real positive $b \neq 1$): $x = b^{\log_b x}$	1.2.2
$\ln x$	natural logarithm: $\log_e x$	1.2.2
$\exp x$	exponential of x: e^x	1.2.2
$\langle X_n \rangle$	the infinite sequence $X_0, X_1, X_2, \ldots$ (here n is a letter which is part of the symbol)	1.2.9
$f'(x)$	derivative of f at x	1.2.9
$f''(x)$	second derivative of f at x	1.2.10
$f^{(n)}(x)$	nth derivative: $(n = 0 \Rightarrow f(x);$ $g'(x) \quad$ where $\quad g(x) = f^{(n-1)}(x))$	1.2.11.2
$f(x) \Big\vert_y^z$	$f(z) - f(y)$	
$H_n^{(x)}$	$1 + 1/2^x + \cdots + 1/n^x = \sum_{1 \leq k \leq n} 1/k^x$	1.2.7
H_n	harmonic number: $H_n^{(1)}$	1.2.7
F_n	Fibonacci number: $(n \leq 1 \Rightarrow n; F_{n-1} + F_{n-2})$	1.2.8
B_n	Bernoulli number	1.2.11.2
$\Re(w)$	real part of the complex number w	
$\Im(w)$	imaginary part of the complex number w	
$\zeta(x)$	zeta function: $H_\infty^{(x)}$ when $x > 1$	1.2.7
$\Gamma(x)$	gamma function: $\gamma(x, \infty)$; $(x - 1)!$ when x is a positive integer	1.2.5
$\gamma(x, y)$	incomplete gamma function	1.2.11.3
γ	Euler's constant	1.2.7
e	base of natural logarithms: $\sum_{k \geq 0} 1/k!$	1.2.2
ϵ	empty string (of length zero)	
∞	infinity: larger than any number; or an artificially high key value	5
$M \uplus N$	sum of multisets M and N; e.g., $\{a, a, b\} \uplus \{a, b, c\} = \{a, a, a, b, b, c\}$	4.6.3
Λ	null link (pointer to no address)	2.1
$\emptyset$	empty set (set with no elements)	
ϕ	golden ratio, $\frac{1}{2}(1 + \sqrt{5})$	1.2.8

Formal symbolism	Meaning	Section reference
$\varphi(n)$	Euler's totient function: $\sum_{\substack{0\le k<n \\ \gcd(k,n)=1}} 1$	1.2.4
$O(f(n))$	big-oh of $f(n)$ as $n \to \infty$: a quantity whose magnitude is less than some constant times $f(n)$, for all large n	1.2.11.1
$O(f(x))$	big-oh of $f(x)$, for small x (or for x in some specified range)	1.2.11.1
(min x_1, ave x_2, max x_3, dev x_4)	a random variable having minimum value x_1, average ("expected") value x_2, maximum value x_3, standard deviation x_4	1.2.10
mean(g)	mean value of probability distribution represented by generating function g: $g'(1)$	1.2.10
var(g)	variance of probability distribution represented by generating function g: $g''(1) + g'(1) - g'(1)^2$	1.2.10
P$	address of symmetric order successor of NODE(P) in a binary tree	2.3.1
∎	end of algorithm, program, or proof	1.1

0H, 1H, 2H, . . . , 9H	"here" local symbol in MIXAL	1.3.2

INDEX AND GLOSSARY

If you don't find it in the Index,
look very carefully through the entire catalogue.

—*Consumer's Guide*, Sears, Roebuck and Co. (1897)

When an index entry refers to a page containing a relevant exercise, see also the *answer* to that exercise for further information; an answer page is not indexed here unless it refers to a topic not included in the statement of the exercise.

Any inaccuracies in this index may be explained by the fact that it has been sorted with the help of a computer. For additional definitions of computer terminology, see Volume 1 and the *IFIP-ICC Vocabulary of Information Processing* (Amsterdam: North-Holland Publ. Co., 1966).

THE ART OF COMPUTER PROGRAMMING

PRE-FASCICLE 2A

A DRAFT OF SECTION 7.2.1.1: GENERATING ALL n-TUPLES

DONALD E. KNUTH *Stanford University*

ADDISON–WESLEY

Internet page `http://www-cs-faculty.stanford.edu/~knuth/taocp.html` contains current information about this book and related books.

See also `http://www-cs-faculty.stanford.edu/~knuth/sgb.html` for information about *The Stanford GraphBase*, including downloadable software for dealing with the graphs used in many of the examples in Chapter 7.

Zeroth printing (revision 6), 30 March 2002

PREFACE

I am grateful to all my friends,
and record here and now my most especial appreciation
to those friends who, after a decent interval,
stopped asking me, "How's the book coming?"

— PETER J. GOMES (1996)

THIS BOOKLET contains draft material that I'm circulating to experts in the field, in hopes that they can help remove its most egregious errors before too many other people see it. I am also, however, posting it on the Internet for courageous and/or random readers who don't mind the risk of reading a few pages that have not yet reached a very mature state. *Beware:* This material has not yet been proofread as thoroughly as the manuscripts of Volumes 1, 2, and 3 were at the time of their first printings. Those volumes, alas, were subsequently found to contain thousands of mistakes.

Given this caveat, I hope that my errors this time will not be so numerous and/or obtrusive that you will be discouraged from reading the material carefully. I did try to make it both interesting and authoritative, as far as it goes. But the field is so vast, I cannot hope to have surrounded it enough to corral it completely. Therefore I beg you to let me know about any deficiencies you discover.

To put the material in context, this is Section 7.2.1.1 of a long, long chapter on combinatorial algorithms. Chapter 7 will eventually fill three volumes (namely Volumes 4A, 4B, and 4C), assuming that I'm able to remain healthy. It will begin with a short review of graph theory, with emphasis on some highlights of significant graphs in The Stanford GraphBase (from which I will be drawing many examples). Then comes Section 7.1, which deals with the topic of bitwise manipulations. (I drafted about 60 pages about that subject in 1977, but those pages need extensive revision; meanwhile I've decided to work for awhile on the material that follows it, so that I can get a better feel for how much to cut.) Section 7.2 is about generating all possibilities, and it begins with Section 7.2.1: Generating Basic Combinatorial Patterns. That sets the stage for the main contents of this booklet, Section 7.2.1.1, where I get the ball rolling at last by dealing with the generation of n-tuples. Then will come Section 7.2.1.2 (about permutations), Section 7.2.1.3 (about combinations), etc. Section 7.2.2 will deal with backtracking in general. And so it will go on, if all goes well; an outline of the entire Chapter 7 as currently envisaged appears on the `taocp` webpage that is cited on page ii.

Even the apparently lowly topic of n-tuple generation turns out to be surprisingly rich, with ties to Sections 1.2.4, 1.3.3, 2.3.1, 2.3.4.2, 3.2.2, 3.5, 4.1, 4.3.1, 4.5.2, 4.5.3, 4.6.1, 4.6.2, 4.6.4, 5.2.1, and 6.3 of the first three volumes. I strongly believe in building up a firm foundation, so I have discussed this topic much more thoroughly than I will be able to do with material that is newer or less basic. To my surprise, I came up with 112 exercises, a new record, even though — believe it or not — I had to eliminate quite a bit of the interesting material that appears in my files.

Some of the material is new, to the best of my knowledge, although I will not be at all surprised to learn that my own little "discoveries" have been discovered before. Please look, for example, at the exercises that I've classed as research problems (rated with difficulty level 46 or higher), namely exercises 43, 46, 47, 53, 55, 62, 66, and 83. Are these problems still open? The questions in exercises 53 and 83 might not have been posed previously, but they seem to deserve attention. Please let me know if you know of a solution to any of these intriguing problems. And of course if no solution is known today but you do make progress on any of them in the future, I hope you'll let me know.

I urgently need your help also with respect to some exercises that I made up as I was preparing this material. I certainly don't like to get credit for things that have already been published by others, and most of these results are quite natural "fruits" that were just waiting to be "plucked." Therefore please tell me if you know who I should have credited, with respect to the ideas found in exercises 15, 16, 31, 37, 38, 69, 73, 76, 86, 87, 89, 90, and/or 109.

I shall happily pay a finder's fee of \$2.56 for each error in this draft when it is first reported to me, whether that error be typographical, technical, or historical. The same reward holds for items that I forgot to put in the index. And valuable suggestions for improvements to the text are worth 32¢ each. (Furthermore, if you find a better solution to an exercise, I'll actually reward you with immortal glory instead of mere money, by publishing your name in the eventual book:–)

Happy reading!

Stanford, California D. E. K.
August 2001 (revised, September 2001)

7.2. GENERATING ALL POSSIBILITIES

All present or accounted for, sir.
— Traditional American military saying

All present and correct, sir.
— Traditional British military saying

7.2.1. Generating Basic Combinatorial Patterns

Our goal in this section is to study methods for running through all of the possibilities in some combinatorial universe, because we often face problems in which an exhaustive examination of all cases is necessary or desirable. For example, we might want to look at all permutations of a given set.

Some authors call this the task of *enumerating* all of the possibilities; but that's not quite the right word, because "enumeration" most often means that we merely want to *count* the total number of cases, not that we actually want to look at them all. If somebody asks you to enumerate the permutations of $\{1, 2, 3\}$, you are quite justified in replying that the answer is $3! = 6$; you needn't give the more complete answer $\{123, 132, 213, 231, 312, 321\}$.

Other authors speak of *listing* all the possibilities; but that's not such a great word either. No sensible person would want to make a list of the $10! = 3{,}628{,}800$ permutations of $\{0, 1, 2, 3, 4, 5, 6, 7, 8, 9\}$ by printing them out on thousands of sheets of paper, nor even by writing them all in a computer file. All we really want is to have them present momentarily in some data structure, so that a program can examine each permutation one at a time.

So we will speak of *generating* all of the combinatorial objects that we need, and *visiting* each object in turn. Just as we studied algorithms for tree traversal in Section 2.3.1, where the goal was to visit every node of a tree, we turn now to algorithms that systematically traverse a combinatorial space of possibilities.

He's got 'em on the list—
he's got 'em on the list;
And they'll none of 'em be missed—
they'll none of 'em be missed.
— WILLIAM S. GILBERT, *The Mikado* (1885)

7.2.1.1. Generating all n-tuples. Let's start small, by considering how to run through all 2^n strings that consist of n binary digits. Equivalently, we want to visit all n-tuples $(a_1, \ldots, a_n)$ where each a_j is either 0 or 1. This task is also, in essence, equivalent to examining all subsets of a given set $\{x_1, \ldots, x_n\}$, because we can say that x_j is in the subset if and only if $a_j = 1$.

Of course such a problem has an absurdly simple solution. All we need to do is start with the binary number $(0 \ldots 00)_2 = 0$ and repeatedly add 1 until we reach $(1 \ldots 11)_2 = 2^n - 1$. We will see, however, that even this utterly trivial problem has astonishing points of interest when we look into it more deeply. And our study of n-tuples will pay off later when we turn to the generation of more difficult kinds of patterns.

In the first place, we can see that the binary-notation trick extends to other kinds of n-tuples. If we want, for example, to generate all $(a_1, \ldots, a_n)$ in which each a_j is one of the decimal digits $\{0, 1, 2, 3, 4, 5, 6, 7, 8, 9\}$, we can simply count from $(0 \ldots 00)_{10} = 0$ to $(9 \ldots 99)_{10} = 10^n - 1$ in the decimal number system. And if we want more generally to run through all cases in which

$$0 \le a_j < m_j \qquad \text{for } 1 \le j \le n, \tag{1}$$

where the upper limits m_j might be different in different components of the vector $(a_1, \ldots, a_n)$, the task is essentially the same as repeatedly adding unity to the number

$$\begin{bmatrix} a_1, & a_2, & \ldots, & a_n \\ m_1, & m_2, & \ldots, & m_n \end{bmatrix} \tag{2}$$

in a mixed-radix number system; see Eq. 4.1–(9) and exercise 4.3.1–9.

We might as well pause to describe the process more formally:

Algorithm M (*Mixed-radix generation*). This algorithm visits all n-tuples that satisfy (1), by repeatedly adding 1 to the mixed-radix number in (2) until overflow occurs. Auxiliary variables a_0 and m_0 are introduced for convenience.

M1. [Initialize.] Set $a_j \leftarrow 0$ for $0 \le j \le n$, and set $m_0 \leftarrow 2$.

M2. [Visit.] Visit the n-tuple $(a_1, \ldots, a_n)$. (The program that wants to examine all n-tuples now does its thing.)

M3. [Prepare to add one.] Set $j \leftarrow n$.

M4. [Carry if necessary.] If $a_j = m_j - 1$, set $a_j \leftarrow 0$, $j \leftarrow j - 1$, and repeat this step.

M5. [Increase, unless done.] If $j = 0$, terminate the algorithm. Otherwise set $a_j \leftarrow a_j + 1$ and go back to step M2. ∎

Algorithm M is simple and straightforward, but we shouldn't forget that nested loops are even simpler, when n is a fairly small constant. When $n = 4$, we could for example write out the following instructions:

```
For a1 = 0, 1, ..., m1 − 1 (in this order) do the following:
  For a2 = 0, 1, ..., m2 − 1 (in this order) do the following:
    For a3 = 0, 1, ..., m3 − 1 (in this order) do the following:
      For a4 = 0, 1, ..., m4 − 1 (in this order) do the following:
        Visit (a1, a2, a3, a4).
```
(3)

These instructions are equivalent to Algorithm M, and they are easily expressed in any programming language.

Gray binary code. Algorithm M runs through all $(a_1, \ldots, a_n)$ in lexicographic order, as in a dictionary. But there are many situations in which we prefer to visit those n-tuples in some other order. The most famous alternative arrangement is the so-called Gray binary code, which lists all 2^n strings of n bits in such a way

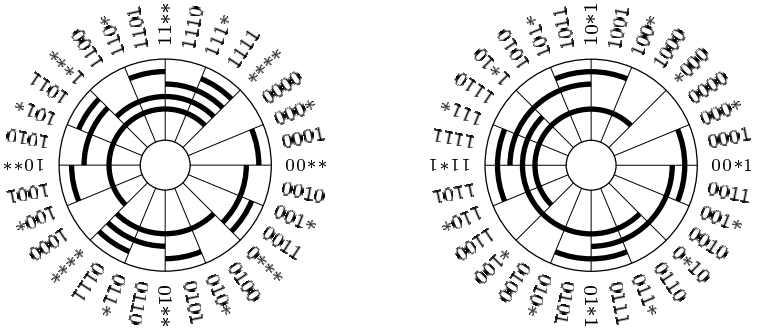

Fig. 10. (a) Lexicographic binary code. (b) Gray binary code.

that only one bit changes each time, in a simple and regular way. For example, the Gray binary code for $n = 4$ is

$$0000, 0001, 0011, 0010, 0110, 0111, 0101, 0100,$$
$$1100, 1101, 1111, 1110, 1010, 1011, 1001, 1000. \tag{4}$$

Such codes are especially important in applications where analog information is being converted to digital or vice versa. For example, suppose we want to identify our current position on a rotating disk that has been divided into 16 sectors, using four sensors that each distinguish black from white. If we use lexicographic order to mark the tracks from 0000 to 1111, as in Fig. 10(a), wildly inaccurate measurements can occur at the boundaries between sectors; but the code in Fig. 10(b) never gives a bad reading.

Gray binary code can be defined in many equivalent ways. For example, if Γ_n stands for the Gray binary sequence of n-bit strings, we can define Γ_n recursively by the two rules

$$\begin{aligned} \Gamma_0 &= \epsilon; \\ \Gamma_{n+1} &= 0\Gamma_n,\ 1\Gamma_n^R. \end{aligned} \tag{5}$$

Here ϵ denotes the empty string, $0\Gamma_n$ denotes the sequence Γ_n with 0 prefixed to each string, and $1\Gamma_n^R$ denotes the sequence Γ_n in *reverse order* with 1 prefixed to each string. Since the last string of Γ_n equals the first string of Γ_n^R, it is clear from (5) that exactly one bit changes in every step of Γ_{n+1} if Γ_n enjoys the same property.

Another way to define the sequence $\Gamma_n = g(0), g(1), \ldots, g(2^n-1)$ is to give an explicit formula for its individual elements $g(k)$. Indeed, since Γ_{n+1} begins with $0\Gamma_n$, the infinite sequence

$$\begin{aligned} \Gamma_\infty &= g(0), g(1), g(2), g(3), g(4), \ldots \\ &= (0)_2, (1)_2, (11)_2, (10)_2, (110)_2, \ldots \end{aligned} \tag{6}$$

is a permutation of all the nonnegative integers, if we regard each string of 0s and 1s as a binary integer with leading 0s suppressed. Then Γ_n consists of the first 2^n elements of (6), converted to n-bit strings by means of leading 0s if needed.

When $k = 2^n + r$, where $0 \le r < 2^n$, relation (5) tells us that $g(k)$ is equal to $2^n + g(2^n - 1 - r)$. Therefore we can prove by induction on n that the integer k whose binary representation is $(\dots b_2 b_1 b_0)_2$ has a Gray binary equivalent $g(k)$ with the representation $(\dots a_2 a_1 a_0)_2$, where

$$a_j = b_j \oplus b_{j+1}, \qquad \text{for } j \ge 0. \tag{7}$$

(See exercise 6.) For example, $g\big((111001000011)_2\big) = (100101100010)_2$. Conversely, if $g(k) = (\dots a_2 a_1 a_0)_2$ is given, we can find $k = (\dots b_2 b_1 b_0)_2$ by inverting the system of equations (7), obtaining

$$b_j = a_j \oplus a_{j+1} \oplus a_{j+2} \oplus \cdots, \qquad \text{for } j \ge 0; \tag{8}$$

this infinite sum is really finite because $a_{j+t} = 0$ for all large t.

One of the many pleasant consequences of Eq. (7) is that $g(k)$ can be computed very easily with bitwise arithmetic:

$$g(k) = k \oplus \lfloor k/2 \rfloor. \tag{9}$$

Similarly, the inverse function in (8) satisfies

$$g^{[-1]}(l) = l \oplus \lfloor l/2 \rfloor \oplus \lfloor l/4 \rfloor \oplus \cdots; \tag{10}$$

this function, however, requires more computation (see exercise 7.1–00). We can also deduce from (7) that, if k and k' are any nonnegative integers,

$$g(k \oplus k') = g(k) \oplus g(k'). \tag{11}$$

Yet another consequence is that the $(n+1)$-bit Gray binary code can be written

$$\Gamma_{n+1} = 0\Gamma_n,\ 1(\Gamma_n \oplus 10\dots0);$$

this pattern is evident, for example, in (4). Comparing with (5), we see that reversing the order of Gray binary code is equivalent to complementing the first bit:

$$\Gamma_n^R = \Gamma_n \oplus 1\overbrace{0\dots0}^{n-1}. \tag{12}$$

The exercises below show that the function $g(k)$ defined in (7), and its inverse $g^{[-1]}$ defined in (8), have many further properties and applications of interest. Sometimes we think of these as functions taking binary strings to binary strings; at other times we regard them as functions from integers to integers, via binary notation, with leading zeros irrelevant.

Gray binary code is named after Frank Gray, a physicist who became famous for helping to devise the method long used for compatible color television broadcasting [*Bell System Tech. J.* **13** (1934), 464–515]. He invented Γ_n for applications to pulse code modulation, a method for analog transmission of digital signals [see *Bell System Tech. J.* **30** (1951), 38–40; *U.S. Patent 2632058* (17 March 1953); W. R. Bennett, *Introduction to Signal Transmission* (1971), 238–240]. But the idea of "Gray binary code" was known long before he worked on it; for example, it appeared in *U.S. Patent 2307868* by George Stibitz (12 January 1943). More significantly, Γ_5 was used in a telegraph machine demonstrated in 1878 by Émile Baudot, after whom the term "baud" was later named. At

about the same time, a similar but less systematic code for telegraphy was independently devised by Otto Schäffler [see *Journal Télégraphique* **4** (1878), 252–253; *Annales Télégraphiques* **6** (1879), 361, 382–383].*

In fact, Gray binary code is implicitly present in a classic toy that has fascinated people for centuries, now generally known as the "Chinese ring puzzle" in English, although Englishmen used to call it the "tiring irons." Fig. 11 shows a seven-ring example. The challenge is to remove the rings from the bar, and the rings are interlocked in such a way that only two basic types of move are possible (although this may not be immediately apparent from the illustration):

a) The rightmost ring can be removed or replaced at any time;
b) Any other ring can be removed or replaced if and only if the ring to its right is on the bar and all rings to the right of that one are off.

We can represent the current state of the puzzle in binary notation, writing 1 if a ring is on the bar and 0 if it is off; thus Fig. 11 shows the rings in state 1011000. (The second ring from the left is encoded as 0, because it lies entirely above the bar.)

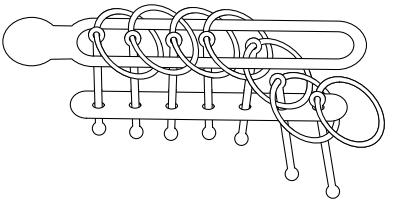

Fig. 11.
The Chinese ring puzzle.

A French magistrate named Louis Gros demonstrated an explicit connection between Chinese rings and binary numbers, in a booklet called *Théorie du Baguenodier* [sic] (Lyon: Aimé Vingtrinier, 1872) that was published anonymously. If the rings are in state $a_{n-1}\ldots a_0$, and if we define the binary number $k = (b_{n-1}\ldots b_0)_2$ by Eq. (8), he showed that exactly k more steps are necessary and sufficient to solve the puzzle. Thus Gros is the true inventor of Gray binary code.

Certainly no home should be without
this fascinating, historic, and instructive puzzle.
— HENRY E. DUDENEY (1901)

When the rings are in any state other than $00\ldots0$ or $10\ldots0$, exactly two moves are possible, one of type (a) and one of type (b). Only one of these moves advances toward the desired goal; the other is a step backward that will need to be undone. A type (a) move changes k to $k \oplus 1$; thus we want to do it when k is odd, since this will decrease k. A type (b) move from a position that ends in $(10^{j-1})_2$ for $1 \le j < n$ changes k to $k \oplus (1^{j+1})_2 = k \oplus (2^{j+1} - 1)$. When k is

* Some authors have asserted that Gray code was invented by Elisha Gray, who developed a printing telegraph machine at the same time as Baudot and Schäffler. Such claims are untrue, although Elisha did get a raw deal with respect to priority for inventing the telephone [see L. W. Taylor, *Amer. Physics Teacher* **5** (1937), 243–251].

even, we want to decrease k by 1, which means that k must be a multiple of 2^j but not a multiple of 2^{j+1}; in other words,

$$j = \rho(k), \tag{13}$$

where ρ is the "ruler function" of Eq. 7.1–(00). Therefore the rings follow a nice pattern when the puzzle is solved properly: If we number them 0, 1, ..., $n-1$ (starting at the free end), the sequence of ring moves on or off the bar is the sequence of numbers that ends with ..., $\rho(4)$, $\rho(3)$, $\rho(2)$, $\rho(1)$.

Going backwards, successively putting rings on or off until we reach the ultimate state $10\ldots0$ (which, as John Wallis observed in 1693, is more difficult to reach than the supposedly harder state $11\ldots1$), yields an algorithm for counting in Gray binary code:

Algorithm G (*Gray binary generation*). This algorithm visits all binary n-tuples $(a_{n-1},\ldots,a_1,a_0)$ by starting with $(0,\ldots,0,0)$ and changing only one bit at a time, also maintaining a parity bit a_∞ such that

$$a_\infty = a_{n-1} \oplus \cdots \oplus a_1 \oplus a_0. \tag{14}$$

It successively complements bits $\rho(1)$, $\rho(2)$, $\rho(3)$, ..., $\rho(2^n-1)$ and then stops.

G1. [Initialize.] Set $a_j \leftarrow 0$ for $0 \le j < n$; also set $a_\infty \leftarrow 0$.

G2. [Visit.] Visit the n-tuple $(a_{n-1},\ldots,a_1,a_0)$.

G3. [Change parity.] Set $a_\infty \leftarrow 1 - a_\infty$.

G4. [Choose j.] If $a_\infty = 1$, set $j \leftarrow 0$. Otherwise let $j \ge 1$ be minimum such that $a_{j-1} = 1$. (After the kth time we have performed this step, $j = \rho(k)$.)

G5. [Complement coordinate j.] Terminate if $j = n$; otherwise set $a_j \leftarrow 1 - a_j$ and return to G2. ∎

The parity bit a_∞ comes in handy if we are computing a sum like

$$X_{000} - X_{100} - X_{010} + X_{110} - X_{001} + X_{101} + X_{011} - X_{111}$$

or

$$X_\emptyset - X_a - X_b + X_{ab} - X_c + X_{ac} + X_{bc} - X_{abc},$$

where the sign depends on the parity of a binary string or the number of elements in a subset. Such sums arise frequently in "inclusion-exclusion" formulas such as Eq. 1.3.3–(29). The parity bit is also necessary, for efficiency: Without it we could not easily choose between the two ways of determining j, which correspond to performing a type (a) or type (b) move in the Chinese ring puzzle. But the most important feature of Algorithm G is that step G5 makes only a single coordinate change, so that only a simple change is usually needed to the terms X that we are summing or to whatever other structures we are concerned with as we visit each n-tuple.

It is impossible, of course, to remove all ambiguity in the lowest-order digit except by a scheme like one the Irish railways are said to have used of removing the last car of every train because it is too susceptible to collision damage.

— G. R. STIBITZ and J. A. LARRIVEE, *Mathematics and Computers* (1957)

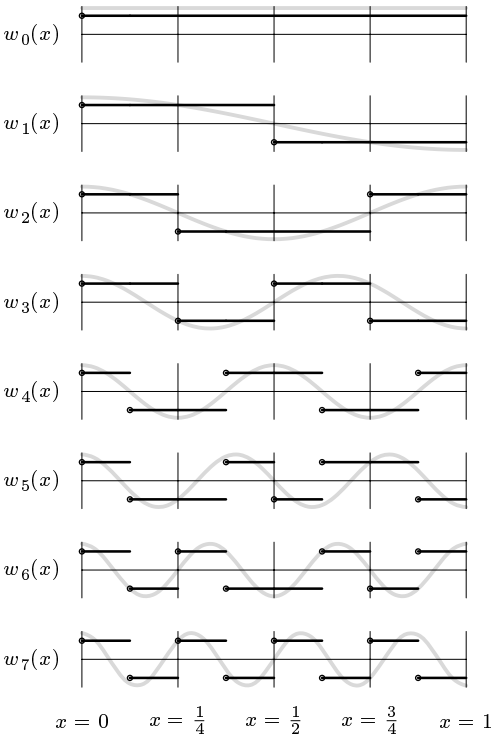

Fig. 12. Walsh functions $w_k(x)$ for $0 \le k < 8$, with the analogous trigonometric functions $\sqrt{2}\cos k\pi x$ shown in gray for comparison.

Another key property of Gray binary code was discovered by J. L. Walsh in connection with an important sequence of functions now known as *Walsh functions* [see *Amer. J. Math.* **45** (1923), 5–24]. Let $w_0(x) = 1$ for all real numbers x, and

$$w_k(x) = (-1)^{\lfloor 2x \rfloor \lceil k/2 \rceil} w_{\lfloor k/2 \rfloor}(2x), \qquad \text{for } k > 0. \tag{15}$$

For example, $w_1(x) = (-1)^{\lfloor 2x \rfloor}$ changes sign whenever x is an integer or an integer plus $\frac{1}{2}$. It follows that $w_k(x) = w_k(x+1)$ for all k, and that $w_k(x) = \pm 1$ for all x. More significantly, $w_k(0) = 1$ and $w_k(x)$ *has exactly* k *sign changes in the interval* $(0\,..\,1)$, so that it approaches $(-1)^k$ as x approaches 1 from the left. Therefore $w_k(x)$ behaves rather like a trigonometric function $\cos k\pi x$ or $\sin k\pi x$, and we can represent other functions as a linear combination of Walsh functions in much the same way as they are traditionally represented as Fourier series. This fact, together with the simple discrete nature of $w_k(x)$, makes Walsh functions extremely useful in computer calculations related to information transmission, image processing, and many other applications.

Fig. 12 shows the first eight Walsh functions together with their trigonometric cousins. Engineers commonly call $w_k(x)$ the Walsh function of *sequency* k, by analogy with the fact that $\cos k\pi x$ and $\sin k\pi x$ have *frequency* $k/2$. [See, for example, the book *Sequency Theory: Foundations and Applications* (New York: Academic Press, 1977), by H. F. Harmuth.]

Although Eq. (15) may look formidable at first glance, it actually provides an easy way to see by induction why $w_k(x)$ has exactly k sign changes as claimed. If k is even, say $k = 2l$, we have $w_{2l}(x) = w_l(2x)$ for $0 \le x < \frac{1}{2}$; the effect is simply to compress the function $w_l(x)$ into half the space, so $w_{2l}(x)$ has accumulated l sign changes so far. Then $w_{2l}(x) = (-1)^l w_l(2x) = (-1)^l w_l(2x-1)$ in the range $\frac{1}{2} \le x < 1$; this concatenates another copy of $w_l(2x)$, flipping the sign if necessary to avoid a sign change at $x = \frac{1}{2}$. The function $w_{2l+1}(x)$ is similar, but it *forces* a sign change when $x = \frac{1}{2}$.

What does this have to do with Gray binary code? Walsh discovered that his functions could all be expressed neatly in terms of simpler functions called *Rademacher functions* [Hans Rademacher, *Math. Annalen* **87** (1922), 112–138],

$$r_k(x) \;=\; (-1)^{\lfloor 2^k x \rfloor}, \tag{16}$$

which take the value $(-1)^{c-k}$ when $(\ldots c_2 c_1 c_0 . c_{-1} c_{-2} \ldots)_2$ is the binary representation of x. Indeed, we have $w_1(x) = r_1(x)$, $w_2(x) = r_1(x) r_2(x)$, $w_3(x) = r_2(x)$, and in general

$$w_k(x) = \prod_{j \ge 0} r_{j+1}(x)^{b_j \oplus b_{j+1}} \qquad \text{when } k = (b_{n-1} \ldots b_1 b_0)_2. \tag{17}$$

(See exercise 33.) Thus the exponent of $r_{j+1}(x)$ in $w_k(x)$ is the jth bit of the Gray binary number $g(k)$, according to (7), and we have

$$w_k(x) \;=\; r_{\rho(k)+1}(x)\, w_{k-1}(x), \qquad \text{for } k > 0. \tag{18}$$

Equation (17) implies the handy formula

$$w_k(x)\, w_{k'}(x) \;=\; w_{k \oplus k'}(x), \tag{19}$$

which is much simpler than the corresponding product formulas for sines and cosines. This identity follows easily because $r_j(x)^2 = 1$ for all j and x, hence $r_j(x)^{a \oplus b} = r_j(x)^{a+b}$. It implies in particular that $w_k(x)$ is *orthogonal* to $w_{k'}(x)$ when $k \ne k'$, in the sense that the average value of $w_k(x) w_{k'}(x)$ is zero. We also can use (17) to define $w_k(x)$ for fractional values of k like $1/2$ or $13/8$.

The *Walsh transform* of 2^n numbers $(X_0, \ldots, X_{2^n-1})$ is the vector defined by the equation $(x_0, \ldots, x_{2^n-1})^T = W_n (X_0, \ldots, X_{2^n-1})^T$, where W_n is the $2^n \times 2^n$ matrix having $w_j(k/2^n)$ in row j and column k, for $0 \le j, k < 2^n$. For example, Fig. 12 tells us that the Walsh transform when $n = 3$ is

$$\begin{pmatrix} x_{000} \\ x_{001} \\ x_{010} \\ x_{011} \\ x_{100} \\ x_{101} \\ x_{110} \\ x_{111} \end{pmatrix} = \begin{pmatrix} 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 \\ 1 & 1 & 1 & 1 & \overline{1} & \overline{1} & \overline{1} & \overline{1} \\ 1 & 1 & \overline{1} & \overline{1} & \overline{1} & \overline{1} & 1 & 1 \\ 1 & 1 & \overline{1} & \overline{1} & 1 & 1 & \overline{1} & \overline{1} \\ 1 & \overline{1} & \overline{1} & 1 & 1 & \overline{1} & \overline{1} & 1 \\ 1 & \overline{1} & \overline{1} & 1 & \overline{1} & 1 & 1 & \overline{1} \\ 1 & \overline{1} & 1 & \overline{1} & \overline{1} & 1 & \overline{1} & 1 \\ 1 & \overline{1} & 1 & \overline{1} & 1 & \overline{1} & 1 & \overline{1} \end{pmatrix} \begin{pmatrix} X_{000} \\ X_{001} \\ X_{010} \\ X_{011} \\ X_{100} \\ X_{101} \\ X_{110} \\ X_{111} \end{pmatrix}. \tag{20}$$

(Here $\overline{1}$ stands for -1, and the subscripts are conveniently regarded as binary strings 000–111 instead of as the integers 0–7.) The *Hadamard transform* is defined similarly, but with the matrix H_n in place of W_n, where H_n has $(-1)^{j\cdot k}$ in row j and column k; here '$j\cdot k$' denotes the dot product $a_{n-1}b_{n-1}+\cdots+a_0b_0$ of the binary representations $j=(a_{n-1}\ldots a_0)_2$ and $k=(b_{n-1}\ldots b_0)_2$. For example, the Hadamard transform for $n=3$ is

$$\begin{pmatrix} x'_{000}\\ x'_{001}\\ x'_{010}\\ x'_{011}\\ x'_{100}\\ x'_{101}\\ x'_{110}\\ x'_{111}\end{pmatrix} = \begin{pmatrix} 1&1&1&1&1&1&1&1\\ 1&\overline{1}&1&\overline{1}&1&\overline{1}&1&\overline{1}\\ 1&1&\overline{1}&\overline{1}&1&1&\overline{1}&\overline{1}\\ 1&\overline{1}&\overline{1}&1&1&\overline{1}&\overline{1}&1\\ 1&1&1&1&\overline{1}&\overline{1}&\overline{1}&\overline{1}\\ 1&\overline{1}&1&\overline{1}&\overline{1}&1&\overline{1}&1\\ 1&1&\overline{1}&\overline{1}&\overline{1}&\overline{1}&1&1\\ 1&\overline{1}&\overline{1}&1&\overline{1}&1&1&\overline{1}\end{pmatrix} \begin{pmatrix} X_{000}\\ X_{001}\\ X_{010}\\ X_{011}\\ X_{100}\\ X_{101}\\ X_{110}\\ X_{111}\end{pmatrix}. \tag{21}$$

This is the same as the discrete Fourier transform on an n-dimensional cube, Eq. 4.6.4–(38), and we can evaluate it quickly "in place" by adapting the method of Yates discussed in Section 4.6.4:

Given	First step	Second step	Third step
X_{000}	$X_{000}+X_{001}$	$X_{000}+X_{001}+X_{010}+X_{011}$	$X_{000}+X_{001}+X_{010}+X_{011}+X_{100}+X_{101}+X_{110}+X_{111}$
X_{001}	$X_{000}-X_{001}$	$X_{000}-X_{001}+X_{010}-X_{011}$	$X_{000}-X_{001}+X_{010}-X_{011}+X_{100}-X_{101}+X_{110}-X_{111}$
X_{010}	$X_{010}+X_{011}$	$X_{000}+X_{001}-X_{010}-X_{011}$	$X_{000}+X_{001}-X_{010}-X_{011}+X_{100}+X_{101}-X_{110}-X_{111}$
X_{011}	$X_{010}-X_{011}$	$X_{000}-X_{001}-X_{010}+X_{011}$	$X_{000}-X_{001}-X_{010}+X_{011}+X_{100}-X_{101}-X_{110}+X_{111}$
X_{100}	$X_{100}+X_{101}$	$X_{100}+X_{101}+X_{110}+X_{111}$	$X_{000}+X_{001}+X_{010}+X_{011}-X_{100}-X_{101}-X_{110}-X_{111}$
X_{101}	$X_{100}-X_{101}$	$X_{100}-X_{101}+X_{110}-X_{111}$	$X_{000}-X_{001}+X_{010}-X_{011}-X_{100}+X_{101}-X_{110}+X_{111}$
X_{110}	$X_{110}+X_{111}$	$X_{100}+X_{101}-X_{110}-X_{111}$	$X_{000}+X_{001}-X_{010}-X_{011}-X_{100}-X_{101}+X_{110}+X_{111}$
X_{111}	$X_{110}-X_{111}$	$X_{100}-X_{101}-X_{110}+X_{111}$	$X_{000}-X_{001}-X_{010}+X_{011}-X_{100}+X_{101}+X_{110}-X_{111}$

Notice that the rows of H_3 are a permutation of the rows of W_3. This is true in general, so we can obtain the Walsh transform by permuting the elements of the Hadamard transform. Exercise 36 discusses the details.

Going faster. When we're running through 2^n possibilities, we usually want to reduce the computation time as much as possible. Algorithm G needs to complement only one bit a_j per visit to $(a_{n-1},\ldots,a_0)$, but it loops in step G4 while choosing an appropriate value of j. Another approach has been suggested by Gideon Ehrlich [*JACM* **20** (1973), 500–513], who introduced the notion of *loopless* combinatorial generation: With a loopless algorithm, the number of operations performed between successive visits is required to be bounded in advance, so there never is a long wait before a new pattern has been generated.

We learned some tricks in Section 7.1 about quick ways to determine the number of leading or trailing 0s in a binary number. Those methods could be used in step G4 to make Algorithm G loopless, assuming that n isn't unreasonably large. But Ehrlich's method is quite different, and much more versatile, so it provides us with a new weapon in our arsenal of techniques for efficient computation. Here is how his approach can be used to generate binary n-tuples.

Algorithm L (*Loopless Gray binary generation*). This algorithm, like Algorithm G, visits all binary n-tuples $(a_{n-1},\ldots,a_0)$ in the order of the Gray binary code. But instead of maintaining a parity bit, it uses an array of "focus pointers" $(f_n,\ldots,f_0)$, whose significance is discussed below.

L1. [Initialize.] Set $a_j \leftarrow 0$ and $f_j \leftarrow j$ for $0 \le j < n$; also set $f_n \leftarrow n$. (A loopless algorithm is allowed to have loops in its initialization step, as long as the initial setup is reasonably efficient; after all, every program needs to be loaded and launched.)

L2. [Visit.] Visit the n-tuple $(a_{n-1},\ldots,a_1,a_0)$.

L3. [Choose j.] Set $j \leftarrow f_0$, $f_0 \leftarrow 0$. (If this is the kth time we are performing the present step, j is now equal to $\rho(k)$.) Terminate if $j = n$; otherwise set $f_j \leftarrow f_{j+1}$ and $f_{j+1} \leftarrow j+1$.

L4. [Complement coordinate j.] Set $a_j \leftarrow 1 - a_j$ and return to L2. ∎

For example, the computation proceeds as follows when $n = 4$. Elements a_j have been underlined in this table if the corresponding bit b_j is 1 in the binary string $b_3b_2b_1b_0$ such that $a_3a_2a_1a_0 = g(b_3b_2b_1b_0)$:

a_3	0	0	0	0	0	0	0	0	1	1	1	1	1	1	1	1
a_2	0	0	0	0	1	1	1	1	1	1	1	1	0	0	0	0
a_1	0	0	1	1	1	1	0	0	0	0	1	1	1	1	0	0
a_0	0	1	1	0	0	1	1	0	0	1	1	0	0	1	1	0
f_3	3	3	3	3	3	3	3	3	4	4	4	4	3	3	3	3
f_2	2	2	2	2	3	3	2	2	2	2	2	2	4	4	2	2
f_1	1	1	2	1	1	1	3	1	1	1	2	1	1	1	4	1
f_0	0	1	0	2	0	1	0	3	0	1	0	2	0	1	0	4

Although the binary number $k = (b_{n-1}\ldots b_0)_2$ never appears explicitly in Algorithm L, the focus pointers f_j represent it implicitly in a clever way, so that we can repeatedly form $g(k) = (a_{n-1}\ldots a_0)_2$ by complementing bit $a_{\rho(k)}$ as we should. Let's say that a_j is *passive* when it is underlined, *active* otherwise. Then the focus pointers satisfy the following invariant relations:

1) If a_j is passive and a_{j-1} is active, then f_j is the smallest index $j' > j$ such that $a_{j'}$ is active. (Bits a_{-1} and a_n are considered to be active for purposes of this rule, although they aren't really present in the algorithm.)
2) Otherwise $f_j = j$.

Thus, the rightmost element a_j of a block of passive elements $a_{i-1}\ldots a_{j+1}a_j$ has a focus f_j that points to the element a_i just to the left of that block. All other elements a_j have f_j pointing to themselves.

In these terms, the first two operations '$j \leftarrow f_0$, $f_0 \leftarrow 0$' in step L3 are equivalent to saying, "Set j to the index of the rightmost active element, and activate all elements to the right of a_j." Notice that if $f_0 = 0$, the operation $f_0 \leftarrow 0$ is redundant; but it doesn't do any harm. The other two operations of L3, '$f_j \leftarrow f_{j+1}$, $f_{j+1} \leftarrow j+1$', are equivalent to saying, "Make a_j passive," because we know that a_j and a_{j-1} are both active at this point in the computation.

(Again the operation $f_{j+1} \leftarrow j+1$ might be harmlessly redundant.) The net effect of activation and passivation is therefore equivalent to counting in binary notation, as in Algorithm M, with 1-bits passive and 0-bits active.

Algorithm L is almost blindingly fast, because it does only five assignment operations and one test for termination between each visit to a generated n-tuple. But we can do even better. In order to see how, let's consider an application to recreational linguistics: Rudolph Castown, in *Word Ways* **1** (1968), 165–169, noted that all 16 of the ways to intermix the letters of `sins` with the corresponding letters of `fate` produce words that are found in a sufficiently large dictionary of English: `sine`, `sits`, `site`, etc.; and all but three of these words (namely `fane`, `fite`, and `sats`) are sufficiently common as to be unquestionably part of standard English. Therefore it is natural to ask the analogous question for five-letter words: What two strings of five letters will produce the maximum number of words in the Stanford GraphBase, when letters in corresponding positions are swapped in all 32 possible ways?

To answer this question, we need not examine all $\binom{26}{2}^5 = 3{,}625{,}908{,}203{,}125$ essentially different pairs of strings; it suffices to look at all $\binom{5757}{2} = 16{,}568{,}646$ pairs of words in the GraphBase, provided that at least one of those pairs produces at least 17 words, because every set of 17 or more five-letter words obtainable from two five-letter strings must contain two that are "antipodal" (with no corresponding letters in common). For every such pair, we want to determine as rapidly as possible whether the 32 possible subset-swaps produce a significant number of English words.

Every 5-letter word can be represented as a 25-bit number using 5 bits per letter, from `"a"` = 00000 to `"z"` = 11001. A table of 2^{25} bits or bytes will then determine quickly whether a given five-letter string is a word. So the problem is reduced to generating the 32 bit patterns of the potential words obtainable by mixing the letters of two given words, and looking those patterns up in the table. We can proceed as follows, for each pair of 25-bit words w and w':

W1. [Check the difference.] Set $z \leftarrow w \oplus w'$. Reject the word pair (w, w') if $\big((z-m)\oplus z\oplus m\big)\wedge m' \neq 0$, where $m = 2^{20}+2^{15}+2^{10}+2^5+1$ and $m' = 2^5 m$; this test eliminates cases where w and w' have a common letter in some position. (See 7.1–(oo); it turns out that 10,614,085 of the 16,568,646 word pairs have no such common letters.)

W2. [Form individual masks.] Set $m_0 \leftarrow z \wedge (2^5-1)$, $m_1 \leftarrow z \wedge (2^{10}-2^5)$, $m_2 \leftarrow z \wedge (2^{15}-2^{10})$, $m_3 \leftarrow z \wedge (2^{20}-2^{15})$, and $m_4 \leftarrow z \wedge (2^{25}-2^{20})$, in preparation for the next step.

W3. [Count words.] Set $l \leftarrow 1$ and $A_0 \leftarrow w$; variable l will count the number of words we have found so far, starting with w. Then perform the operations *swap*(4) defined below.

W4. [Print a record-setting solution.] If l exceeds or equals the current maximum, print A_j for $0 \le j < l$. ∎

The heart of this high-speed method is the sequence of operations *swap*(4), which should be expanded inline (for example with a macro-processor) to eliminate all

unnecessary overhead. It is defined in terms of the basic operation

$sw(j)$: Set $w \leftarrow w \oplus m_j$. Then if w is a word, set $A_l \leftarrow w$ and $l \leftarrow l+1$.

Given $sw(j)$, which flips the letters in position j, we define

$$\begin{aligned} swap(0) &= sw(0); \\ swap(1) &= swap(0), sw(1), swap(0); \\ swap(2) &= swap(1), sw(2), swap(1); \\ swap(3) &= swap(2), sw(3), swap(2); \\ swap(4) &= swap(3), sw(4), swap(3). \end{aligned} \tag{22}$$

Thus $swap(4)$ expands into a sequence of 31 steps $sw(0)$, $sw(1)$, $sw(0)$, $sw(2)$, $\ldots$, $sw(0) = sw(\rho(1))$, $sw(\rho(2))$, $\ldots$, $sw(\rho(31))$; these steps will be used 10 million times. We clearly gain speed by embedding the ruler function values $\rho(k)$ directly into our program, instead of recomputing them repeatedly for each word pair via Algorithm M, G, or L.

The winning pair of words generates a set of 21, namely

```
ducks  ducky  duces  dunes  dunks  dinks  dinky
dines  dices  dicey  dicky  dicks  picks  picky
pines  piney  pinky  pinks  punks  punky  pucks
```
(23)

If, for example, $w =$ `ducks` and $w' =$ `piney`, then $m_0 =$ `s` $\oplus$ `y`, so the first operation $sw(0)$ changes `ducks` to `ducky`, which is seen to be a word. The next operation $sw(1)$ applies m_1, which is `k` $\oplus$ `e` in the next-to-last letter position, so it produces the nonword `ducey`. Another application of $sw(0)$ changes `ducey` to `duces` (a legal term generally followed by the word `tecum`). And so on. All word pairs can be processed by this method in at most a few seconds.

Further streamlining is also possible. For example, once we have found a pair that yields k words, we can reject later pairs as soon as they generate $33-k$ nonwords. But the method we've discussed is already quite fast, and it demonstrates the fact that even the loopless Algorithm L can be beaten.

Fans of Algorithm L may, of course, complain that we have speeded up the process only in the small special case $n = 5$, while Algorithm L solves the generation problem for n in general. A similar idea does, however, work also for general values of $n > 5$: We can expand out a program so that it rapidly generates all 32 settings of the rightmost bits $a_4a_3a_2a_1a_0$, as above; then we can apply Algorithm L after every 32 steps, using it to generate successive changes to the other bits $a_{n-1}\ldots a_5$. This approach reduces the amount of work done by Algorithm L by nearly a factor of 32.

Other binary Gray codes. The Gray binary code $g(0)$, $g(1)$, $\ldots$, $g(2^n-1)$ is only one of many ways to traverse all possible n-bit strings while changing only a single bit at each step. Let us say that, in general, a "Gray code" on binary n-tuples is *any* cycle $(v_0, v_1, \ldots, v_{2^n-1})$ that includes every n-tuple and has the property that v_k differs from $v_{(k+1) \bmod 2^n}$ in just one bit position. Thus, in the

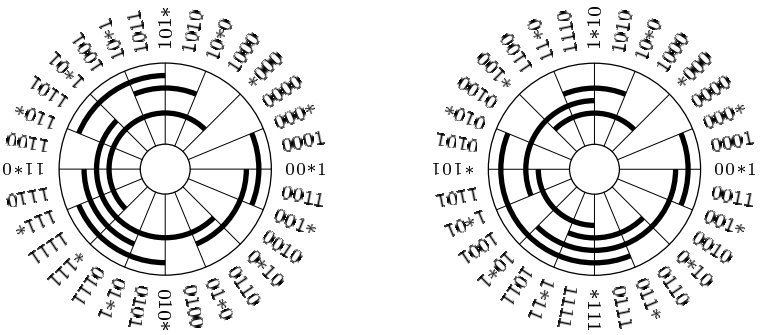

Fig. 13. (a) Complementary Gray code. (b) Balanced Gray code.

terminology of graph theory, a Gray code is an oriented Hamiltonian circuit on the n-cube. We can assume that subscripts have been chosen so that $v_0 = 0 \ldots 0$.

If we think of the v's as binary numbers, there are integers $\delta_0 \ldots \delta_{2^n-1}$ such that

$$v_{(k+1) \bmod 2^n} \;=\; v_k \oplus 2^{\delta_k}, \qquad \text{for } 0 \le k < 2^n; \tag{24}$$

this so-called "delta sequence" is another way to describe a Gray code. For example, the delta sequence for standard Gray binary when $n = 3$ is 01020102; it is essentially the ruler function $\delta_k = \rho(k+1)$ of (13), but the final value δ_{2^n-1} is $n-1$ instead of n, so that the cycle closes. The individual elements δ_k always lie in the range $0 \le \delta_k < n$, and they are called "coordinates."

Let $d(n)$ be the number of different delta sequences that define an n-bit Gray code, and let $c(n)$ be the number of "canonical" delta sequences in which each coordinate k appears before the first appearance of $k+1$. Then $d(n) = n!\, c(n)$, because every permutation of the coordinate numbers in a delta sequence obviously produces another delta sequence. The only possible canonical delta sequences for $n \le 3$ are easily seen to be

$$00; \qquad 0101; \qquad 01020102 \quad \text{and} \quad 01210121. \tag{25}$$

Therefore $c(1) = c(2) = 1$, $c(3) = 2$; $d(1) = 1$, $d(2) = 2$, and $d(3) = 12$. A straightforward computer calculation, using techniques for the enumeration of Hamiltonian circuits that we will study later, establishes the next values,

$$\begin{aligned} c(4) &= 112; & d(4) &= 2688; \\ c(5) &= 15{,}109{,}096; & d(5) &= 1{,}813{,}091{,}520. \end{aligned} \tag{26}$$

No simple pattern is evident, and the numbers grow quite rapidly (see exercise 45); therefore it's a fairly safe bet that nobody will ever know the exact values of $c(8)$ and $d(8)$.

Since the number of possibilities is so huge, people have often attempted to find Gray codes that have additional useful properties. For example, Fig. 13(a) shows a 4-bit Gray code in which every string $a_3a_2a_1a_0$ is diametrically opposite to its complement $\overline{a}_3\overline{a}_2\overline{a}_1\overline{a}_0$. Such codes are possible whenever the number of bits is even (see exercise 49).

An even more interesting Gray code, found by G. C. Tootill [*Proc. IEE* **103**, Part B Supplement (1956), 435], is shown in Fig. 13(b). This one has the same number of changes in each of the four coordinate tracks, hence all coordinates share equally in the activities. Gray codes that are balanced in a similar way can in fact be constructed for all larger values of n, by using the following versatile method to extend a code from n bits to $n+2$ bits:

Theorem D. *Let $\alpha_1 j_1 \alpha_2 j_2 \ldots \alpha_l j_l$ be a delta sequence for an n-bit Gray code, where each j_k is a single coordinate, each α_k is a possibly empty sequence of coordinates, and l is odd. Then*

$$\begin{aligned}&\alpha_1(n{+}1)\alpha_1^R n\alpha_1\\ &\quad j_1\alpha_2 n\alpha_2^R(n{+}1)\alpha_2\ j_2\alpha_3(n{+}1)\alpha_3^R n\alpha_3\ \ldots\ j_{l-1}\alpha_l(n{+}1)\alpha_l^R n\alpha_l\\ &\qquad\qquad (n{+}1)\alpha_l^R j_{l-1}\alpha_{l-1}^R\ldots\alpha_2^R j_1\alpha_1^R n\end{aligned}\tag{27}$$

is the delta sequence of an $(n+2)$-bit Gray code.

For example, if we start with the sequence $01\underline{0}201\underline{02}$ for $n=3$ and let the three underlined elements be j_1, j_2, j_3, the new sequence (27) for a 5-bit code is

$$01410301020131024201043401020103.\tag{28}$$

Proof. Let α_k have length m_k and let v_{kt} be the vertex reached if we start at $0\ldots0$ and apply the coordinate changes $\alpha_1 j_1 \ldots \alpha_{j-1} j_{k-1}$ and the first t of α_k. We need to prove that all vertices $00v_{kt}$, $01v_{kt}$, $10v_{kt}$, and $11v_{kt}$ occur when (27) is used, for $1\le k\le l$ and $0\le t\le m_k$. (The leftmost coordinate is $n{+}1$.)

Starting with $000\ldots0 = 00v_{10}$, we proceed to obtain the vertices

$$00v_{11},\ \ldots,\ 00v_{1m_1},\ 10v_{1m_1},\ \ldots,\ 10v_{10}, 11v_{10},\ \ldots,\ 11v_{1m_1};$$

then j_1 yields $11v_{20}$, which is followed by

$$11v_{21},\ \ldots,\ 11v_{2m_2},\ 10v_{2m_2},\ \ldots,\ 10v_{20}, 00v_{20},\ \ldots,\ 00v_{2m_2};$$

then comes $00v_{30}$, etc., and we eventually reach $11v_{lm_l}$. The glorious finale then uses the third line of (27) to generate all the missing vertices $01v_{lm_l}$, $\ldots$, $01v_{10}$ and take us back to $000\ldots0$. ∎

The *transition counts* $(c_0,\ldots,c_{n-1})$ of a delta sequence are defined by letting c_j be the number of times $\delta_k = j$. For example, (28) has transition counts $(12,8,4,4,4)$, and it arose from a sequence with transition counts $(4,2,2)$. If we choose the original delta sequence carefully and underline appropriate elements j_k, we can obtain transition counts that are as equal as possible:

Corollary B. *For all $n\ge4$, there is an n-bit Gray code with transition counts $(c_0,c_1,\ldots,c_{n-1})$ that satisfy the condition*

$$|c_j - c_k| \le 2 \qquad \text{for } 0\le j<k<n.\tag{29}$$

(This is the best possible balance condition, because each c_j must be an even number, and we must have $c_0+c_1+\cdots+c_{n-1}=2^n$. Indeed, condition (29)

holds if and only if $n-r$ of the counts are equal to $2q$ and r are equal to $2q+2$, where $q=\lfloor 2^{n-1}/n\rfloor$ and $r=2^{n-1} \bmod n$.)

Proof. Given a delta sequence for an n-bit Gray code with transition counts $(c_0,\ldots,c_{n-1})$, the counts for code (27) are obtained by starting with the values $(c'_0,\ldots,c'_{n-1},c'_n,c'_{n+1})=(4c_0,\ldots,4c_{n-1},l{+}1,l{+}1)$, then subtracting 2 from c'_{j_k} for $1\le k<l$ and subtracting 4 from c'_{j_l}. For example, when $n=3$ we can obtain a balanced 5-bit Gray code having transition counts $(8-2,16-10,8,6,6)=(6,6,8,6,6)$ if we apply Theorem D to the delta sequence $\underline{01}2\underline{1}0\underline{12}\underline{1}$. Exercise 51 works out the details for other values of n. ∎

Another important class of n-bit Gray codes in which each of the coordinate tracks has equal responsibility arises when we consider *run lengths*, namely the distances between consecutive appearances of the same δ value. Standard Gray binary code has run length 2 in the least significant position, and this can lead to a loss of accuracy when precise measurements need to be made [see, for example, the discussion by G. M. Lawrence and W. E. McClintock, *Proc. SPIE* **2831** (1996), 104–111]. But all runs have length 4 or more in the remarkable 5-bit Gray code whose delta sequence is

$$(0123042103210423)^2. \tag{30}$$

Let $r(n)$ be the maximum value r such that an n-bit Gray code can be found in which all runs have length $\ge r$. Clearly $r(1)=1$, and $r(2)=r(3)=r(4)=2$; and it is easy to see that $r(n)$ must be less than n when $n>2$, hence (30) proves that $r(5)=4$. Exhaustive computer searches establish the values $r(6)=4$ and $r(7)=5$. Indeed, a fairly straightforward backtrack calculation for the case $n=7$ needs a tree of only about 60 million nodes to determine that $r(7)<6$, and exercise 61(a) constructs a 7-bit code with no run shorter than 5. The exact values of $r(n)$ are unknown for $n\ge 8$; but $r(10)$ is almost certainly 8, and interesting constructions are known by which we can prove that $r(n)=n-O(\log n)$ as $n\to\infty$. (See exercises 60–64.)

***Binary Gray paths.** We have defined an n-bit Gray code as a periodic sequence $v_0, v_1, \ldots$, in which v_k is adjacent to v_{k+1} in the n-cube for all $k\ge 0$, each binary n-tuple occurs in $(v_0,v_1,\ldots,v_{2^n-1})$, and $v_{k+2^n}=v_k$. The periodic property is nice, but not always essential; and sometimes we can do better without it. Therefore we say that an n-bit *Gray path* is any ordering $v_0, v_1, \ldots, v_{2^n-1}$ of the 2^n possible n-tuples in such a way that v_k is adjacent to v_{k+1} for $0\le k<2^n-1$. In other words, a Gray code is a Hamiltonian *circuit* on the vertices of the n-cube, but a Gray path is simply a Hamiltonian *path* on that graph.

The most important binary Gray paths that are not also Gray codes are n-bit paths $v_0, v_1, \ldots, v_{2^n-1}$ that are *monotonic*, in the sense that

$$\nu(v_k)\ \le\ \nu(v_{k+2}) \qquad \text{for } 0\le k<2^n-2. \tag{31}$$

(Here, as elsewhere, we use ν to denote the "weight" or the "sideways sum" of a binary string, namely the number of 1s that it has.) Trial and error shows that

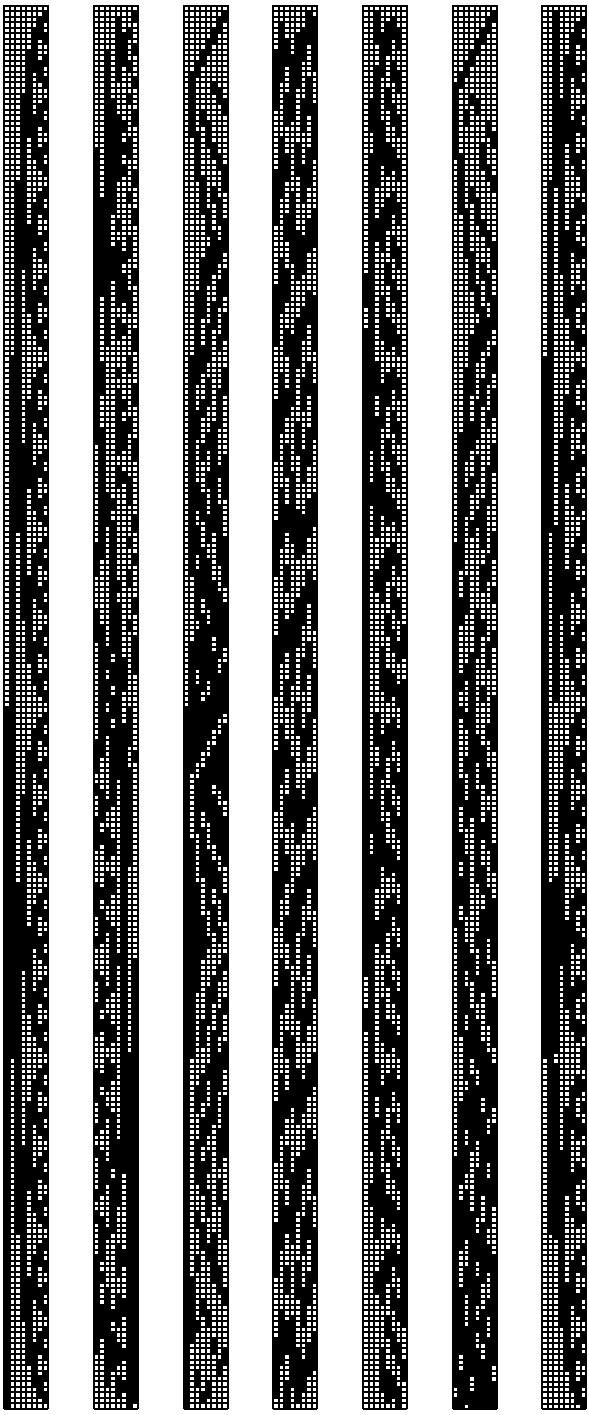

Fig. 14. Examples of 8-bit Gray paths:

a) standard;
b) balanced;
c) complementary;
d) long-run;
e) nonlocal;
f) monotonic;
g) trend-free.

there are essentially only two monotonic n-bit Gray paths for each $n \le 4$, one starting with 0^n and the other starting with $0^{n-1}1$. The two for $n = 3$ are

$$000,\ 001,\ 011,\ 010,\ 110,\ 100,\ 101,\ 111; \tag{32}$$

$$001,\ 000,\ 010,\ 110,\ 100,\ 101,\ 111,\ 011. \tag{33}$$

The two for $n = 4$ are slightly less obvious, but not really difficult to discover.

Since $\nu(v_{k+1}) = \nu(v_k) \pm 1$ whenever v_k is adjacent to v_{k+1}, we obviously can't strengthen (31) to the requirement that all n-tuples be strictly sorted by weight. But relation (31) is strong enough to determine the weight of each v_k, given k and the weight of v_0, because we know that exactly $\binom{n}{j}$ of the n-tuples have weight j.

Fig. 14 summarizes our discussions so far, by illustrating seven of the zillions of Gray codes and Gray paths that make a grand tour through all 256 of the possible 8-bit bytes. Black squares represent ones and white squares represent zeros. Fig. 14(a) is the standard Gray binary code, while Fig. 14(b) is balanced with exactly $256/8 = 32$ transitions in each coordinate position. Fig. 14(c) is a Gray code analogous to Fig. 13(a), in which the bottom 128 codes are complements of the top 128. In Fig. 14(d), the transitions in each coordinate position never occur closer than five steps apart; in other words, all run lengths are at least 5. The code in Fig. 14(e) is *nonlocal* in the sense of exercise 59. Fig. 14(f) shows a monotonic path for $n = 8$; notice how black it gets near the bottom. Finally, Fig. 14(g) illustrates a Gray path that is totally nonmonotonic, in the sense that the center of gravity of the black squares lies exactly at the halfway point in each column. Standard Gray binary code has this property in seven of the coordinate positions, but Fig. 14(g) achieves perfect black-white weight balance in all eight. Such paths are called *trend-free*; they are important in the design of agricultural and other experiments (see exercises 75 and 76).

Carla Savage and Peter Winkler [*J. Combinatorial Theory* **A70** (1995), 230–248] found an elegant way to construct monotonic binary Gray paths for all $n > 0$. Such paths are necessarily built from subpaths P_{nj} in which all transitions are between n-tuples of weights j and $j + 1$. Savage and Winkler defined suitable subpaths recursively by letting $P_{10} = 0, 1$ and, for all $n > 0$,

$$P_{(n+1)j} = 1P^{\pi_n}_{n(j-1)},\ 0P_{nj}; \tag{34}$$

$$P_{nj} = \emptyset \quad \text{if } j < 0 \text{ or } j \ge n. \tag{35}$$

Here π_n is a permutation of the coordinates that we will specify later, and the notation P^π means that every element $a_{n-1} \ldots a_1 a_0$ of the sequence P is replaced by $b_{n-1} \ldots b_1 b_0$, where $b_{j\pi} = a_j$. (We don't define P^π by letting $b_j = a_{j\pi}$, because we want $(2^j)^\pi$ to be $2^{j\pi}$.) It follows, for example, that

$$P_{20} = 0P_{10} = 00,\ 01 \tag{36}$$

because $P_{1(-1)}$ is vacuous; also

$$P_{21} = 1P^{\pi_1}_{10} = 10,\ 11 \tag{37}$$

because P_{11} is vacuous and π_1 must be the identity permutation. In general, P_{nj} is a sequence of n-bit strings containing exactly $\binom{n-1}{j}$ strings of weight j interleaved with $\binom{n-1}{j}$ strings of weight $j+1$.

Let α_{nj} and ω_{nj} be the first and last elements of P_{nj}. Then we easily find

$$\omega_{nj} = 0^{n-j-1}1^{j+1}, \qquad \text{for } 0 \le j < n; \tag{38}$$

$$\alpha_{n0} = 0^n, \qquad \text{for } n > 0; \tag{39}$$

$$\alpha_{nj} = 1\alpha_{(n-1)(j-1)}^{\pi_{n-1}}, \qquad \text{for } 1 \le j < n. \tag{40}$$

In particular, α_{nj} always has weight j, and ω_{nj} always has weight $j+1$. We will define permutations π_n of $\{0, 1, \ldots, n-1\}$ so that both of the sequences

$$P_{n0},\ P_{n1}^R,\ P_{n2},\ P_{n3}^R,\ \ldots \tag{41}$$

$$\text{and } P_{n0}^R,\ P_{n1},\ P_{n2}^R,\ P_{n3},\ \ldots \tag{42}$$

are monotonic binary Gray paths for $n = 1, 2, 3, \ldots$. In fact, the monotonicity is clear, so only the Grayness is in doubt; and the sequences (41), (42) link up nicely because the adjacencies

$$\alpha_{n0} \text{—} \alpha_{n1} \text{—} \cdots \text{—} \alpha_{n(n-1)}, \qquad \omega_{n0} \text{—} \omega_{n1} \text{—} \cdots \text{—} \omega_{n(n-1)} \tag{43}$$

follow immediately from (34), regardless of the permutations π_n. Thus the crucial point is the transition at the comma in formula (34), which makes $P_{(n+1)j}$ a Gray subpath if and only if

$$\omega_{n(j-1)}^{\pi_n} = \alpha_{nj} \qquad \text{for } 0 < j < n. \tag{44}$$

For example, when $n = 2$ and $j = 1$ we need $(01)^{\pi_2} = \alpha_{21} = 10$, by (38)–(40); hence π_2 must transpose coordinates 0 and 1. The general formula (see exercise 71) turns out to be

$$\pi_n = \sigma_n \pi_{n-1}^2, \tag{45}$$

where σ_n is the n-cycle $(n{-}1\ \ldots\ 1\,0)$. The first few cases are therefore

$$\pi_1 = (0), \qquad \pi_4 = (0\,3),$$
$$\pi_2 = (0\,1), \qquad \pi_5 = (0\,4\,3\,2\,1),$$
$$\pi_3 = (0\,2\,1), \qquad \pi_6 = (0\,5\,2\,4\,1\,3);$$

no simple "closed form" for the magic permutations π_n is apparent. Exercise 73 shows that the Savage–Winkler paths can be generated efficiently.

Nonbinary Gray codes. We have studied the case of binary n-tuples in great detail, because it is the simplest, most classical, most applicable, and most thoroughly explored part of the subject. But of course there are numerous applications in which we want to generate $(a_1, \ldots, a_n)$ with coordinates in the more general ranges $0 \le a_j < m_j$, as in Algorithm M. Gray codes and Gray paths apply to this case as well.

Consider, for example, decimal digits, where we want $0 \le a_j < 10$ for each j. Is there a decimal way to count that is analogous to the Gray binary code, changing only one digit at a time? Yes; in fact, *two* natural schemes are

available. In the first, called *reflected Gray decimal*, the sequence for counting up to a thousand with 3-digit strings has the form

$$000, 001, \ldots, 009, 019, 018, \ldots, 011, 010, 020, 021, \ldots, 091, 090, 190, 191, \ldots, 900,$$

with each coordinate moving alternately from 0 up to 9 and then back down from 9 to 0. In the second, called *modular Gray decimal*, the digits always increase by 1 mod 10, therefore they "wrap around" from 9 to 0:

$$000, 001, \ldots, 009, 019, 010, \ldots, 017, 018, 028, 029, \ldots, 099, 090, 190, 191, \ldots, 900.$$

In both cases the digit that changes on step k is determined by the radix-ten ruler function $\rho_{10}(k)$, the largest power of 10 that divides k. Therefore each n-tuple of digits occurs exactly once: We generate 10^j different settings of the rightmost j digits before changing any of the others, for $1 \le j \le n$.

In general, the reflected Gray code in any mixed-radix system can be regarded as a permutation of the nonnegative integers, a function that maps an ordinary mixed-radix number

$$k = \left[\begin{matrix} b_{n-1}, & \ldots, & b_1, & b_0 \\ m_{n-1}, & \ldots, & m_1, & m_0 \end{matrix}\right] = b_{n-1}m_{n-2}\ldots m_1 m_0 + \cdots + b_1 m_0 + b_0 \tag{46}$$

into its reflected-Gray equivalent

$$rg(k) = \left[\begin{matrix} a_{n-1}, & \ldots, & a_1, & a_0 \\ m_{n-1}, & \ldots, & m_1, & m_0 \end{matrix}\right] = a_{n-1}m_{n-2}\ldots m_1 m_0 + \cdots + a_1 m_0 + a_0, \tag{47}$$

just as (7) does this in the special case of binary numbers. Let

$$A_j = \left[\begin{matrix} a_{n-1}, & \ldots, & a_j \\ m_{n-1}, & \ldots, & m_j \end{matrix}\right], \qquad B_j = \left[\begin{matrix} b_{n-1}, & \ldots, & b_j \\ m_{n-1}, & \ldots, & m_j \end{matrix}\right], \tag{48}$$

so that

$$A_j = m_j A_{j+1} + a_j \qquad \text{and} \qquad B_j = m_j B_{j+1} + b_j. \tag{49}$$

The rule connecting the a's and b's is not difficult to derive by induction:

$$a_j = \begin{cases} b_j, & \text{if } B_{j+1} \text{ is even;} \\ m_j - 1 - b_j, & \text{if } B_{j+1} \text{ is odd.} \end{cases} \tag{50}$$

(Here we are numbering the coordinates of the n-tuples $(a_{n-1}, \ldots, a_1, a_0)$ and $(b_{n-1}, \ldots, b_1, b_0)$ from right to left, for consistency with (7) and the conventions of mixed-radix notation in Eq. 4.1–(9). Readers who prefer notations like $(a_1, \ldots, a_n)$ can change j to $n - j$ in all the formulas if they wish.) Going the other way, we have

$$b_j = \begin{cases} a_j, & \text{if } a_{j+1} + a_{j+2} + \cdots \text{ is even;} \\ m_j - 1 - a_j, & \text{if } a_{j+1} + a_{j+2} + \cdots \text{ is odd.} \end{cases} \tag{51}$$

Curiously, rule (50) and its inverse in (51) are exactly the same when all of the radices m_j are odd. In Gray ternary code, for example, when $m_0 = m_1 = \cdots = 3$, we have $rg\big((10010211012)_3\big) = (12210211010)_3$ and also $rg\big((12210211010)_3\big) = (10010211012)_3$. Exercise 78 proves (50) and (51), and discusses similar formulas

that hold in the modular case. People often call these sequences "Gray codes," although strictly speaking they might only be Gray paths (see exercise 79).

We can in fact generate such Gray sequences looplessly, generalizing Algorithms M and L:

Algorithm H (*Loopless reflected mixed-radix Gray generation*). This algorithm visits all n-tuples $(a_{n-1},\ldots,a_0)$ such that $0\le a_j<m_j$ for $0\le j<n$, changing only one coordinate by ±1 at each step. It maintains an array of focus pointers $(f_n,\ldots,f_0)$ to control the actions as in Algorithm L, together with an array of directions $(d_{n-1},\ldots,d_0)$. We assume that each radix m_j is ≥ 2.

H1. [Initialize.] Set $a_j\leftarrow 0$, $f_j\leftarrow j$, and $d_j\leftarrow 1$, for $0\le j<n$; also set $f_n\leftarrow n$.

H2. [Visit.] Visit the n-tuple $(a_{n-1},\ldots,a_1,a_0)$.

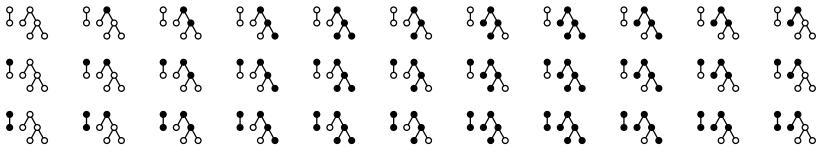
H3. [Choose j.] Set $j\leftarrow f_0$ and $f_0\leftarrow 0$. (As in Algorithm L, j was the rightmost active coordinate; all elements to its right have now been activated.)

H4. [Change coordinate j.] Terminate if $j=n$; otherwise set $a_j\leftarrow a_j+d_j$.

H5. [Reflect?] If $a_j=0$ or $a_j=m_j-1$, set $d_j\leftarrow -d_j$, $f_j\leftarrow f_{j+1}$, and $f_{j+1}\leftarrow j+1$. (Coordinate j has thus become passive.) Return to H2. ∎

A similar algorithm generates the modular variation (see exercise 77).

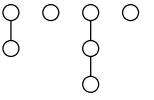
***Subforests.** An interesting and instructive generalization of Algorithm H, discovered by Y. Koda and F. Ruskey [*J. Algorithms* **15** (1993), 324–340], sheds further light on the subject of Gray codes and loopless generation. Suppose we have a forest of n nodes, and we want to visit all of its "principal subforests," namely all subsets of nodes S such that if x is in S and x is not a root, the parent of x is also in S. For example, the 7-node forest has 33 such subsets, corresponding to the black nodes in the following 33 diagrams:



(52)

Notice that if we read the top row from left to right, the middle row from right to left, and the bottom row from left to right, the status of exactly one node changes at each step.

If the given forest consists of degenerate nonbranching trees, the principal subforests are equivalent to mixed-radix numbers. For example, a forest like

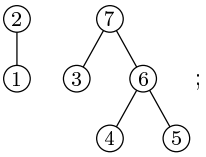


has $3\times2\times4\times2$ principal subforests, corresponding to 4-tuples (x_1,x_2,x_3,x_4) such that $0\le x_1<3$, $0\le x_2<2$, $0\le x_3<4$, and $0\le x_4<2$; the value of x_j is the number of nodes selected in the jth forest. When the algorithm of Koda

and Ruskey is applied to such a forest, it will visit the subforests in the same order as the reflected Gray code on radices $(3, 2, 4, 2)$.

Algorithm K (*Loopless reflected subforest generation*). Given a forest whose nodes are $(1, \ldots, n)$ when arranged in postorder, this algorithm visits all binary n-tuples $(a_1, \ldots, a_n)$ such that $a_p \geq a_q$ whenever p is a parent of q. (Thus, $a_p = 1$ means that p is a node in the current subforest.) Exactly one bit a_j changes between one visit and the next. Focus pointers $(f_0, f_1, \ldots, f_n)$ analogous to those of Algorithm L are used together with additional arrays of pointers $(l_0, l_1, \ldots, l_n)$ and $(r_0, r_1, \ldots, r_n)$, which represent a doubly linked list called the "current fringe." The current fringe contains all nodes of the current subforest and their children; r_0 points to its leftmost node and l_0 to its rightmost.

An auxiliary array $(c_0, c_1, \ldots, c_n)$ defines the forest as follows: If p has no children, $c_p = 0$; otherwise c_p is the leftmost (smallest) child of p. Also c_0 is the leftmost root of the forest itself. When the algorithm begins, we assume that $r_p = q$ and $l_q = p$ whenever p and q are consecutive children of the same family. Thus, for example, the forest in (52) has the postorder numbering



;

therefore we should have $(c_0, \ldots, c_7) = (2, 0, 1, 0, 0, 0, 4, 3)$ and $r_2 = 7$, $l_7 = 2$, $r_3 = 6$, $l_6 = 3$, $r_4 = 5$, and $l_5 = 4$ at the beginning of step K1 in this case.

K1. [Initialize.] Set $a_j \leftarrow 0$ and $f_j \leftarrow j$ for $1 \leq j \leq n$, thereby making the initial subforest empty and all nodes active. Set $f_0 \leftarrow 0$, $l_0 \leftarrow n$, $r_n \leftarrow 0$, $r_0 \leftarrow c_0$, and $l_{c_0} \leftarrow 0$, thereby putting all roots into the current fringe.

K2. [Visit.] Visit the subforest defined by $(a_1, \ldots, a_n)$.

K3. [Choose p.] Set $q \leftarrow l_0$, $p \leftarrow f_q$. (Now p is the rightmost active node of the fringe.) Also set $f_q \leftarrow q$ (thereby activating all nodes to p's right).

K4. [Check a_p.] Terminate the algorithm if $p = 0$. Otherwise go to K6 if $a_p = 1$.

K5. [Insert p's children.] Set $a_p \leftarrow 1$. Then, if $c_p \neq 0$, set $q \leftarrow r_p$, $l_q \leftarrow p - 1$, $r_{p-1} \leftarrow q$, $r_p \leftarrow c_p$, $l_{c_p} \leftarrow p$ (thereby putting p's children to the right of p in the fringe). Go to K7.

K6. [Delete p's children.] Set $a_p \leftarrow 0$. Then, if $c_p \neq 0$, set $q \leftarrow r_{p-1}$, $r_p \leftarrow q$, $l_q \leftarrow p$ (thereby removing p's children from the fringe).

K7. [Make p passive.] (At this point we know that p is active.) Set $f_p \leftarrow f_{l_p}$ and $f_{l_p} \leftarrow l_p$. Return to K2. ∎

The reader is encouraged to play through this algorithm on examples like (52), in order to understand the beautiful mechanism by which the fringe grows and shrinks at just the right times.

***Shift register sequences.** A completely different way to generate all n-tuples of m-ary digits is also possible: We can generate one digit at a time, and repeatedly work with the n most recently generated digits, thus passing from one n-tuple $(x_0, x_1, \ldots, x_{n-1})$ to another one $(x_1, \ldots, x_{n-1}, x_n)$ by shifting an appropriate new digit in at the right. For example, Fig. 15 shows how all 5-bit numbers can be obtained as blocks of 5 consecutive bits in a certain cyclic pattern of length 32. This general idea has already been discussed in some of the exercises of Sections 2.3.4.2 and 3.2.2, and we now are ready to explore it further.

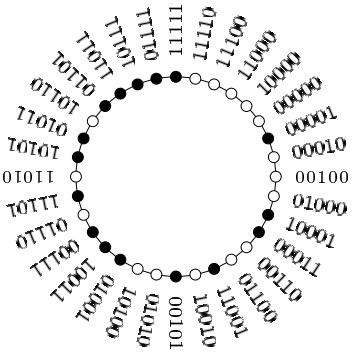


Fig. 15.
A de Bruijn cycle for 5-bit numbers.

Algorithm S (*Generic shift register generation*). This algorithm visits all n-tuples $(a_1, \ldots, a_n)$ such that $0 \le a_j < m$ for $1 \le j \le n$, provided that a suitable function f is used in step S3.

S1. [Initialize.] Set $a_j \leftarrow 0$ for $-n < j \le 0$ and $k \leftarrow 1$.

S2. [Visit.] Visit the n-tuple $(a_{k-n}, \ldots, a_{k-1})$. Terminate if $k = m^n$.

S3. [Advance.] Set $a_k \leftarrow f(a_{k-n}, \ldots, a_{k-1})$, $k \leftarrow k + 1$, and return to S2. ▮

Every function f that makes Algorithm S valid corresponds to a cycle of m^n radix-m digits such that every combination of n digits occurs consecutively in the cycle. For example, the case $m = 2$ and $n = 5$ illustrated in Fig. 15 corresponds to the binary cycle

$$00000100011001010011101011011111; \tag{53}$$

and the first m^2 digits of the infinite sequence

$$00110212203132330414243 44\ldots \tag{54}$$

yield an appropriate cycle for $n = 2$ and arbitrary m. Such cycles are commonly called m-ary *de Bruijn cycles*, because N. G. de Bruijn treated the binary case for arbitrary n in *Indagationes Mathematicæ* **8** (1946), 461–467.

Exercise 2.3.4.2–23 proves that exactly $m!^{m^{n-1}}/m^n$ functions f have the required properties. That's a huge number, but only a few of those functions are known to be efficiently computable. We will discuss three kinds of f that appear to be the most useful.

Table 1
PARAMETERS FOR ALGORITHM A

3 : 1	8 : 1,5	13 : 1,3	18 : 7	23 : 5	28 : 3
4 : 1	9 : 4	14 : 1,11	19 : 1,5	24 : 1,3	29 : 2
5 : 2	10 : 3	15 : 1	20 : 3	25 : 3	30 : 1,15
6 : 1	11 : 2	16 : 2,3	21 : 2	26 : 1,7	31 : 3
7 : 1	12 : 3,4	17 : 3	22 : 1,7	27 : 1,7	32 : 1,27

The entries '$n : s$' or '$n : s,t$' mean that the polynomials $x^n + x^s + 1$ or $x^n + (x^s + 1)(x^t + 1)$ are primitive modulo 2. Additional values up to $n = 168$ have been tabulated by W. Stahnke, *Math. Comp.* **27** (1973), 977–980.

The first important case occurs when m is a prime number, and f is the almost-linear recurrence

$$f(x_1, \ldots, x_n) = \begin{cases} c_1, & \text{if } (x_1, x_2, \ldots, x_n) = (0, 0, \ldots, 0); \\ 0, & \text{if } (x_1, x_2, \ldots, x_n) = (1, 0, \ldots, 0); \\ (c_1 x_1 + c_2 x_2 + \cdots + c_n x_n) \bmod m, & \text{otherwise.} \end{cases} \tag{55}$$

Here the coefficients $(c_1, \ldots, c_n)$ must be such that

$$x^n - c_n x^{n-1} - \cdots - c_2 x - c_1 \tag{56}$$

is a primitive polynomial modulo m, in the sense discussed following Eq. 3.2.2–(9). The number of such polynomials is $\varphi(m^n - 1)/n$, large enough to allow us to find one in which only a few of the c's are nonzero. [This construction goes back to a pioneering paper of Willem Mantel, *Nieuw Archief voor Wiskunde* (2) **1** (1897), 172–184.]

For example, suppose $m = 2$. We can generate binary n-tuples with a very simple loopless procedure:

Algorithm A (*Almost-linear bit-shift generation*). This algorithm visits all n-bit vectors, by using either a special offset s [Case 1] or two special offsets s and t [Case 2], as found in Table 1.

A1. [Initialize.] Set $(x_0, x_1, \ldots, x_{n-1}) \leftarrow (1, 0, \ldots, 0)$ and $k \leftarrow 0$, $j \leftarrow s$. In Case 2, also set $i \leftarrow t$ and $h \leftarrow s + t$.

A2. [Visit.] Visit the n-tuple $(x_{k-1}, \ldots, x_0, x_{n-1}, \ldots, x_{k+1}, x_k)$.

A3. [Test for end.] If $x_k \neq 0$, set $r \leftarrow 0$; otherwise set $r \leftarrow r + 1$, and go to A6 if $r = n - 1$. (We have just seen r consecutive zeros.)

A4. [Shift.] Set $k \leftarrow (k - 1) \bmod n$ and $j \leftarrow (j - 1) \bmod n$. In Case 2 also set $i \leftarrow (i - 1) \bmod n$ and $h \leftarrow (h - 1) \bmod n$.

A5. [Compute a new bit.] Set $x_k \leftarrow x_k \oplus x_j$ [Case 1] or $x_k \leftarrow x_k \oplus x_j \oplus x_i \oplus x_h$ [Case 2]. Return to A2.

A6. [Finish.] Visit $(0, \ldots, 0)$ and terminate. ∎

Appropriate offset parameters s and possibly t almost certainly exist for all n, because primitive polynomials are so abundant; for example, eight different choices of (s, t) would work when $n = 32$, and Table 1 merely lists the smallest.

However, a rigorous proof of existence in all cases lies well beyond the present state of mathematical knowledge.

Our first construction of de Bruijn cycles, in (55), was algebraic, relying for its validity on the theory of finite fields. A similar method that works when m is not a prime number appears in exercise 3.2.2–21. Our next construction, by contrast, will be purely combinatorial. In fact, it is strongly related to the idea of modular Gray m-ary codes.

Algorithm R (*Recursive de Bruijn cycle generation*). Suppose $f()$ is a coroutine that will output the successive digits of an m-ary de Bruijn cycle of length m^n, beginning with n zeros, when it is invoked repeatedly. This algorithm is a similar coroutine that outputs a cycle of length m^{n+1}, provided that $n \geq 2$. It maintains three private variables x, y, and t; variable x should initially be zero.

R1. [Output.] Output x. Go to R3 if $x \neq 0$ and $t \geq n$.

R2. [Invoke f.] Set $y \leftarrow f()$.

R3. [Count ones.] If $y = 1$, set $t \leftarrow t + 1$; otherwise set $t \leftarrow 0$.

R4. [Skip one?] If $t = n$ and $x \neq 0$, go back to R2.

R5. [Adjust x.] Set $x \leftarrow (x + y) \bmod m$ and return to R1. ∎

For example, let $m = 3$ and $n = 2$. If $f()$ produces the infinite 9-cycle

$$001102122\ \ 001102122\ \ 0\ldots, \tag{57}$$

then Algorithm R will produce the following infinite 27-cycle at step R1:

$$\begin{aligned} y &= \ 001021220011110212200102122\ 001\ldots \\ t &= \ 001001000012340010000100100\ 001\ldots \\ x &= 000110102220120020211122121\ 0001\ldots \end{aligned}$$

The proof that Algorithm R works correctly is interesting and instructive (see exercise 93). And the proof of the next algorithm, which *doubles* the window size n, is even more so (see exercise 95).

Algorithm D (*Doubly recursive de Bruijn cycle generation*). Suppose $f()$ and $g()$ are coroutines that each will output the successive digits of m-ary de Bruijn cycles of length m^n when invoked repeatedly, beginning with n zeros. (The two cycles might be identical, but they must be generated by independent coroutines because we will consume their values at different rates of speed.) This algorithm is a similar coroutine that outputs a cycle of length m^{2n}. It maintains six private variables x, y, t, x', y', and t'; variables x and x' should initially be m.

The special parameter r must be set to a constant value such that

$$0 \leq r \leq m \qquad \text{and} \qquad \gcd(m^n - r,\ m^n + r) = 2. \tag{58}$$

The best choice is usually $r = 1$ when m is odd and $r = 2$ when m is even.

D1. [Possibly invoke f.] If $t \neq n$ or $x \geq r$, set $y \leftarrow f()$.

D2. [Count repeats.] If $x \neq y$, set $x \leftarrow y$ and $t \leftarrow 1$. Otherwise set $t \leftarrow t + 1$.

D3. [Output from f.] Output the current value of x.

D4. [Invoke g.] Set $y' \leftarrow g()$.

D5. [Count repeats.] If $x' \neq y'$, set $x' \leftarrow y'$ and $t' \leftarrow 1$. Otherwise set $t' \leftarrow t'+1$.

D6. [Possibly reject g.] If $t' = n$ and $x' < r$ and either $t < n$ or $x' < x$, go to D4. If $t' = n$ and $x' < r$ and $x' = x$, go to D3.

D7. [Output from g.] Output the current value of x'. Return to D3 if $t' = n$ and $x' < r$; otherwise return to D1. ∎

The basic idea of Algorithm D is to output from $f()$ and $g()$ alternately, making special adjustments when either sequence generates n consecutive x's for $x < r$. For example, when $f()$ and $g()$ produce the 9-cycle (57), we take $r = 1$ and get

t in step D2: 12 31211112 12312111 12123121 11121231 21111212 ...
x in step D3: 00001102122 00011021 22000110 21220001 102122000 ...
t' in step D6: 12121111212121111212121111212121111212121111212121 ...
x' in step D7: 0 11021220 11021220 11021220 11021220 11021220 1 ...;

so the 81-cycle produced in steps D3 and **D7** is $0\mathbf{0}0\mathbf{0}1\mathbf{0}1\mathbf{1}0\mathbf{1}\mathbf{2}\ldots2\mathbf{2}\mathbf{2}\mathbf{2}\,0\mathbf{0}0\mathbf{0}1\ldots$.

The case $m = 2$ of Algorithm R was discovered by Abraham Lempel [*IEEE Trans.* **C-19** (1970), 1204–1209]; Algorithm D was not discovered until more than 25 years later [C. J. Mitchell, T. Etzion, and K. G. Paterson, *IEEE Trans.* **IT-42** (1996), 1472–1478]. By using them together, starting with simple coroutines for $n = 2$ based on (54), we can build up an interesting family of cooperating coroutines that will generate a de Bruijn cycle of length m^n for any desired $m \geq 2$ and $n \geq 2$, using only $O(\log n)$ simple computations for each digit of output. (See exercise 96.) Furthermore, in the simplest case $m = 2$, this combination "R&D method" has the property that its kth output can be computed directly, as a function of k, by doing $O(n \log n)$ simple operations on n-bit numbers. Conversely, given any n-bit pattern β, the position of β in the cycle can also be computed in $O(n \log n)$ steps. (See exercises 97–99.) No other family of binary de Bruijn cycles is presently known to have the latter property.

Our third construction of de Bruijn cycles is based on the theory of prime strings, which will be of great importance to us when we study pattern matching in Chapter 9. Suppose $\gamma = \alpha\beta$ is the concatenation of two strings; we say that α is a *prefix* of γ and β is a *suffix*. A prefix or suffix of γ is called *proper* if its length is positive but less than the length of γ. Thus β is a proper suffix of $\alpha\beta$ if and only if $\alpha \neq \epsilon$ and $\beta \neq \epsilon$.

Definition P. *A string is prime if it is nonempty and (lexicographically) less than all of its proper suffixes.*

For example, 01101 is not prime, because it is greater than 01; but 01102 is prime. (We assume that strings are composed of letters, digits, or other symbols from a linearly ordered alphabet. Lexicographic or dictionary order is the normal way to compare strings, so we write $\alpha < \beta$ and say that α is less than β when α is lexicographically less than β. In particular, we always have $\alpha \leq \alpha\beta$, and $\alpha < \alpha\beta$ if and only if $\beta \neq \epsilon$.)

Prime strings have often been called *Lyndon words*, because they were introduced by R. C. Lyndon [*Trans. Amer. Math. Soc.* **77** (1954), 202–215]; Lyndon called them "standard sequences." The simpler term "prime" is justified because of the fundamental factorization theorem in exercise 101. We will, however, continue to pay respect to Lyndon implicitly by often using the letter λ to denote strings that are prime.

Several of the most important properties of prime strings were derived by Chen, Fox, and Lyndon in an important paper on group theory [*Annals of Math.* **68** (1958), 81–95], including the following easy but basic result:

Theorem P. *A nonempty string that is less than all its cyclic shifts is prime.*

(The cyclic shifts of $a_1 \dots a_n$ are $a_2 \dots a_n a_1$, $a_3 \dots a_n a_1 a_2$, $\dots$, $a_n a_1 \dots a_{n-1}$.)

Proof. Suppose $\gamma = \alpha\beta$ is not prime, because $\alpha \neq \epsilon$ and $\gamma \geq \beta \neq \epsilon$; but suppose γ is also less than its cyclic shift $\beta\alpha$. Then the conditions $\beta \leq \gamma < \beta\alpha$ imply that $\gamma = \beta\theta$ for some string $\theta < \alpha$. Therefore, if γ is also less than its cyclic shift $\theta\beta$, we have $\theta < \alpha < \alpha\beta < \theta\beta$. But that is impossible, because α and θ have the same length. ∎

Let $L_m(n)$ be the number of m-ary primes of length n. Every string $a_1 \dots a_n$, together with its cyclic shifts, yields d distinct strings for some divisor d of n, corresponding to exactly one prime of length d. For example, from 010010 we get also 100100 and 001001 by cyclic shifting, and the smallest of the periodic parts $\{010, 100, 001\}$ is the prime 001. Therefore we must have

$$\sum_{d \backslash n} d L_m(d) \;=\; m^n, \qquad \text{for all } m, n \geq 1. \tag{59}$$

This family of equations can be solved for $L_m(n)$ using exercise 4.5.3–28(a), and we obtain

$$L_m(n) \;=\; \frac{1}{n} \sum_{d \backslash n} \mu(d) m^{n/d}. \tag{60}$$

During the 1970s, Harold Fredricksen and James Maiorana discovered a beautifully simple way to generate all of the m-ary primes of length n or less, in increasing order [*Discrete Math.* **23** (1978), 207–210]. Before we are ready to understand their algorithm, we need to consider the *n-extension* of a nonempty string λ, namely the first n characters of the infinite string $\lambda\lambda\lambda\dots$. For example, the 10-extension of 123 is 1231231231. In general if $|\lambda| = k$, its n-extension is $\lambda^{\lfloor n/k \rfloor}\lambda'$, where λ' is the prefix of λ whose length is $n \bmod k$.

Definition Q. *A string is preprime if it is a nonempty prefix of a prime.*

Theorem Q. *A string of length $n > 0$ is preprime if and only if it is the n-extension of a prime string λ of length $k \leq n$. This prime string is uniquely determined.*

Proof. See exercise 105. ∎

Theorem Q states, in essence, that there is a one-to-one correspondence between primes of length $\le n$ and preprimes of length n. The following algorithm generates all of the m-ary ones, in increasing order.

Algorithm F (*Prime and preprime string generation*). This algorithm visits all m-ary n-tuples $(a_1, \ldots, a_n)$ such that the string $a_1 \ldots a_n$ is preprime. It also identifies the index j such that $a_1 \ldots a_n$ is the n-extension of the prime $a_1 \ldots a_j$.

F1. [Initialize.] Set $a_0 \leftarrow -1$, $a_1 \leftarrow \cdots \leftarrow a_n \leftarrow 0$, and $j \leftarrow 1$.

F2. [Visit.] Visit $(a_1, \ldots, a_n)$ with index j.

F3. [Prepare to increase.] Set $j \leftarrow n$. Then if $a_j = m-1$, decrease j until finding $a_j < m-1$.

F4. [Add one.] Terminate if $j = 0$. Otherwise set $a_j \leftarrow a_j + 1$. (Now $a_1 \ldots a_j$ is prime, by exercise 105(a).)

F5. [Make n-extension.] For $k \leftarrow j+1, \ldots, n$ (in this order) set $a_k \leftarrow a_{k-j}$. Return to F2. ∎

For example, Algorithm F visits 32 ternary preprimes when $m = 3$ and $n = 4$:

$$\begin{array}{cccccccc} 0000^{\wedge} & 0011^{\wedge} & 0022^{\wedge} & 0111^{\wedge} & 0122^{\wedge} & 0212^{\wedge} & 1111^{\wedge} & 1212^{\wedge} \\ 0001^{\wedge} & 0012^{\wedge} & 0101^{\wedge} & 0112^{\wedge} & 0202^{\wedge} & 0220^{\wedge} & 1112^{\wedge} & 1221^{\wedge} \\ 0002^{\wedge} & 0020^{\wedge} & 0102^{\wedge} & 0120^{\wedge} & 0210^{\wedge} & 0221^{\wedge} & 1121^{\wedge} & 1222^{\wedge} \\ 0010^{\wedge} & 0021^{\wedge} & 0110^{\wedge} & 0121^{\wedge} & 0211^{\wedge} & 0222^{\wedge} & 1122^{\wedge} & 2222^{\wedge} \end{array} \qquad (61)$$

(The digits preceding '$^{\wedge}$' are the prime strings 0, 0001, 0002, 001, 0011, ..., 2.)

Theorem Q explains why this algorithm is correct, because steps F3 and F4 obviously find the smallest m-ary prime of length $\le n$ that exceeds the previous preprime $a_1 \ldots a_n$. Notice that after a_1 increases from 0 to 1, the algorithm proceeds to visit all the $(m-1)$-ary primes and preprimes, increased by $1 \ldots 1$.

Algorithm F is quite beautiful, but what does it have to do with de Bruijn cycles? Here now comes the punch line: If we output the digits $a_1, \ldots, a_j$ in step F2 whenever j is a divisor of n, the sequence of all such digits forms a de Bruijn cycle! For example, in the case $m = 3$ and $n = 4$, the following 81 digits are output:

$$0\,0001\,0002\,0011\,0012\,0021\,0022\,01\,0102\,0111\,0112$$
$$0121\,0122\,02\,0211\,0212\,0221\,0222\,1\,1112\,1122\,12\,1222\,2. \qquad (62)$$

(We omit the primes 001, 002, 011, ..., 122 of (61) because their length does not divide 4.) The reasons underlying this almost magical property are explored in exercise 108. Notice that the cycle has the correct length, by (59).

There is a sense in which the outputs of this procedure are actually equivalent to the "granddaddy" of all de Bruijn cycle constructions that work for all m and n, namely the construction first published by M. H. Martin in *Bull. Amer. Math. Soc.* **40** (1934), 859–864: Martin's original cycle for $m = 3$ and $n = 4$ was 2222122202211...10000, the twos' complement of (62). In fact, Fredricksen and Maiorana discovered Algorithm F almost by accident while looking for a

simple way to generate Martin's sequence; the explicit connection between their algorithm and preprime strings was not noticed until many years later, when Ruskey, Savage, and Wang carried out a careful analysis of the running time [*J. Algorithms* **13** (1992), 414–430]. The principal results of that analysis appear in exercise 107, namely

i) The average value of $n-j$ in steps F3 and F5 is approximately $m/(m-1)^2$.
ii) The total running time to produce a de Bruijn cycle like (62) is $O(m^n)$.

EXERCISES

1. [*10*] Explain how to generate all n-tuples $(a_1,\ldots,a_n)$ in which $l_j \le a_j \le u_j$, given lower bounds l_j and upper bounds u_j for each coordinate. (Assume that $l_j \le u_j$.)

2. [*15*] What is the 1000000th n-tuple visited by Algorithm M if $n = 10$ and $m_j = j$ for $1 \le j \le n$? *Hint:* $\left[\begin{smallmatrix}0,&0,&1,&2,&3,&0,&2,&7,&1,&0\\1,&2,&3,&4,&5,&6,&7,&8,&9,&10\end{smallmatrix}\right] = 1000000$.

▶ **3.** [*M20*] How many times does Algorithm M perform step M4?

▶ **4.** [*18*] On most computers it is faster to count down to 0 rather than up to m. Revise Algorithm M so that it visits all n-tuples in the opposite order, starting with $(m_1-1,\ldots,m_n-1)$ and finishing with $(0,\ldots,0)$.

▶ **5.** [*20*] Algorithms such as the "fast Fourier transform" (exercise 4.6.4–14) often end with an array of answers in bit-reflected order, having $A[(b_0\ldots b_{n-1})_2]$ in the place where $A[(b_{n-1}\ldots b_0)_2]$ is desired. What is a good way to rearrange the answers into proper order? [*Hint:* Reflect Algorithm M.]

6. [*M17*] Prove (7), the basic formula for Gray binary code.

7. [*20*] Fig. 10(b) shows the Gray binary code for a disk that is divided into 16 sectors. What would be a good Gray-like code to use if the number of sectors were 12 or 60 (for hours or minutes on a clock), or 360 (for degrees in a circle)?

8. [*15*] What's an easy way to run through all n-bit strings of even parity, changing only two bits at each step?

9. [*16*] What move should follow Fig. 11, when solving the Chinese ring puzzle?

▶ **10.** [*M21*] Find a simple formula for the total number of steps A_n or B_n in which a ring is (a) removed or (b) replaced, in the shortest procedure for removing n Chinese rings. For example, $A_3 = 4$ and $B_3 = 1$.

11. [*M22*] (H. J. Purkiss, 1865.) The two smallest rings of the Chinese ring puzzle can actually be taken on or off the bar simultaneously. How many steps does the puzzle require when such accelerated moves are permitted?

▶ **12.** [*23*] The *compositions* of n are the sequences of positive integers that sum to n. For example, the compositions of 4 are 1111, 112, 121, 13, 211, 22, 31, and 4. An integer n has exactly 2^{n-1} compositions, corresponding to all subsets of the points $\{1,\ldots,n-1\}$ that might be used to break the interval $(0\,..\,n)$ into integer-sized subintervals.

a) Design a loopless algorithm to generate all compositions of n, representing each composition as a sequential array of integers $s_1 s_2 \ldots s_j$.
b) Similarly, design a loopless algorithm that represents the compositions implicitly in an array of pointers $q_0 q_1 \ldots q_t$, where the elements of the composition are $(q_0-q_1)(q_1-q_2)\ldots(q_{t-1}-q_t)$ and we have $q_0 = n$, $q_t = 0$. For example, the composition 211 would be represented under this scheme by the pointers $q_0 = 4$, $q_1 = 2$, $q_2 = 1$, $q_3 = 0$, and with $t = 3$.

13. [*21*] Continuing the previous exercise, compute also the multinomial coefficient $C = \binom{n}{s_1,\ldots,s_j}$ for use as the composition $s_1 \ldots s_j$ is being visited.

14. [*20*] Design an algorithm to generate all strings $a_1 \ldots a_j$ such that $0 \le j \le n$ and $0 \le a_i < m_i$ for $1 \le i \le j$, in lexicographic order. For example, if $m_1 = m_2 = n = 2$, your algorithm should successively visit ϵ, 0, 00, 01, 1, 10, 11.

▸ **15.** [*25*] Design a *loopless* algorithm to generate the strings of the previous exercise. All strings of the same length should be visited in lexicographic order as before, but strings of different lengths can be intermixed in any convenient way. For example, 0, 00, 01, ϵ, 10, 11, 1 is an acceptable order when $m_1 = m_2 = n = 2$.

▸ **16.** [*23*] A loopless algorithm obviously cannot generate all binary vectors $(a_1, \ldots, a_n)$ in lexicographic order, because the number of coordinates a_j that need to change between successive visits is not bounded. Show, however, that loopless lexicographic generation does become possible if a *linked* representation is used instead of a sequential one: Suppose there are $2n$ nodes $\{1{:}0, 1{:}1, 2{:}0, 2{:}1, \ldots, n{:}0, n{:}1\}$, each containing a `DIGIT` field and a `LINK` field, where $\texttt{DIGIT}(j{:}b) = b$ for $1 \le j \le n$ and $0 \le b \le 1$. An n-tuple like $(0, 1, 0)$ is represented by

$$\texttt{LINK}(0{:}0) = 1{:}0, \quad \texttt{LINK}(1{:}0) = 2{:}1, \quad \texttt{LINK}(2{:}1) = 3{:}0, \quad \texttt{LINK}(3{:}0) = \Lambda,$$

where 0:0 is a special header node; the other `LINK` fields can have any convenient values.

17. [*20*] A well-known construction called the *Karnaugh map* [M. Karnaugh, *Amer. Inst. Elect. Eng. Trans.* **72**, part I (1953), 593–599] uses Gray binary code in two dimensions to display all 4-bit numbers in a 4×4 torus:

0000	0001	0011	0010
0100	0101	0111	0110
1100	1101	1111	1110
1000	1001	1011	1010

(The entries of a torus "wrap around" at the left and right and also at the top and bottom — just as if they were tiles, replicated infinitely often in a plane.) Show that, similarly, all 6-bit numbers can be arranged in an 8×8 torus so that only one coordinate changes when we move north, south, east, or west from any point.

▸ **18.** [*20*] The *Lee weight* of a vector $u = (u_1, \ldots, u_n)$, where each component satisfies $0 \le u_j < m_j$, is defined to be

$$\nu_L(u) = \sum_{j=1}^{n} \min(u_j, m_j - u_j);$$

and the *Lee distance* between two such vectors u and v is

$$d_L(u, v) = \nu_L(u - v), \qquad \text{where } u - v = \big((u_1 - v_1) \bmod m_1, \ldots, (u_n - v_n) \bmod m_n\big).$$

(This is the minimum number of steps needed to change u to v if we adjust some component u_j by ± 1 (modulo m_j) in each step.)

A quaternary vector has $m_j = 4$ for $1 \le j \le n$, and a binary vector has all $m_j = 2$. Find a simple one-to-one correspondence between quaternary vectors $u = (u_1, \ldots, u_n)$ and binary vectors $u' = (u'_1, \ldots, u'_{2n})$, with the property that $\nu_L(u) = \nu(u')$ and $d_L(u, v) = \nu(u' \oplus v')$.

19. [*21*] (*The octacode.*) Let $g(x) = x^3 + 2x^2 + x - 1$.

a) Use one of the algorithms in this section to evaluate $\sum z_{u_0} z_{u_1} z_{u_2} z_{u_3} z_{u_4} z_{u_5} z_{u_6} z_{u_\infty}$, summed over all 256 polynomials

$$(v_0 + v_1 x + v_2 x^2 + v_3 x^3) g(x) \bmod 4 = u_0 + u_1 x + u_2 x^2 + u_3 x^3 + u_4 x^4 + u_5 x^5 + u_6 x^6$$

for $0 \le v_0, v_1, v_2, v_3 < 4$, where u_∞ is chosen so that $0 \le u_\infty < 4$ and $(u_0 + u_1 + u_2 + u_3 + u_4 + u_5 + u_6 + u_\infty) \bmod 4 = 0$.

b) Construct a set of 256 16-bit numbers that differ from each other in at least six different bit positions. (Such a set, first discovered by Nordstrom and Robinson [*Information and Control* **11** (1967), 613–616], is essentially unique.)

20. [*M36*] The 16-bit codewords in the previous exercise can be used to transmit 8 bits of information, allowing transmission errors to be corrected if any one or two bits are corrupted; furthermore, mistakes will be detected (but not necessarily correctable) if any three bits are received incorrectly. Devise an algorithm that either finds the nearest codeword to a given 16-bit number u' or determines that at least three bits of u' are erroneous. How does your algorithm decode the number $(1100100100001111)_2$? [*Hint:* Use the facts that $x^7 \equiv 1$ (modulo $g(x)$ and 4), and that every quaternary polynomial of degree < 3 is congruent to $x^j + 2x^k$ (modulo $g(x)$ and 4) for some $j, k \in \{0, 1, 2, 3, 4, 5, 6, \infty\}$, where $x^\infty = 0$.]

21. [*M30*] A t-subcube of an n-cube can be represented by a string like $**10**0*$, containing t asterisks and $n - t$ specified bits. If all 2^n binary n-tuples are written in lexicographic order, the elements belonging to such a subcube appear in $2^{t'}$ clusters of consecutive entries, where t' is the number of asterisks that lie to the left of the rightmost specified bit. (In the example given, $n = 8$, $t = 5$, and $t' = 4$.) But if the n-tuples are written in Gray binary order, the number of clusters might be reduced. For example, the $(n-1)$-subcubes $*\ldots*0$ and $*\ldots*1$ occur in only $2^{n-2} + 1$ and 2^{n-2} clusters, respectively, when Gray binary order is used, not in 2^{n-1} of them.

a) Explain how to compute $C(\alpha)$, the number of Gray binary clusters of the subcube defined by a given string α of asterisks, 0s, and 1s. What is $C(**10**0*)$?

b) Prove that $C(\alpha)$ always lies between $2^{t'-1}$ and $2^{t'}$, inclusive.

c) What is the average value of $C(\alpha)$, over all $2^{n-t}\binom{n}{t}$ possible t-subcubes?

▸ **22.** [*22*] A "right subcube" is a subcube such as $0110**$ in which all the asterisks appear after all the specified digits. Any binary trie (Section 6.3) can be regarded as a way to partition a cube into disjoint right subcubes, as in Fig. 16(a). If we interchange the left and right subtries of every right subtrie, proceeding downward from the root, we obtain a *Gray binary trie*, as in Fig. 16(b).

Prove that if the "lieves" of a Gray binary trie are traversed in order, from left to right, consecutive lieves correspond to adjacent subcubes. (Subcubes are adjacent if they contain adjacent vertices. For example, $00**$ is adjacent to $011*$ because the first contains 0010 and the second contains 0110; but $011*$ is not adjacent to $10**$.)

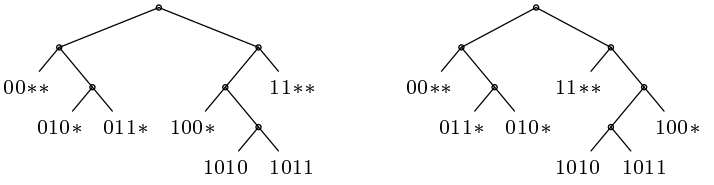

Fig. 16. (a) Normal binary trie. (b) Gray binary trie.

23. [*20*] Suppose $g(k) \oplus 2^j = g(l)$. What is a simple way to find l, given j and k?

24. [*M21*] Consider extending the Gray binary function g to all 2-adic integers (see exercise 4.1–31). What is the corresponding inverse function $g^{[-1]}$?

▸ **25.** [*M25*] Prove that if $g(k)$ and $g(l)$ differ in $t > 0$ bits, and if $0 \le k, l < 2^n$, then $\lceil 2^t/3 \rceil \le |k - l| \le 2^n - \lceil 2^t/3 \rceil$.

26. [*25*] (Frank Ruskey.) For which integers N is it possible to generate all of the nonnegative integers less than N in such a way that only one bit of the binary representation changes at each step?

▸ **27.** [*20*] Let $S_0 = \{1\}$ and $S_{n+1} = 1/(2 + S_n) \cup 1/(2 - S_n)$; thus, for example,

$$S_2 = \left\{ \frac{1}{2 + \frac{1}{2+1}}, \frac{1}{2 + \frac{1}{2-1}}, \frac{1}{2 - \frac{1}{2+1}}, \frac{1}{2 - \frac{1}{2-1}} \right\} = \left\{ \frac{3}{7}, \frac{1}{3}, \frac{3}{5}, 1 \right\},$$

and S_n has 2^n elements that lie between $\frac{1}{3}$ and 1. Compute the 10^{10}th smallest element of S_{100}.

28. [*M26*] A *median* of n-bit strings $\{\alpha_1, \ldots, \alpha_t\}$, where α_k has the binary representation $\alpha_k = a_{k(n-1)} \ldots a_{k0}$, is a string $\hat{\alpha} = a_{n-1} \ldots a_0$ whose bits a_j for $0 \le j < n$ agree with the majority of the bits a_{kj} for $1 \le k \le t$. (If t is even and the bits α_{kj} are half 0 and half 1, the median bit a_j can be either 0 or 1.) For example, the strings $\{0010, 0100, 0101, 1110\}$ have two medians, 0100 and 0110, which we can denote by 01*0.

a) Find a simple way to describe the medians of $G_t = \{g(0), \ldots, g(t-1)\}$, the first t Gray binary strings, when $0 < t \le 2^n$.

b) Prove that if $\alpha = a_{n-1} \ldots a_0$ is such a median, and if $\alpha' = a'_{n-1} \ldots a'_0$ is any element of G_t with $a'_j \ne a_j$, then the string β obtained from α by changing a_j to a'_j is also an element of G_t.

29. [*M24*] If integer values k are transmitted as n-bit Gray binary codes $g(k)$ and received with errors described by a bit pattern $p = (p_{n-1} \ldots p_0)_2$, the average numerical error is

$$\frac{1}{2^n} \sum_{k=0}^{2^n-1} \Big| \big(g^{[-1]}(k) \oplus p\big) - k \Big|,$$

assuming that all values of k are equally likely. Show that this sum is equal to $\sum_{k=0}^{2^n-1} |(k \oplus p) - k|/2^n$, just as if Gray binary code were not used, and evaluate it explicitly.

▸ **30.** [*M27*] (*Gray permutation.*) Design a one-pass algorithm to replace the array elements $(X_0, X_1, X_2, \ldots, X_{2^n-1})$ by $(X_{g(0)}, X_{g(1)}, X_{g(2)}, \ldots, X_{g(2^n-1)})$, using only a constant amount of auxiliary storage. *Hint:* Considering the function $g(n)$ as a permutation of all nonnegative integers, show that the set

$$L = \{0, 1, (10)_2, (100)_2, (100*)_2, (100*0)_2, (100*0*)_2, \ldots\}$$

is the set of *cycle leaders* (the smallest elements of the cycles).

31. [*HM35*] (*Gray fields.*) Let $f_n(x) = g\big(r_n(x)\big)$ denote the operation of reflecting the bits of an n-bit binary string as in exercise 5 and then converting to Gray binary code. For example, the operation $f_3(x)$ takes $(001)_2 \mapsto (110)_2 \mapsto (010)_2 \mapsto (011)_2 \mapsto (101)_2 \mapsto (111)_2 \mapsto (100)_2 \mapsto (001)_2$, hence all of the nonzero possibilities appear in

a single cycle. Therefore we can use f_3 to define a field of 8 elements, with $\oplus$ as the addition operator and with multiplication defined by the rule

$$f_3^{[j]}(1) \times f_3^{[k]}(1) = f_3^{[j+k]}(1) = f_3^{[j]}\big(f_3^{[k]}(1)\big).$$

The functions f_2, f_5, and f_6 have the same nice property. But f_4 does not, because $f_4\big((1011)_2\big) = (1011)_2$.

Find all $n \le 100$ for which f_n defines a field of 2^n elements.

32. [*M20*] True or false: Walsh functions satisfy $w_k(-x) = (-1)^k w_k(x)$.

▶ **33.** [*M20*] Prove the Rademacher-to-Walsh law (17).

34. [*M21*] The *Paley functions* $p_k(x)$ are defined by

$$p_0(x) = 1 \qquad \text{and} \qquad p_k(x) = (-1)^{\lfloor 2x \rfloor k} p_{\lfloor k/2 \rfloor}(2x).$$

Show that $p_k(x)$ has a simple expression in terms of Rademacher functions, analogous to (17), and relate Paley functions to Walsh functions.

35. [*HM23*] The $2^n \times 2^n$ Paley matrix P_n is obtained from Paley functions just as the Walsh matrix W_n is obtained from Walsh functions. (See (20).) Find interesting relations between P_n, W_n, and the Hadamard matrix H_n. Prove that all three matrices are symmetric.

36. [*21*] Spell out the details of an efficient algorithm to compute the Walsh transform $(x_0, \ldots, x_{2^n-1})$ of a given vector $(X_0, \ldots, X_{2^n-1})$.

37. [*HM23*] Let z_{kl} be the location of the lth sign change in $w_k(x)$, for $1 \le l \le k$ and $0 < z_{kl} < 1$. Prove that $|z_{kl} - l/(k+1)| = O\big((\log k)/k\big)$.

▶ **38.** [*M25*] Devise a ternary generalization of Walsh functions.

▶ **39.** [*HM30*] (J. J. Sylvester.) The rows of $\left(\begin{smallmatrix} a & b \\ b & -a \end{smallmatrix}\right)$ are orthogonal to each other and have the same magnitude; therefore the matrix identity

$$\begin{aligned}(\,A\;B\,)\begin{pmatrix} a^2+b^2 & 0 \\ 0 & a^2+b^2 \end{pmatrix}\begin{pmatrix} A \\ B \end{pmatrix} &= (\,A\;B\,)\begin{pmatrix} a & b \\ b & -a \end{pmatrix}\begin{pmatrix} a & b \\ b & -a \end{pmatrix}\begin{pmatrix} A \\ B \end{pmatrix} \\ &= (\,Aa+Bb\;\; Ab-Ba\,)\begin{pmatrix} aA+bB \\ bA-aB \end{pmatrix}\end{aligned}$$

implies the sum-of-two-squares identity $(a^2+b^2)(A^2+B^2) = (aA+bB)^2 + (bA-aB)^2$. Similarly, the matrix

$$\begin{pmatrix} a & b & c & d \\ b & -a & d & -c \\ d & c & -b & -a \\ c & -d & -a & b \end{pmatrix}$$

leads to the sum-of-four-squares identity

$$\begin{aligned}(a^2+b^2+c^2+d^2)(A^2+B^2+C^2+D^2) = {}& (aA+bB+cC+dD)^2 + (bA-aB+dC-cD)^2 \\ & + (dA+cB-bC-aD)^2 + (cA-dB-aC+bD)^2.\end{aligned}$$

a) Attach the signs of the matrix H_3 in (21) to the symbols $\{a, b, c, d, e, f, g, h\}$, obtaining a matrix with orthogonal rows and a sum-of-eight-squares identity.

b) Generalize to H_4 and higher-order matrices.

▶ **40.** [*21*] Would the text's five-letter word computation scheme produce correct answers also if the masks in step W2 were computed as $m_j = x \wedge (2^{5^j} - 1)$ for $0 \le j < 5$?

41. [*25*] If we restrict the five-letter word problem to the most common 3000 words — thereby eliminating `ducky`, `duces`, `dunks`, `dinks`, `dinky`, `dices`, `dicey`, `dicky`, `dicks`, `picky`, `pinky`, `punky`, and `pucks` from (23) — how many valid words can still be generated from a single pair?

42. [*35*] (M. L. Fredman.) Algorithm L uses $\Theta(n \log n)$ bits of auxiliary memory for focus pointers as it decides what Gray binary bit a_j should be complemented next. On each step L3 it examines $\Theta(\log n)$ of the auxiliary bits, and it occasionally changes $\Omega(\log n)$ of them.

Show that, from a theoretical standpoint, we can do better: The n-bit Gray binary code can be generated by changing at most 2 auxiliary bits between visits. (We still allow ourselves to examine $O(\log n)$ of the auxiliary bits on each step, so that we know which of them should be changed.)

43. [*47*] Determine $d(6)$, the number of 6-bit Gray codes.

44. [*M35*] How many of the delta sequences for n-bit Gray codes have the property that exactly (a) one or (b) two of the coordinate names occur only twice? Express your answers in terms of $d(n-1)$ and $d(n-2)$.

45. [*M25*] Show that the sequence $d(n)$ has doubly exponential growth: There is a constant $A > 1$ such that $d(n) = \Omega(A^{2^n})$.

46. [*HM48*] Determine the asymptotic behavior of $d(n)^{1/2^n}$ as $n \to \infty$.

47. [*M46*] (Silverman, Vickers, and Sampson.) Let $S_k = \{g(0), \ldots, g(k-1)\}$ be the first k elements of the standard Gray binary code, and let $H(k, v)$ be the number of Hamiltonian paths in S_k that begin with 0 and end with v. Prove or disprove: $H(k, v) \le H(k, g(k-1))$ for all $v \in S_k$ that are adjacent to $g(k)$.

48. [*36*] Prove that $d(n) \le 4(n/2)^{2^n}$ if the conjecture in the previous exercise is true. [*Hint:* Let $d(n, k)$ be the number of n-bit Gray codes that begin with $g(0) \ldots g(k-1)$; the conjecture implies that $d(n) \le c_{n1} \ldots c_{n(k-1)} d(n, k)$, where c_{nk} is the number of vertices adjacent to $g(k-1)$ in the n-cube but not in S_k.]

49. [*20*] Prove that for all $n \ge 1$ there is a $2n$-bit Gray code in which $v_{k+2^{2n-1}}$ is the complement of v_k, for all $k \ge 0$.

▸ **50.** [*21*] Find a construction like that of Theorem D but with l even.

51. [*M24*] Complete the proof of Corollary B to Theorem D.

52. [*M20*] Prove that if the transition counts of an n-bit Gray code satisfy $c_0 \le c_1 \le \cdots \le c_{n-1}$, we must have $c_0 + \cdots + c_{j-1} \ge 2^j$, with equality when $j = n$.

53. [*M46*] If the numbers $(c_0, \ldots, c_{n-1})$ are even and satisfy the condition of the previous exercise, is there always an n-bit Gray code with these transition counts?

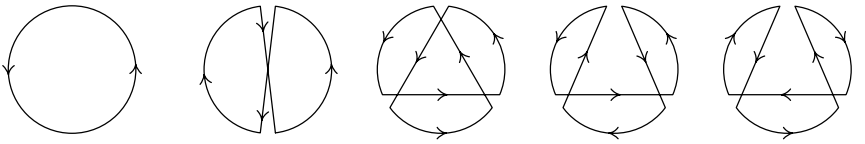
54. [*M20*] (H. S. Shapiro, 1953.) Show that if a sequence of integers $(a_1, \ldots, a_{2^n})$ contains only n distinct values, then there is a subsequence whose product $a_{k+1} a_{k+2} \ldots a_l$ is a perfect square, for some $0 \le k < l \le 2^n$. However, this conclusion might not be true if we disallow the case $l = 2^n$.

55. [*47*] (F. Ruskey and C. Savage, 1993.) If $(v_0, \ldots, v_{2^n-1})$ is an n-bit Gray code, the pairs $\{\, \{v_{2k}, v_{2k+1}\} \mid 0 \le k < 2^{n-1} \,\}$ form a perfect matching between the vertices of even and odd parity in the n-cube. Conversely, does every such perfect matching arise as "half" of some n-bit Gray code?

56. [*M30*] (E. N. Gilbert, 1958.) Say that two Gray codes are equivalent if their delta sequences can be made equal by permuting the coordinate names, or by reversing the

cycle and/or starting the cycle at a different place. Show that the 2688 different 4-bit Gray codes fall into just 9 equivalence classes.

57. [*32*] Consider a graph whose vertices are the 2688 possible 4-bit Gray codes, where two such Gray codes are adjacent if they are related by one of the following simple transformations:



Before After Type 1 After Type 2 After Type 3 After Type 4

(Type 1 changes arise when the cycle can be broken into two parts and reassembled with one part reversed. Types 2, 3, and 4 arise when the cycle can be broken into three parts and reassembled after reversing 0, 1, or 2 of the parts. The parts need not have equal size. Such transformations of Hamiltonian circuits are often possible.)

Write a program to discover which 4-bit Gray codes are transformable into each other, by finding the connected components of the graph; restrict consideration to only one of the four types at a time.

▸ **58.** [*21*] Let α be the delta sequence of an n-bit Gray code, and obtain β from α by changing q occurrences of 0 to n, where q is odd. Prove that $\beta\beta$ is the delta sequence of an $(n+1)$-bit Gray code.

59. [*22*] The 5-bit Gray code of (30) is *nonlocal* in the sense that no 2^t consecutive elements belong to a single t-subcube, for $1 < t < n$. Prove that nonlocal n-bit Gray codes exist for all $n \geq 5$. [*Hint:* See the previous exercise.]

60. [*20*] Show that the run-length-bound function satisfies $r(n+1) \geq r(n)$.

61. [*M30*] Show that $r(m+n) \geq r(m) + r(n) - 1$ if (a) $m = 2$ and $2 < r(n) < 8$; or (b) $m \leq n$ and $r(n) \leq 2^{m-3}$.

62. [*46*] Does $r(8) = 6$?

63. [*30*] (Luis Goddyn.) Prove that $r(10) \geq 8$.

▸ **64.** [*HM35*] (L. Goddyn and P. Gvozdjak.) An n-bit *Gray stream* is a sequence of permutations $(\sigma_0, \sigma_1, \ldots, \sigma_{l-1})$ where each σ_k is a permutation of the vertices of the n-cube, taking every vertex to one of its neighbors.

a) Suppose $(u_0, \ldots, u_{2^m-1})$ is an m-bit Gray code and $(\sigma_0, \sigma_1, \ldots, \sigma_{2^m-1})$ is an n-bit Gray stream. Let $v_0 = 0 \ldots 0$ and $v_{k+1} = v_k\sigma_k$, where $\sigma_k = \sigma_{k \bmod 2^m}$ if $k \geq 2^m$. Under what conditions is the sequence

$$W = (u_0v_0,\ u_0v_1,\ u_1v_1,\ u_1v_2,\ \ldots,\ u_{2^{m+n-1}-1}v_{2^{m+n-1}-1},\ u_{2^{m+n-1}-1}v_{2^{m+n-1}})$$

an $(m+n)$-bit Gray code?

b) Show that if m is sufficiently large, there is an n-bit Gray stream satisfying the conditions of (a) for which all run lengths of the sequence $(v_0, v_1, \ldots)$ are $\geq n-2$.

c) Apply these results to prove that $r(n) \geq n - O(\log n)$.

65. [*30*] (Brett Stevens.) In Samuel Beckett's play *Quad*, the stage begins and ends empty; n actors enter and exit one at a time, running through all 2^n possible subsets, and the actor who leaves is always the one whose previous entrance was earliest. When $n = 4$, as in the actual play, some subsets are necessarily repeated. Show, however, that there is a perfect pattern with exactly 2^n entrances and exits when $n = 5$.

66. [*40*] Is there a perfect Beckett–Gray pattern for 8 actors?

67. [*20*] Sometimes it is desirable to run through all n-bit binary strings by changing as *many* bits as possible from one step to the next, for example when testing a physical circuit for reliable behavior in worst-case conditions. Explain how to traverse all binary n-tuples in such a way that each step changes n or $n-1$ bits, alternately.

68. [*21*] Peter Q. Perverse decided to construct an *anti-Gray* ternary code, in which each n-trit number differs from its neighbors in *every* digit position. Is such a code possible for all n?

▸ **69.** [*M25*] Modify the definition of Gray binary code (7) by letting

$$h(k) = \big(\dots(b_6 \oplus b_5)(b_5 \oplus b_4)(b_4 \oplus b_3 \oplus b_2 \oplus b_0)(b_3 \oplus b_0)(b_2 \oplus b_1 \oplus b_0)b_1\big)_2,$$

when $k = (\dots b_5 b_4 b_3 b_2 b_1 b_0)_2$.

a) Show that the sequence $h(0)$, $h(1)$, $\dots$, $h(2^n-1)$ runs through all n-bit numbers in such a way that exactly 3 bits change each time, when $n > 3$.

b) Generalize this rule to obtain sequences in which exactly t bits change at each step, when t is odd and $n > t$.

70. [*21*] How many monotonic n-bit Gray paths exist for $n = 5$ and $n = 6$?

71. [*M22*] Derive (45), the recurrence that defines the Savage–Winkler permutations.

72. [*20*] What is the Savage–Winkler path from 00000 to 11111?

▸ **73.** [*32*] Design an efficient algorithm to construct the delta sequence of an n-bit monotonic Gray path.

74. [*M25*] (Savage and Winkler.) How far apart can adjacent vertices of the n-cube be, in a monotonic Gray path?

75. [*32*] Find all 5-bit Gray paths v_0, $\dots$, v_{31} that are *trend-free*, in the sense that $\sum_{k=0}^{31} k(-1)^{v_{kj}} = 0$ in each coordinate position j.

76. [*M25*] Prove that trend-free n-bit Gray paths exist for all $n \geq 5$.

77. [*21*] Modify Algorithm H in order to visit mixed-radix n-tuples in *modular* Gray order.

78. [*M26*] Prove the conversion formulas (50) and (51) for reflected mixed-radix Gray paths, and derive analogous formulas for the modular case.

▸ **79.** [*M22*] When is the last n-tuple of the (a) reflected (b) modular mixed-radix Gray path adjacent to the first?

80. [*M20*] Explain how to run through all divisors of a number, given its prime factorization $p_1^{e_1} \dots p_t^{e_t}$, repeatedly multiplying or dividing by a single prime at each step.

81. [*M21*] Let (a_0, b_0), (a_1, b_1), $\dots$, (a_{m^2-1}, b_{m^2-1}) be the 2-digit m-ary modular Gray code. Show that, if $m > 2$, every edge (x, y) — $\big(x, (y+1) \bmod m\big)$ and (x, y) — $\big((x+1) \bmod m, y\big)$ occurs in one of the two cycles

$$(a_0, b_0) — (a_1, b_1) — \cdots — (a_{m^2-1}, b_{m^2-1}) — (a_0, b_0),$$
$$(b_0, a_0) — (b_1, a_1) — \cdots — (b_{m^2-1}, a_{m^2-1}) — (b_0, a_0).$$

▸ **82.** [*M25*] (G. Ringel, 1956.) Use the previous exercise to deduce that there exist four 8-bit Gray codes that, together, cover all edges of the 8-cube.

83. [*M46*] Can four *balanced* 8-bit Gray codes cover all edges of the 8-cube?

▸ **84.** [*25*] (Howard L. Dyckman.) Fig. 17 shows a fascinating puzzle called Loony Loop or the Gordian Knot, in which the object is to remove a flexible cord from the rigid loops that surround it. Show that the solution to this puzzle is inherently related to the reflected Gray ternary path.

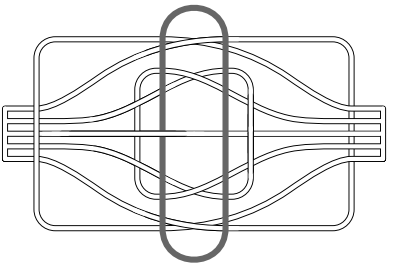


Fig. 17. The Loony Loop puzzle.

▸ **85.** [*M25*] (Dana Richards.) If $\Gamma = (\alpha_0, \ldots, \alpha_{t-1})$ is a sequence of t strings of length n and $\Gamma' = (\alpha'_0, \ldots, \alpha'_{t'-1})$ is a sequence of t' strings of length n', the *boustrophedon product* $\Gamma \boxtimes \Gamma'$ is the sequence of tt' strings of length $n+n'$ that begins

$$(\alpha_0\alpha'_0, \ldots, \alpha_0\alpha'_{t'-1}, \alpha_1\alpha'_{t'-1}, \ldots, \alpha_1\alpha'_0, \alpha_2\alpha'_0, \ldots, \alpha_2\alpha'_{t'-1}, \alpha_3\alpha'_{t'-1}, \ldots)$$

and ends with $\alpha_{t-1}\alpha'_0$ if t is even, $\alpha_{t-1}\alpha'_{t'-1}$ if t is odd. For example, the basic definition of Gray binary code in (5) can be expressed in this notation as $\Gamma_n = (0,1) \boxtimes \Gamma_{n-1}$ when $n > 0$. Prove that the operation $\boxtimes$ is associative, hence $\Gamma_{m+n} = \Gamma_m \boxtimes \Gamma_n$.

▸ **86.** [*26*] Define an infinite Gray path that runs through all possible nonnegative integer n-tuples $(a_1, \ldots, a_n)$ in such a way that $\max(a_1, \ldots, a_n) \le \max(a'_1, \ldots, a'_n)$ when $(a_1, \ldots, a_n)$ is followed by $(a'_1, \ldots, a'_n)$.

87. [*27*] Continuing the previous exercise, define an infinite Gray path that runs through *all* integer n-tuples $(a_1, \ldots, a_n)$, in such a way that $\max(|a_1|, \ldots, |a_n|) \le \max(|a'_1|, \ldots, |a'_n|)$ when $(a_1, \ldots, a_n)$ is followed by $(a'_1, \ldots, a'_n)$.

▸ **88.** [*25*] After Algorithm K has terminated in step K4, what would happen if we immediately restarted it in step K2?

▸ **89.** [*25*] (*Gray code for Morse code.*) The Morse code words of length n (exercise 4.5.3–32) are strings of dots and dashes, where n is the number of dots plus twice the number of dashes.

a) Show that it is possible to generate all Morse code words of length n by successively changing a dash to two dots or vice versa. For example, the path for $n = 3$ must be •—, •••, —• or its reverse.

b) What string follows •— —•• — — •— • in your sequence for $n = 15$?

90. [*26*] For what values of n can the Morse code words be arranged in a *cycle*, under the ground rules of exercise 89? [*Hint:* The number of code words is F_{n+1}.]

▸ **91.** [*34*] Design a loopless algorithm to visit all binary n-tuples $(a_1, \ldots, a_n)$ such that $a_1 \le a_2 \ge a_3 \le a_4 \ge \cdots$. [The number of such n-tuples is F_{n+2}.]

92. [*M30*] Is there an infinite sequence Φ_n whose first m^n elements form an m-ary de Bruijn cycle, for all m? [The case $n = 2$ is solved in (54).]

▸ **93.** [*M28*] Prove that Algorithm R outputs a de Bruijn cycle as advertised.

94. [*22*] What is the output of Algorithm D when $m = 5$, $n = 1$, $r = 3$, and both $f()$ and $g()$ are the trivial cycles 01234 01234 01...?

▸ **95.** [*M23*] Suppose an infinite sequence $a_0a_1a_2\ldots$ of period p is interleaved with an infinite sequence $b_0b_1b_2\ldots$ of period q to form the infinite cyclic sequence

$$c_0\,c_1c_2\,c_3c_4\,c_5\ldots = a_0\,b_0\,a_1b_1a_2\,b_2\ldots.$$

a) Under what circumstances does $c_0\,c_1c_2\ldots$ have period pq? (The "period" of a sequence $a_0a_1a_2\ldots$, for the purposes of this exercise, is the smallest integer $p>0$ such that $a_k=a_{k+p}$ for all $k\ge 0$.)

b) Which $2n$-tuples would occur as consecutive outputs of Algorithm D if step D6 were changed to say simply "If $t'=n$ and $x'<r$, go to D4"?

c) Prove that Algorithm D outputs a de Bruijn cycle as advertised.

▸ **96.** [*M23*] Suppose a family of coroutines has been set up to generate a de Bruijn cycle of length m^n using Algorithms R and D, based recursively on simple coroutines for the base case $n=2$.

a) How many coroutines of each type will there be?

b) What is the maximum number of coroutine activations needed to get one top-level digit of output?

97. [*M29*] The purpose of this exercise is to analyze the de Bruijn cycles constructed by Algorithms R and D in the important special case $m=2$. Let $f_n(k)$ be the $(k+1)$st bit of the 2^n-cycle, so that $f_n(k)=0$ for $0\le k<n$. Also let j_n be the index such that $0\le j_n<2^n$ and $f_n(k)=1$ for $j_n\le k<j_n+n$.

a) Write out the cycles $\big(f_n(0)\ldots f_n(2^n-1)\big)$ for $n=2$, 3, 4, and 5.

b) Prove that, for all even values of n, there is a number $\delta_n=\pm1$ such that we have

$$f_{n+1}(k)\equiv\begin{cases}\Sigma f_n(k), & \text{if } 0<k\le j_n \text{ or } 2^n+j_n<k\le 2^{n+1},\\ 1+\Sigma f_n(k+\delta_n), & \text{if } j_n<k\le 2^n+j_n,\end{cases}$$

where the congruence is modulo 2. (In this formula Σf stands for the summation function $\Sigma f(k)=\sum_{j=0}^{k-1}f(j)$.) Hence $j_{n+1}=2^n-\delta_n$ when n is even.

c) Let $\big(c_n(0)\,c_n(1)\ldots c_n(2^{2n}-5)\big)$ be the cycle produced when the simplified version of Algorithm D in exercise 95(b) is applied to $f_n()$. Where do the $(2n-1)$-tuples 1^{2n-1} and $(01)^{n-1}0$ occur in this cycle?

d) Use the results of (c) to express $f_{2n}(k)$ in terms of $f_n()$.

e) Find a (somewhat) simple formula for j_n as a function of n.

98. [*M34*] Continuing the previous exercise, design an efficient algorithm to compute $f_n(k)$, given $n\ge 2$ and $k\ge 0$.

▸ **99.** [*M23*] Exploit the technology of the previous exercises to design an efficient algorithm that locates any given n-bit string in the cycle $\big(f_n(0)f_n(1)\ldots f_n(2^n-1)\big)$.

100. [*40*] Do the de Bruijn cycles of exercise 97 provide a useful source of pseudo-random bits when n is large?

▸ **101.** [*M30*] (*Unique factorization of strings into nonincreasing primes.*)

a) Prove that if λ and λ' are prime, then $\lambda\lambda'$ is prime if $\lambda<\lambda'$.

b) Consequently every string α can be written in the form

$$\alpha=\lambda_1\lambda_2\ldots\lambda_t,\qquad \lambda_1\ge\lambda_2\ge\cdots\ge\lambda_t,\qquad \text{where each } \lambda_j \text{ is prime.}$$

c) In fact, only one such factorization is possible. *Hint:* Show that λ_t must be the lexicographically smallest nonempty suffix of α.

d) True or false: λ_1 is the longest prime prefix of α.

e) What are the prime factors of 31415926535897932384626433832795028841971?

102. [*HM28*] Deduce the number of m-ary primes of length n from the unique factorization theorem in the previous exercise.

103. [*M20*] Use Eq. (59) to prove Fermat's theorem that $m^p \equiv m$ (modulo p).

104. [*17*] According to formula (6o), about $1/n$ of all n-letter words are prime. How many of the 5757 five-letter GraphBase words are prime? Which of them is the smallest nonprime? The largest prime?

105. [*M31*] Let α be a preprime of length n.

a) Show that if the final letter of α is increased, the resulting string is prime.

b) If α has been factored as in exercise 101, show that it is the n-extension of λ_1.

c) Furthermore α cannot be the n-extension of two different primes.

▸ **106.** [*M30*] By reverse-engineering Algorithm F, design an algorithm that visits all m-ary primes and preprimes in *decreasing* order.

107. [*HM30*] Analyze the running time of Algorithm F.

108. [*M35*] Let $\lambda_1 < \cdots < \lambda_t$ be the m-ary prime strings whose lengths divide n, and let $a_1 \ldots a_n$ be any m-ary string. The object of this exercise is to prove that $a_1 \ldots a_n$ appears in $\lambda_1 \ldots \lambda_t \lambda_1 \lambda_2$; hence $\lambda_1 \ldots \lambda_t$ is a de Bruijn cycle (since it has length m^n). For convenience we may assume that $m = 10$ and that strings correspond to decimal numbers; the same arguments will apply for arbitrary $m \geq 2$.

a) Show that if $a_1 \ldots a_n = \alpha\beta$ is distinct from all its cyclic shifts, and if $\beta\alpha = \lambda_k$ is prime, then $\alpha\beta$ is a substring of $\lambda_k\lambda_{k+1}$, unless $\alpha = 9^j$ for some $j \geq 1$.

b) Where does $\alpha\beta$ appear in $\lambda_1 \ldots \lambda_t$ if $\beta\alpha$ is prime and α consists of all 9s? *Hint:* Show that if $a_{n+1-j} \ldots a_n = 9^l$ in step F2 for some $l > 0$, and if j is not a divisor of n, the previous step F2 had $a_{n-l} \ldots a_n = 9^{l+1}$.

c) Now consider n-tuples of the form $(\alpha\beta)^d$, where $d > 1$ is a divisor of n and $\beta\alpha = \lambda_k$ is prime.

d) Identify the positions of 899135, 997879, 913131, 090909, 909090, and 911911 when $n = 6$.

109. [*M22*] An m-ary de Bruijn torus of size $m^2 \times m^2$ for 2×2 windows is a matrix of m-ary digits a_{ij} such that each of the m^4 submatrices

$$\begin{pmatrix} a_{ij} & a_{i(j+1)} \\ a_{(i+1)j} & a_{(i+1)(j+1)} \end{pmatrix}, \qquad 0 \leq i, j < m^2$$

is different, where subscripts wrap around modulo m^2. Thus every possible m-ary 2×2 submatrix occurs exactly once; Ian Stewart [*Game, Set, and Math* (Oxford: Blackwell, 1989), Chapter 4] has therefore called it an m-ary *ourotorus*. For example,

$$\begin{pmatrix} 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 1 & 1 & 1 \\ 1 & 0 & 1 & 1 \end{pmatrix}$$

is a binary ourotorus; indeed, it is essentially the only such matrix when $m = 2$, except for shifting and/or transposition.

Consider the infinite matrix A whose entry in row $i = (\ldots a_2 a_1 a_0)_2$ and column $j = (\ldots b_2 b_1 b_0)_2$ is $a_{ij} = (\ldots c_2 c_1 c_0)_2$, where

$$c_0 = (a_0 \oplus b_0)(a_1 \oplus b_1) \oplus b_1;$$
$$c_k = (a_{2k} a_0 \oplus b_{2k})b_0 \oplus (a_{2k+1} a_0 \oplus b_{2k+1})(b_0 \oplus 1), \quad \text{for } k > 0.$$

Show that the upper left $2^{2n} \times 2^{2n}$ submatrix of A is a 2^n-ary ourotorus for all $n \geq 0$.

110. [*M25*] Continuing the previous exercise, construct m-ary ourotoruses for all m.

111. [*20*] We can obtain the number 100 in twelve ways by inserting + and − signs into the sequence 123456789; for example, $100 = 1 + 23 - 4 + 5 + 6 + 78 - 9 = 123 - 45 - 67 + 89 = -1 + 2 - 3 + 4 + 5 + 6 + 78 + 9$.

a) What is the smallest positive integer that cannot be represented in such a way?

b) Consider also inserting signs into the 10-digit sequence 9876543210.

▸ **112.** [*25*] Continuing the previous exercise, how far can we go by inserting signs into 123456789876543 21? For example, $100 = -1234 - 5 - 6 + 7898 - 7 - 6543 - 2 - 1$.

ANSWERS TO EXERCISES

All that heard him were astonished
at his understanding and answers.
— Luke 2:47

SECTION 7.2.1.1

1. Let $m_j = u_j - l_j + 1$, and visit $(a_1 + l_1, \ldots, a_n + l_n)$ instead of visiting $(a_1, \ldots, a_n)$ in Algorithm M. Or, change '$a_j \leftarrow 0$' to '$a_j \leftarrow l_j$' and '$a_j = m_j - 1$' to '$a_j = u_j$' in that algorithm, and set $l_0 \leftarrow 0$, $u_0 \leftarrow 1$ in step M1.

2. $(0, 0, 1, 2, 3, 0, 2, 7, 0, 9)$.

3. Step M4 is performed $m_1 m_2 \ldots m_k$ times when $j = k$; therefore the total is $\sum_{k=0}^{n} \prod_{j=1}^{k} m_j = m_1 \ldots m_n (1 + 1/m_n + 1/m_n m_{n-1} + \cdots + 1/m_n \ldots m_1)$. If all m_j are 2 or more, this is less than $2m_1 \ldots m_n$. [Thus, we should keep in mind that fancy Gray-code methods, which change only one digit per visit, actually reduce the total number of digit changes by at most a factor of 2.]

4. **N1.** [Initialize.] Set $a_j \leftarrow m_j - 1$ for $0 \le j \le n$, where $m_0 = 2$.

N2. [Visit.] Visit the n-tuple $(a_1, \ldots, a_n)$.

N3. [Prepare to subtract one.] Set $j \leftarrow n$.

N4. [Borrow if necessary.] If $a_j = 0$, set $a_j \leftarrow m_j - 1$, $j \leftarrow j - 1$, and repeat this step.

N5. [Decrease, unless done.] If $j = 0$, terminate the algorithm. Otherwise set $a_j \leftarrow a_j - 1$ and go back to step N2. ∎

5. Bit reflection is easy on a machine like `MMIX`, but on other computers we can proceed as follows:

R1. [Initialize.] Set $j \leftarrow k \leftarrow 0$.

R2. [Swap.] Interchange $A[j + 1] \leftrightarrow A[k + 2^{n-1}]$. Also, if $j > k$, interchange $A[j] \leftrightarrow A[k]$ and $A[j + 2^{n-1} + 1] \leftrightarrow A[k + 2^{n-1} + 1]$.

R3. [Advance k.] Set $k \leftarrow k + 2$, and terminate if $k \ge 2^{n-1}$.

R4. [Advance j.] Set $h \leftarrow 2^{n-2}$. If $j \ge h$, repeatedly set $j \leftarrow j - h$ and $h \leftarrow h/2$ until $j < h$. Then set $j \leftarrow j + h$. (Now $j = (b_0 \ldots b_{n-1})_2$ if $k = (b_{n-1} \ldots b_0)_2$.) Return to R2. ∎

6. If $g\big((0b_{n-1} \ldots b_1 b_0)_2\big) = \big(0(b_{n-1}) \ldots (b_2 \oplus b_1)(b_1 \oplus b_0)\big)_2$ then $g\big((1b_{n-1} \ldots b_1 b_0)_2\big) = 2^n + g\big((0\overline{b}_{n-1} \ldots \overline{b}_1 \overline{b}_0)_2\big) = \big(1(\overline{b}_{n-1}) \ldots (\overline{b}_2 \oplus \overline{b}_1)(\overline{b}_1 \oplus \overline{b}_0)\big)_2$, where $\overline{b} = b \oplus 1$.

7. To accommodate $2r$ sectors one can use $g(k)$ for $2^n - r \le k < 2^n + r$, where $n = \lceil \lg r \rceil$, because $g(2^n - r) \oplus g(2^n + r - 1) = 2^n$ by (5). [G. C. Tootill, *Proc. IEE* **103**, Part B Supplement (1956), 434.] See also exercise 26.

8. Use Algorithm G with $n \leftarrow n-1$ and include the parity bit a_∞ at the right. (This yields $g(0)$, $g(2)$, $g(4)$, ...)

9. Replace the rightmost ring, since $\nu(1011000)$ is odd.

10. $A_n + B_n = g^{[-1]}(2^n - 1) = \lfloor 2^{n+1}/3 \rfloor$ and $A_n = B_n + n$. Hence $A_n = \lfloor 2^n/3 + n/2 \rfloor$ and $B_n = \lfloor 2^n/3 - n/2 \rfloor$.

Historical notes: The early Japanese mathematician Yoriyuki Arima (1714–1783) treated this problem in his *Shūki Sanpō* (1769), Problem 44, observing that the n-ring puzzle reduces to an $(n-1)$-ring puzzle after a certain number of steps. Let $C_n = A_n - A_{n-1} = B_n - B_{n-1} + 1$ be the number of rings removed during this reduction. Arima noticed that $C_n = 2C_{n-1} - [n \text{ even}]$; thus he could compute $A_n = C_1 + C_2 + \cdots + C_n$ for $n = 9$ without actually knowing the formula $C_n = \lceil 2^{n-1}/3 \rceil$.

More than two centuries earlier, Cardano had already mentioned the "complicati annuli" in his *De Subtilitate Libri XXI* (Nuremberg: 1550), Book 15. He wrote that they are "useless yet admirably subtle," stating erroneously that 95 moves are needed to remove seven rings and 95 more to put them back. John Wallis devoted seven pages to this puzzle in the Latin edition of his *Algebra* **2** (Oxford: 1693), Chapter 111, presenting detailed but nonoptimum methods for the nine-ring case. He included the operation of sliding a ring through the bar as well as putting it on or off, and he hinted that shortcuts were available, but he did not attempt to find a shortest solution.

11. The solution to $S_n = S_{n-2} + 1 + S_{n-2} + S_{n-1}$ when $S_1 = S_2 = 1$ is $S_n = 2^{n-1} - [n \text{ even}]$. [*Math. Quest. Educational Times* **3** (1865), 66–67.]

12. (a) The theory of $n-1$ Chinese rings proves that Gray binary code yields the compositions in a convenient order (4, 31, 211, 22, 112, 1111, 121, 13):

A1. [Initialize.] Set $t \leftarrow 0$, $j \leftarrow 1$, $s_1 \leftarrow n$. (We assume that $n > 1$.)

A2. [Visit.] Visit $s_1 \ldots s_j$. Then set $t \leftarrow 1 - t$, and go to A4 if $t = 0$.

A3. [Odd step.] If $s_j > 1$, set $s_j \leftarrow s_j - 1$, $s_{j+1} \leftarrow 1$, $j \leftarrow j + 1$; otherwise set $j \leftarrow j - 1$ and $s_j \leftarrow s_j + 1$. Return to A2.

A4. [Even step.] If $s_{j-1} > 1$, set $s_{j-1} \leftarrow s_{j-1} - 1$, $s_{j+1} \leftarrow s_j$, $s_j \leftarrow 1$, $j \leftarrow j + 1$; otherwise set $j \leftarrow j - 1$, $s_j \leftarrow s_{j+1}$, $s_{j-1} \leftarrow s_{j-1} + 1$ (but terminate if $j - 1 = 0$). Return to A2. ∎

(b) Now $q_1, \ldots, q_{t-1}$ represent rings on the bar:

B1. [Initialize.] Set $t \leftarrow 1$, $q_0 \leftarrow n$. (We assume that $n > 1$.)

B2. [Visit.] Set $q_t \leftarrow 0$ and visit $(q_0 - q_1) \ldots (q_{t-1} - q_t)$. Go to B4 if t is even.

B3. [Odd step.] If $q_{t-1} = 1$, set $t \leftarrow t - 1$; otherwise set $q_t \leftarrow 1$ and $t \leftarrow t + 1$. Return to step B2.

B4. [Even step.] If $q_{t-2} = q_{t-1} + 1$, set $q_{t-2} \leftarrow q_{t-1}$ and $t \leftarrow t - 1$ (but terminate if $t = 2$); otherwise set $q_t \leftarrow q_{t-1}$, $q_{t-1} \leftarrow q_t + 1$, $t \leftarrow t + 1$. Return to B2. ∎

These algorithms [see J. Misra, *ACM Trans. Math. Software* **1** (1975), 285] are loopless even in their initialization steps.

13. In step A1, also set $C \leftarrow 1$. In step A3, set $C \leftarrow s_j C$ if $s_j > 1$, otherwise $C \leftarrow C/(s_{j-1}+1)$. In step A4, set $C \leftarrow s_{j-1} C$ if $s_{j-1} > 1$, otherwise $C \leftarrow C/(s_{j-2}+1)$.

Similar modifications apply to steps B1, B3, B4. Sufficient precision is needed to accommodate the value $C = n!$ for the composition $1 \ldots 1$; we are stretching the definition of looplessness by assuming that arithmetic operations take unit time.

14. **S1.** [Initialize.] Set $j \leftarrow 0$.

S2. [Visit.] Visit the string $a_1 \ldots a_j$.

S3. [Lengthen.] If $j < n$, set $j \leftarrow j + 1$, $a_j \leftarrow 0$, and return to S2.

S4. [Increase.] If $a_j < m_j - 1$, set $a_j \leftarrow a_j + 1$ and return to S2.

S5. [Shorten.] Set $j \leftarrow j - 1$, and return to S4 if $j > 0$. ∎

15. **T1.** [Initialize.] Set $j \leftarrow 0$.

T2. [Even visit.] If j is even, visit the string $a_1 \ldots a_j$.

T3. [Lengthen.] If $j < n$, set $j \leftarrow j + 1$, $a_j \leftarrow 0$, and return to T2.

T4. [Odd visit.] If j is odd, visit the string $a_1 \ldots a_j$.

T5. [Increase.] If $a_j < m_j - 1$, set $a_j \leftarrow a_j + 1$ and return to T2.

T6. [Shorten.] Set $j \leftarrow j - 1$, and return to T4 if $j > 0$. ∎

This algorithm is loopless, although it may appear at first glance to contain loops, because four steps separate consecutive visits. The basic idea is related to exercise 2.3.1–5 and to "prepostorder" traversal (exercise 7.2.1.3–00).

16. Suppose $\texttt{LINK}(j-1{:}b) = j{:}(b \oplus a_j)$ for $1 \le j \le n$, and $\texttt{LINK}(n{:}b) = \Lambda$. These links represent $(b_1, \ldots, b_n)$ if and only if $g(b_1 \ldots b_n) = a_1 \ldots a_n$, so we can use a loopless Gray binary generator to achieve the desired result.

17. Put the concatenation of 3-bit codes $\big(g(j), g(k)\big)$ in row j and column k, for $0 \le j, k < 8$. [It is not difficult to prove that this is essentially the *only* solution, except for permuting and/or complementing coordinates and/or rotating rows, because the coordinate that changes when moving north or south depends only on the row, and a similar statement applies to columns. Karnaugh's isomorphism between the 4-cube and the 4×4 torus can be traced back to *The Design of Switching Circuits* by W. Keister, A. E. Ritchie, and S. H. Washburn (1951), page 174. Incidentally, Keister went on to design an ingenious variant of Chinese rings called SpinOut, and a generalization called The Hexadecimal Puzzle, *U.S. Patents 3637215–3637216* (1972).]

18. Use 2-bit Gray code to represent the digits $u_j = (0, 1, 2, 3)$ respectively as the bit pairs $u'_{2j-1}u'_{2j} = (00, 01, 11, 10)$. [C. Y. Lee introduced his metric in *IEEE Trans.* **IT-4** (1958), 77–82. A similar $m/2$-bit encoding works for even values of m; for example, when $m = 8$ we can represent $(0, 1, 2, 3, 4, 5, 6, 7)$ by $(0000, 0001, 0011, 0111, 1111, 1110, 1100, 1000)$. But such a scheme leaves out some of the binary patterns when $m > 4$.]

19. (a) A modular Gray quaternary algorithm needs slightly less computation than Algorithm M, but it doesn't matter because 256 is so small. The result is $z_0^8 + z_1^8 + z_2^8 + z_3^8 + 14(z_0^4 z_2^4 + z_1^4 z_3^4) + 56 z_0 z_1 z_2 z_3 (z_0^2 + z_2^2)(z_1^2 + z_3^2)$.

(b) Replacing (z_0, z_1, z_2, z_3) by $(1, z, z^2, z)$ gives $1 + 112z^6 + 30z^8 + 112z^{10} + z^{16}$; thus all of the nonzero Lee weights are ≥ 6. Now use the construction in the previous exercise to convert each $(u_0, u_1, u_2, u_3, u_4, u_5, u_6, u_\infty)$ into a 16-bit number.

20. Recover the quaternary vector $(u_0, u_1, u_2, u_3, u_4, u_5, u_6, u_\infty)$ from u', and use Algorithm 4.6.1D to find the remainder of $u_0 + u_1 x + \cdots + u_6 x^6$ divided by $g(x)$, mod 4; that algorithm can be used in spite of the fact that the coefficients do not belong to a field, because $g(x)$ is monic. Express the remainder as $x^j + 2x^k$ (modulo $g(x)$ and 4), and let $d = (k - j) \bmod 4$, $s = (u_0 + \cdots + u_6 + u_\infty) \bmod 4$.

Case 1, $s = 1$: If $k = \infty$, the error was x^j (in other words, the correct vector has $u_j \leftarrow (u_j - 1) \bmod 4$); otherwise there were three or more errors.

Case 2, $s = 3$: If $j = k$ the error was x^j; otherwise ≥ 3 errors occurred.

Case 3, $s = 0$: If $j = k = \infty$, no errors were made; if $j = \infty$ and $k < \infty$, at least four errors were made. Otherwise the errors were $x^a - x^b$, where $a = \big(j + (\infty, 3, 6, 1, 5, 4, 2, 0)\big) \bmod 7$ according as $d = (0, 1, 2, 3, 4, 5, 6, \infty)$, and $b = (j+2d) \bmod 7$.

Case 4, $s = 2$: If $j = \infty$ the errors were $2x^k$. Otherwise the errors were

$$\begin{aligned} x^j + x^\infty&, \text{ if } k = \infty; \\ -x^j - x^\infty&, \text{ if } d = 0; \\ x^a + x^b&, \text{ if } d \in \{1, 2, 4\},\ a = (j - 3d) \bmod 7,\ b = (j - 2d) \bmod 7; \\ -x^a - x^b&, \text{ if } d \in \{3, 5, 6\},\ a = (j - 3d) \bmod 7,\ b = (j - d) \bmod 7. \end{aligned}$$

Given $u' = (1100100100001111)_2$, we have $u = (2, 0, 3, 1, 0, 0, 2, 2)$ and $2 + 3x^2 + x^3 + 2x^6 \equiv 1 + 3x + 3x^2 \equiv x^5 + 2x^6$; also $s = 2$. Thus the errors are $x^2 + x^3$, and the nearest errorfree codeword is $(2, 0, 2, 0, 0, 0, 2, 2)$. Algorithm 4.6.1D tells us that $2 + 2x^2 + 2x^6 \equiv (2 + 2x + 2x^3)g(x)$ (modulo 4); so the eight information bits are $(11110011)_2$, corresponding to $(v_0, v_1, v_2, v_3) = (2, 2, 0, 2)$. [A more intelligent algorithm would also say, "Aha: The first 16 bits of π."]

For generalizations to other efficient coding schemes based on quaternary vectors, see the classic paper by Hammons, Kumar, Calderbank, Sloane, and Solé, *IEEE Trans.* **IT-40** (1994), 301–319.

21. (a) $C(\epsilon) = 1$, $C(0\alpha) = C(1\alpha) = C(\alpha)$, and $C(*\alpha) = 2C(\alpha) - [10\ldots0 \in \alpha]$. Iterating this recurrence gives $C(\alpha) = 2^t - 2^{t-1}e_t - 2^{t-2}e_{t-1} - \cdots - 2^0 e_1$, where $e_j = [10\ldots0 \in \alpha_j]$ and α_j is the suffix of α following the jth asterisk. In the example we have $\alpha_1 = *10{*}{*}0*$, $\alpha_2 = 10{*}{*}0*$, ..., $\alpha_5 = \epsilon$; thus $e_1 = 0$, $e_2 = 1$, $e_3 = 1$, $e_4 = 0$, and $e_5 = 1$ (by convention), hence $C({*}{*}10{*}{*}0*) = 2^5 - 2^4 - 2^2 - 2^1 = 10$.

(b) We may remove trailing asterisks so that $t = t'$. Then $e_t = 1$ implies $e_{t-1} = \cdots = e_1 = 0$. [The case $C(\alpha) = 2^{t'-1}$ occurs if and only if α ends in 10^j*^k.]

(c) To compute the sum of $C(\alpha)$ over all t-subcubes, note that $\binom{n}{t}$ clusters begin at the n-tuple $0\ldots0$, and $\binom{n-1}{t}$ begin at each succeeding n-tuple (namely one cluster for each t-subcube containing that n-tuple and specifying the bit that changed). Thus the average is $\big(\binom{n}{t} + (2^n - 1)\binom{n-1}{t}\big)/2^{n-t}\binom{n}{t} = 2^t(1 - t/n) + 2^{t-n}(t/n)$. [The formula in (c) holds for *any* n-bit Gray path, but (a) and (b) are specific to the reflected Gray binary code. These results are due to C. Faloutsos, *IEEE Trans.* **SE-14** (1988), 1381–1393.]

22. Let $\alpha*^j$ and $\beta*^k$ be consecutive lieves of a Gray binary trie, where α and β are binary strings and $j \leq k$. Then the last $k - j$ bits of α are a string α' such that α and $\beta\alpha'$ are consecutive elements of Gray binary code, hence adjacent. [Interesting applications of this property to cube-connected message-passing concurrent computers are discussed in *A VLSI Architecture for Concurrent Data Structures* by William J. Dally (Kluwer, 1987), Chapter 3.]

23. $2^j = g(k) \oplus g(l) = g(k \oplus l)$ implies that $l = k \oplus g^{[-1]}(2^j) = k \oplus (2^{j+1} - 1)$. In other words, if $k = (b_{n-1}\ldots b_0)_2$ we have $l = (b_{n-1}\ldots b_{j+1}\overline{b}_j\ldots\overline{b}_0)_2$.

24. Defining $g(k) = k \oplus \lfloor k/2 \rfloor$ as usual, we find $g(k) = g(-1-k)$; hence there are *two* 2-adic integers k such that $g(k)$ has a given 2-adic value l. One of them is even, the other is odd. We can conveniently define $g^{[-1]}$ to be the solution that is even; then (8) is replaced by $b_j = a_{j-1} \oplus \cdots \oplus a_0$, for $j \geq 0$. For example, $g^{[-1]}(1) = -2$ by this definition; when l is a normal integer, the "sign" of $g^{[-1]}(l)$ is the parity of l.

25. Let $p = k \oplus l$; exercise 7.1–00 tells us that $2^{\lfloor \lg p \rfloor + 1} - p \le |k - l| \le p$. We have $\nu(g(p)) = \nu(g(k) \oplus g(l)) = t$ if and only if there are positive integers $j_1, \ldots, j_t$ such that $p = (1^{j_1}0^{j_2}1^{j_3}\ldots(0 \text{ or } 1)^{j_t})_2$. The largest possible $p < 2^n$ occurs when $j_1 = n + 1 - t$ and $j_2 = \cdots = j_t = 1$, yielding $p = 2^n - \lceil 2^t/3 \rceil$. The smallest possible $2^{\lfloor \lg p \rfloor + 1} - p = (1^{j_2}0^{j_3}\ldots(1 \text{ or } 0)^{j_t})_2 + 1$ occurs when $j_2 = \cdots = j_t = 1$, yielding $p = \lceil 2^t/3 \rceil$. [C. K. Yuen, *IEEE Trans.* **IT-20** (1974), 668; S. R. Cavior, *IEEE Trans.* **IT-21** (1975), 596.]

26. Let $N = 2^{n_t} + \cdots + 2^{n_1}$ where $n_t > \cdots > n_1 \ge 0$; also, let Γ_n be any Gray code for $\{0, 1, \ldots, 2^n - 1\}$ that begins at 0 and ends at 1, except that Γ_0 is simply 0. Use

$$\Gamma^R_{n_t},\ 2^{n_t}+\Gamma_{n_{t-1}},\ \ldots,\ 2^{n_t}+\cdots+2^{n_3}+\Gamma^R_{n_2},\ 2^{n_t}+\cdots+2^{n_2}+\Gamma_{n_1},\ \text{if } t \text{ is even;}$$

$$\Gamma_{n_t},\ 2^{n_t}+\Gamma^R_{n_{t-1}},\ \ldots,\ 2^{n_t}+\cdots+2^{n_3}+\Gamma^R_{n_2},\ 2^{n_t}+\cdots+2^{n_2}+\Gamma_{n_1},\ \text{if } t \text{ is odd.}$$

27. In general, if $k = (b_{n-1}\ldots b_0)_2$, the $(k+1)$st largest element of S_n is equal to

$$1/\big(2 - (-1)^{a_{n-1}}/\big(2 - \cdots/\big(2 - (-1)^{a_1}/\big(2 - (-1)^{a_0}\big)\big)\ldots\big)\big),$$

corresponding to the sign pattern $g(k) = (a_{n-1}\ldots a_0)_2$. Thus we can compute any element of S_n in $O(n)$ steps, given its rank. Setting $k = 2^{100} - 10^{10}$ and $n = 100$ yields the answer 373065177/1113604409. [Whenever $f(x)$ is a positive and monotonic function, the 2^n elements $f(\pm f(\ldots \pm f(\pm x)\ldots))$ are ordered according to Gray binary code, as observed by H. E. Salzer, *CACM* **16** (1973), 180. In this particular case there is, however, another way to get the answer, because we also have $S_n = //2, \pm 2, \ldots, \pm 2, \pm 1//$ using the notation of Section 4.5.3; continued fractions in this form are ordered by complementing alternate bits of k.]

28. (a) As $t = 1, 2, \ldots$, bit a_j of median(G_t) runs through the periodic sequence

$$0, \ldots, 0, *, 1, \ldots, 1, *, 0, \ldots, 0, *, \ldots$$

with asterisks at every 2^{1+j}th step. Thus the strings that correspond to the binary representations of $\lfloor (t-1)/2 \rfloor$ and $\lfloor t/2 \rfloor$ are medians. And those strings are in fact "extreme" cases, in the sense that all medians agree with the common bits of $\lfloor (t-1)/2 \rfloor$ and $\lfloor t/2 \rfloor$, hence asterisks appear where they disagree. For example, when $t = 100 = (01100100)_2$ and $n = 8$, we have median$(G_{100}) = 001100{*}{*}$.

(b) If α is $g(p)$ and β is $g(q)$ in Gray binary, we have $p = (p_{n-1}\ldots p_0)_2$ and $q = (p_{n-1}\ldots p_{j+1}\overline{p}_j\ldots\overline{p}_0)_2$, where $p_{j+1} \oplus p_j = a'_j \ne a_j$. By (a), either t or $t-1$ lies in $(a_{n-1}\ldots a_0{*})_2$. Now if $p_j = 1$, clearly $q < p < t$. And if $p_j = 0$ we have $p_{j+1} = \overline{a}_j$; hence $p < t$ implies $q < t$. [See A. J. Bernstein, K. Steiglitz, and J. E. Hopcroft, *IEEE Trans.* **IT-12** (1966), 425–430.]

29. Assuming that $p \ne 0$, let $l = \lfloor \lg p \rfloor$ and $S_a = \{s \mid 2^l a \le s < 2^l(a+1)\}$ for $0 \le a < 2^{n-l}$. Then $(k \oplus p) - k$ has a constant sign for all $k \in S_a$, and

$$\sum_{k \in S_a} \Big|(k \oplus p) - k\Big| = 2^l \|S_a\| = 2^{2l}.$$

Also $g^{[-1]}(g(k) \oplus p) = k \oplus g^{[-1]}(p)$, and $\lfloor \lg g^{[-1]}(p) \rfloor = \lfloor \lg p \rfloor$. Therefore

$$\frac{1}{2^n}\sum_{k=0}^{2^n-1}\Big|g^{[-1]}(g(k)\oplus p) - k\Big| = \frac{1}{2^n}\sum_{a=0}^{2^{n-l}-1}\sum_{k\in S_a}\Big|(k \oplus g^{[-1]}(p)) - k\Big| = \frac{1}{2^n}\sum_{a=0}^{2^{n-l}-1} 2^{2l} = 2^l.$$

[See Morgan M. Buchner, Jr., *Bell System Tech. J.* **48** (1969), 3113–3130.]

30. The cycle containing $k > 1$ has length $2^{\lfloor \lg \lg k \rfloor + 1}$, because it is easy to show from Eq. (7) that if $k = (b_{n-1} \dots b_0)_2$ we have

$$g^{[2^l]}(k) = (c_{n-1} \dots c_0)_2, \qquad \text{where } c_j = b_j \oplus b_{j+l+1}.$$

To permute all elements k such that $\lfloor \lg k \rfloor = t$, there are two cases: If t is a power of 2, the cycle containing $2\lfloor k/2 \rfloor$ also contains $2\lfloor k/2 \rfloor + 1$, so we must double the cycle leaders for $t-1$. Otherwise the cycle containing $2\lfloor k/2 \rfloor$ is disjoint from the cycle containing $2\lfloor k/2 \rfloor + 1$, so $L_t = (2L_{t-1}) \cup (2L_{t-1}+1) = (L_{t-1}*)_2$. This argument, discovered by Jörg Arndt in 2001, establishes the hint and yields the following algorithm:

P1. [Initialize.] Set $t \leftarrow 1$, $m \leftarrow 0$. (We may assume that $n \geq 2$.)

P2. [Loop through leaders.] Set $r \leftarrow m$. Perform Algorithm Q with $k = 2^t + r$; then if $r > 0$, set $r \leftarrow (r-1) \wedge m$ and repeat until $r = 0$. [See exercise 7.1–00.]

P3. [Increase $\lg k$.] Set $t \leftarrow t + 1$. Terminate if t is now equal to n; otherwise set $m \leftarrow 2m + [t \wedge (t-1) \neq 0]$ and return to P2. ▮

Q1. [Begin a cycle.] Set $s \leftarrow X_k$, $l \leftarrow k$, $j \leftarrow l \oplus \lfloor l/2 \rfloor$.

Q2. [Follow the cycle.] If $j \neq k$ set $X_l \leftarrow X_j$, $l \leftarrow j$, $j \leftarrow l \oplus \lfloor l/2 \rfloor$, and repeat until $j = k$. Then set $X_l \leftarrow s$. ▮

31. We get a field from f_n if and only if we get one from $f_n^{[2]}$, which takes $(a_{n-1} \dots a_0)_2$ to $\big((a_{n-1} \oplus a_{n-2})(a_{n-1} \oplus a_{n-3})(a_{n-2} \oplus a_{n-4}) \dots (a_2 \oplus a_0)(a_1)\big)_2$. Let $c_n(x)$ be the characteristic polynomial of the matrix A defining this transformation, mod 2; then $c_1(x) = x + 1$, $c_2(x) = x^2 + x + 1$, and $c_{n+1}(x) = xc_n(x) + c_{n-1}(x)$. Since $c_n(A)$ is the zero matrix, by the Cayley–Hamilton theorem, a field is obtained if and only if $c_n(x)$ is a primitive polynomial, and this condition can be tested as in Section 3.2.2. The first such values of n are 1, 2, 3, 5, 6, 9, 11, 14, 23, 29, 30, 33, 35, 39, 41, 51, 53, 65, 69, 74, 81, 83, 86, 89, 90, 95.

[Running the recurrence backwards shows that $c_{-j-2}(x) = c_j(x)$, hence $c_j(x)$ divides $c_{(2j+1)k+j}(x)$; for example, $c_{3k+1}(x)$ is always a multiple of $x+1$. All numbers n of the form $2jk + j + k$ are therefore excluded when $j > 0$ and $k > 0$. The polynomials $c_{18}(x)$, $c_{50}(x)$, $c_{98}(x)$, and $c_{99}(x)$ are irreducible but not primitive.]

32. Mostly true, but false at the points where x changes sign. (Walsh originally suggested that $w_k(x)$ should be zero at such points; but the convention adopted here is better, because it makes simple formulas like (15)–(19) valid for all x.)

33. By induction on k, we have

$$w_k(x) = w_{\lfloor k/2 \rfloor}(2x) = r_1(2x)^{b_1+b_2} r_2(2x)^{b_2+b_3} \dots = r_1(x)^{b_0+b_1} r_2(x)^{b_1+b_2} r_3(x)^{b_2+b_3} \dots$$

for $0 \leq x < \frac{1}{2}$, because $r_j(2x) = r_{j+1}(x)$ and $r_1(x) = 1$ in this range. And when $\frac{1}{2} \leq x < 1$,

$$\begin{aligned} w_k(x) = (-1)^{\lceil k/2 \rceil} w_{\lfloor k/2 \rfloor}(2x-1) &= r_1(x)^{b_0+b_1} r_1(2x-1)^{b_1+b_2} r_2(2x-1)^{b_2+b_3} \dots \\ &= r_1(x)^{b_0+b_1} r_2(x)^{b_1+b_2} r_3(x)^{b_2+b_3} \dots \end{aligned}$$

because $\lceil k/2 \rceil \equiv b_0 + b_1$ (modulo 2) and $r_j(2x-1) = r_{j+1}(x - \frac{1}{2}) = r_{j+1}(x)$ for $j \geq 1$.

34. $p_k(x) = \prod_{j \geq 0} r_{j+1}^{b_j}$; hence $w_k(x) = p_k(x) p_{\lfloor k/2 \rfloor}(x) = p_{g(k)}(x)$. [R. E. A. C. Paley, *Proc. London Math. Soc.* (2) **34** (1932), 241–279.]

35. If $j = (a_{n-1}\dots a_0)_2$ and $k = (b_{n-1}\dots b_0)_2$, the element in row j and column k is $(-1)^{f(j,k)}$, where $f(j,k)$ is the sum of all $a_r b_s$ such that: $r = s$ (Hadamard); $r+s = n-1$ (Paley); $r + s = n$ or $n-1$ (Walsh).

Let R_n, F_n, and G_n be permutation matrices for the permutations that take $j = (a_{n-1}\dots a_0)_2$ to $k = (a_0\dots a_{n-1})_2$, $k = 2^n - 1 - j = (\overline{a}_{n-1}\dots\overline{a}_0)_2$, and $k = g^{[-1]}(j) = \big((a_{n-1})\dots(a_{n-1}\oplus\cdots\oplus a_0)\big)_2$, respectively. Then, using the Kronecker product of matrices, we have the recursive formulas

$$R_{n+1} = \begin{pmatrix} R_n\otimes(1\ 0)\\ R_n\otimes(0\ 1)\end{pmatrix},\qquad F_{n+1} = F_n\otimes\begin{pmatrix}0&1\\1&0\end{pmatrix},\qquad G_{n+1} = \begin{pmatrix}G_n&0\\0&G_nF_n\end{pmatrix},$$

$$H_{n+1} = H_n\otimes\begin{pmatrix}1&1\\1&\overline{1}\end{pmatrix},\qquad P_{n+1} = \begin{pmatrix}P_n\otimes(1\ 1)\\ P_n\otimes(1\ \overline{1})\end{pmatrix},\qquad W_{n+1} = \begin{pmatrix}W_n\otimes(1\ 1)\\ F_nW_n\otimes(1\ \overline{1})\end{pmatrix}.$$

Thus $W_n = G_n^TP_n = P_nG_n$; $H_n = P_nR_n = R_nP_n$; and $P_n = W_nG_n^T = G_nW_n = H_nR_n = R_nH_n$.

36. **W1.** [Hadamard transform.] For $k = 0, 1, \dots, n-1$, replace the pair (X_j, X_{j+2^k}) by $(X_j + X_{j+2^k}, X_j - X_{j+2^k})$ for all j with $\lfloor j/2^k\rfloor$ even, $0 \le j < 2^n$. (These operations effectively set $X^T \leftarrow H_nX^T$.)

W2. [Bit reversal.] Apply the algorithm of exercise 5 to the vector X. (These operations effectively set $X^T \leftarrow R_nX^T$, in the notation of exercise 35.)

W3. [Gray binary permutation.] Apply the algorithm of exercise 30 to the vector X. (These operations effectively set $X^T \leftarrow G_n^TX^T$.) ∎

If n has one of the special values in exercise 31, it may be faster to combine steps W2 and W3 into a single permutation step.

37. If $k = 2^{e_1}+\cdots+2^{e_t}$ with $e_1 > \cdots > e_t \ge 0$, the sign changes occur at $S_{e_1}\cup\cdots\cup S_{e_t}$, where

$$S_0 = \Big\{\frac12\Big\},\quad S_1 = \Big\{\frac14,\frac34\Big\},\quad \dots,\quad S_e = \Big\{\frac{2j+1}{2^e}\ \Big|\ 0\le j<2^e\Big\}.$$

Therefore the number of sign changes in $(0\,..\,x)$ is $\sum_{j=1}^t\lfloor 2^{e_j}x+\frac12\rfloor$. Setting $x = l/(k+1)$ gives $l+O(t)$ changes; so the lth is at a distance of at most $O(\nu(k))/2^{\lfloor\lg k\rfloor}$ from $l/(k+1)$.

[This argument makes it plausible that infinitely many pairs (k,l) exist with $|z_{kl} - l/(k+1)| = \Omega\big((\log k)/k\big)$. But no explicit construction of such "bad" pairs is immediately apparent.]

38. Let $t_0(x) = 1$ and $t_k(x) = \omega^{\lfloor 3x\rfloor\lceil 2k/3\rceil}t_{\lfloor k/3\rfloor}(3x)$, where $\omega = e^{2\pi i/3}$. Then $t_k(x)$ winds around the origin $\frac23k$ times as x increases from 0 to 1. If $s_k(x) = \omega^{\lfloor 3^kx\rfloor}$ is the ternary analog of the Rademacher function $r_k(x)$, we have $t_k(x) = \prod_{j\ge0}s_{j+1}(x)^{b_j-b_{j+1}}$ when $k = (b_{n-1}\dots b_0)_3$, as in the modular ternary Gray code.

39. Let's call the symbols $\{x_0, x_1, \dots, x_7\}$ instead of $\{a,b,c,d,e,f,g,h\}$. We want to find a permutation p of $\{0,1,\dots,7\}$ such that the matrix with $(-1)^{j\cdot k}x_{p(j)\oplus k}$ in row j and column k has orthogonal rows; this condition is equivalent to requiring that

$$(j+j')\cdot\big(p(j)+p(j')\big)\equiv 1\ (\text{modulo }2),\qquad \text{for } 0\le j<j'<8.$$

One solution is $p(0)\dots p(7) = 0\,1\,7\,2\,5\,6\,3\,4$, yielding the identity $(a^2+b^2+c^2+d^2+e^2+f^2+g^2+h^2)(A^2+B^2+C^2+D^2+E^2+F^2+G^2+H^2) = \mathcal{A}^2+\mathcal{B}^2+\mathcal{C}^2+\mathcal{D}^2+$

$\mathcal{E}^2+\mathcal{F}^2+\mathcal{G}^2+\mathcal{H}^2$, where

$$\begin{pmatrix}\mathcal{A}\\ \mathcal{B}\\ \mathcal{C}\\ \mathcal{D}\\ \mathcal{E}\\ \mathcal{F}\\ \mathcal{G}\\ \mathcal{H}\end{pmatrix} = \begin{pmatrix} a & b & c & d & e & f & g & h\\ b & -a & d & -c & f & -e & h & -g\\ h & g & -f & -e & d & c & -b & -a\\ c & -d & -a & b & g & -h & -e & f\\ f & e & h & g & -b & -a & -d & -c\\ g & -h & e & -f & -c & d & -a & b\\ d & c & -b & -a & -h & -g & f & e\\ e & -f & -g & h & -a & b & c & -d\end{pmatrix}\begin{pmatrix}A\\ B\\ C\\ D\\ E\\ F\\ G\\ H\end{pmatrix}.$$

(b) There *is* no 16×16 solution. The closest one can come is

$$p(0)\ldots p(15) \;=\; 0\ 1\ 11\ 2\ 14\ 15\ 13\ 4\ 9\ 10\ 7\ 12\ 5\ 6\ 3\ 8,$$

which fails if and only if $j\oplus j'=5$. [See *Philos. Mag.* **34** (1867), 461–475. In §9, §10, §11, and §13 of this paper, Sylvester stated and proved the basic results about what has somehow come to be known as the Hadamard transform — although Hadamard himself gave credit to Sylvester [*Bull. des Sciences Mathématiques* (2) **17** (1893), 240–246]. Moreover, Sylvester introduced transforms of m^n elements in §14, using mth roots of unity.]

40. Yes; this change would in fact run through the swapped subsets in lexicographic binary order rather than in Gray binary order. (Any 5×5 matrix of 0s and 1s that is nonsingular mod 2 will generate all 32 possibilities when we run through all linear combinations of its rows.) The most important thing is the appearance of the ruler function, or some other Gray code delta sequence, not the fact that only one a_j changes per step, in cases like this where any number of the a_j can be changed simultaneously at the same cost.

41. At most 16; for example, `fired`, `fires`, `finds`, `fines`, `fined`, `fares`, `fared`, `wares`, `wards`, `wands`, `wanes`, `waned`, `wines`, `winds`, `wires`, `wired`. We also get 16 from `paced`/`links` and `paled`/`mints`; perhaps also from a word mixed with an antipodal nonword.

42. Suppose $n\le 2^{2^r}+r+1$, and let $s=2^r$. We use an auxiliary table of 2^{r+s} bits f_{jk} for $0\le j<2^s$ and $0\le k<s$, representing focus pointers as in Algorithm L, together with an auxiliary s-bit "register" $j=(j_{s-1}\ldots j_0)_2$ and an $(r+2)$-bit "program counter" $p=(p_{r+1}\ldots p_0)_2$. At each step we examine the program counter and possibly the j register and one of the f bits; then, based on the bits seen, we complement a bit of the Gray code, complement a bit of the program counter, and possibly change a j or f bit, thereby emulating step L3 with respect to the most significant $n-r-2$ bits.

For example, here is the construction when $r=1$:

$p_2p_1p_0$	Change	Set		$p_2p_1p_0$	Change	Set	
0 0 0	a_0,p_0	$j_0\leftarrow f_{00}$	$\}\ j\leftarrow f_0$	1 1 0	a_0,p_0	$f_{j0}\leftarrow f_{(j+1)0}$	$\}\ f_j\leftarrow f_{j+1}$
0 0 1	a_1,p_1	$j_1\leftarrow f_{01}$		1 1 1	a_1,p_1	$f_{j1}\leftarrow f_{(j+1)1}$	
0 1 1	a_0,p_0	$f_{00}\leftarrow 0$	$\}\ f_0\leftarrow 0$	1 0 1	a_0,p_0	$f_{(j+1)0}\leftarrow (j+1)_0$	$\}\ f_{j+1}\leftarrow j+1$
0 1 0	a_2,p_2	$f_{01}\leftarrow 0$		1 0 0	a_{j+3},p_2	$f_{(j+1)1}\leftarrow (j+1)_1$	

The process stops when it attempts to change bit a_n.

[In fact, we need change only *one* auxiliary bit per step if we allow ourselves to examine some Gray binary bits as well as the auxiliary bits, because $p_r\ldots p_0=a_r\ldots a_0$, and we can set $f_0\leftarrow0$ in a more clever way when j doesn't have its final value 2^s-1. This construction, suggested by Fredman in 2001, improves on another that he had

published in *SICOMP* **7** (1978), 134–146. With a more elaborate construction it is possible to reduce the number of auxiliary bits to $O(n)$.]

43. This number was estimated by Silverman, Vickers, and Sampson [*IEEE Trans.* **IT-29** (1983), 894–901] to be about 7×10^{22}. Exact calculation might be feasible because every 6-bit Gray code has only five or fewer segments that lie in a 5-cube corresponding to at least one of the six coordinates. (In unpublished work, Steve Winker had used a similar idea to evaluate $d(5)$ in less than 15 minutes on a "generic" computer in 1972.)

44. All $(n+1)$-bit delta sequences with just two occurrences of the coordinate j are produced by the following construction: Take n-bit delta sequences $\delta_0 \ldots \delta_{2^n-1}$ and $\varepsilon_0 \ldots \varepsilon_{2^n-1}$ and find an index k with $\delta_k = \varepsilon_0$. Form the cycle

$$\delta_0 \ldots \delta_{k-1}\, n\, \varepsilon_1 \ldots \varepsilon_{2^n-1}\, n\, \delta_{k+1} \ldots \delta_{2^n-1}$$

and then interchange $n \leftrightarrow j$.

All $(n-2)$-bit delta sequences with just two occurrences of coordinates h and j (with h before j) are, similarly, produced from four n-bit sequences $\delta_0 \ldots \delta_{2^n-1}$, $\ldots$, $\eta_0 \ldots \eta_{2^n-1}$ and an index k with $\delta_k = \varepsilon_0 = \zeta_0 = \eta_0$, by interchanging $n \leftrightarrow h$ and $n+1 \leftrightarrow j$ in

$$\delta_0 \ldots \delta_{k-1}\, n\, \varepsilon_1 \ldots \varepsilon_{2^n-1} (n{+}1)\, \zeta_1 \ldots \zeta_{2^n-1}\, n\, \eta_1 \ldots \eta_{2^n-1} (n{+}1)\, \delta_{k+1} \ldots \delta_{2^n-1}.$$

Let $a(n)$ and $b(n)$ be the answers to (a) and (b), for $n \geq 1$. The first construction shows that $a(n+1) + 2b(n+1) = 2^n(n+1)\,d(n)^2/n$, because it produces the delta sequences enumerated by $b(n+1)$ in two ways. The second construction shows that $b(n+2) = 2^n(n+2)(n+1)\,d(n)^4/n^3$.

45. We have $d(n+1) \geq 2^n d(n)^2/n$, because $2^n d(n)^2/n$ is the number of $(n+1)$-bit delta sequences with exactly two appearances of 0. Hence $d(n) > \frac{5}{32}2^{2^n}$ for $n \geq 5$, by induction on n.

Indeed, we can establish even faster growth by using the previous exercise, because $d(n+1) \geq a(n+1) + b(n+1)$ and $b(n+1) \leq \frac{25}{64}(n+1)\,d(n)^2/n$ for $n \geq 5$. Hence $d(n+1) \geq \left(2^n - \frac{25}{64}\right)(n+1)\,d(n)^2/n$ for $n \geq 5$, and iteration of this relation shows that

$$\lim_{n\to\infty} d(n)^{1/2^n} \geq d(5)^{1/32} \prod_{n=5}^{\infty} \left(2^n - \frac{25}{64}\right)^{1/2^{n+1}} \left(\frac{n+1}{n}\right)^{1/2^{n+1}} \approx 2.3606.$$

[See R. J. Douglas, *Disc. Math.* **17** (1977), 143–146; M. Mollard, *European J. Comb.* **9** (1988), 49–52.] But the true value of this limit is probably ∞.

46. Leo Moser (unpublished) has conjectured that it is $\sim n/e$. So far only an upper bound of about $n/\sqrt{2}$ has been established; see the references in the previous answer.

48. If $d(n,k,v)$ of the codes begin with $g(0) \ldots g(k-1)\,v$, the conjecture implies that $d(n,k,v) \leq d(n,k,g(k))$, because the reverse of a Gray code is a Gray code. Thus the hint follows from $d(n) = d(n,1)$ and

$$d(n,k) = \sum_v \{\, d(n,k,v) \mid v \mathrel{-\!\!-} g(k-1), v \notin S_k \,\} \leq c_{nk} d(n,k,g(k)) = d(n,k+1).$$

Finally, $d(n,2^n) = 1$, hence $d(n) \leq \prod_{k=1}^{2^n-1} c_{nk} = \prod_{k=1}^{n} k^{\binom{n}{k}} = n \prod_{k=1}^{n-1} \big(k(n-k)\big)^{\binom{n}{k}/2} \leq n \prod_{k=1}^{n-1} (n/2)^{\binom{n}{k}} = n(n/2)^{2^n-2}$. [*IEEE Trans.* **IT-29** (1983), 894–901.]

49. Take any Hamiltonian path P from $0 \ldots 0$ to $1 \ldots 1$ in the $(2n-1)$-cube, such as the Savage–Winkler path, and use $0P$, $1P^R$. (All such codes are obtained by this construction when $n = 1$ or $n = 2$, but many more possibilities exist when $n > 2$.)

50. $\alpha_1(n+1)\alpha_1^R n\,\alpha_1 j_1\alpha_2 n\alpha_2^R(n+1)\alpha_2\ldots j_{l-1}\alpha_l n\,\alpha_l^R(n+1)\alpha_l n\,\alpha_l^R j_{l-1}\ldots j_1\alpha_1^R n$.

51. We can assume that $n>3$ and that we have an n-bit Gray code with transition counts $c_j=2\lfloor(2^{n-1}+j)/n\rfloor$; we want to construct an $(n+2)$-bit code with transition counts $c'_j=2\lfloor(2^{n+1}+j)/(n+2)\rfloor$. If $2^{n+1}\bmod(n+2)\ge 2$, we can use Theorem D with $l=2\lfloor 2^{n+1}/(n+2)\rfloor+1$, underlining b_j copies of j where $b_j=4\lfloor(2^{n-1}+j)/n\rfloor-\lfloor(2^{n+1}+j)/(n+2)\rfloor-[j=0]$ and putting an underlined 0 last. This is always easy to do because $\left|b_j-2^{n+2}/n(n+2)\right|<5$. A similar construction works if $2^{n+1}\bmod(n+2)\le n$, with $l=2\lfloor 2^{n+1}/(n+2)\rfloor-1$ and $b_j=4\lfloor(2^{n-1}+j)/n\rfloor-\lfloor(2^{n+1}+j+2)/(n+2)\rfloor-[j=0]$. In fact, $2^{n+1}\bmod(n+2)$ is always $\le n$ [see K. Kedlaya, *Electronic J. Combinatorics* **3** (1996), comment on #R25 (9 April 1997)]. The basic idea of this proof is due to J. P. Robinson and M. Cohn [*IEEE Trans.* **C-30** (1981), 17–23].

52. The number of different code patterns in the smallest j coordinate positions is at most $c_0+\cdots+c_{j-1}$.

53. Notice that Theorem D produces only codes with $c_j=c_{j+1}$ for some j, so it cannot produce the counts $(2,4,6,8,12)$. The extension in exercise 50 gives also $c_j=c_{j+1}-2$, but it cannot produce $(6,10,14,18,22,26,32)$. The sets of numbers satisfying the conditions of exercise 52 are precisely those obtainable by starting with $\{2,2,4,\ldots,2^{n-1}\}$ and repeatedly replacing some pair $\{c_j,c_k\}$ for which $c_j<c_k$ by the pair $\{c_j+2,c_k-2\}$.

54. Suppose the values are $\{p_1,\ldots,p_n\}$, and let x_{jk} be the number of times p_j occurs in $(a_1,\ldots,a_k)$. We must have $(x_{1k},\ldots,x_{nk})\equiv(x_{1l},\ldots,x_{nl})$ (modulo 2) for some $k<l$. But if the p's are prime numbers, varying as the delta sequence of an n-bit Gray code, the only solution is $k=0$ and $l=2^n$. [*AMM* **60** (1953), 418; **83** (1976), 54.]

56. [*Bell System Tech. J.* **37** (1958), 815–826.] The 112 canonical delta sequences yield

A	0102101302012023	2	D	0102013201020132	4	G	0102030201020302	8
B	0102303132101232	2	E	0102032021202302	4	H	0102101301021013	8
C	0102030130321013	2	F	0102013102010232	4	I	0102013121012132	1

Here B is the balanced code (Fig. 13(b)), G is standard Gray binary (Fig. 10(b)), and H is the complementary code (Fig. 13(a)). Class H is also equivalent to the modular $(4,4)$ Gray code under the correspondence of exercise 18. A class with t automorphisms corresponds to $32\times 24/t$ of the 2688 different delta sequences $\delta_0\delta_1\ldots\delta_{15}$.

Similarly (see exercise 7.2.3–00), the 5-bit Gray codes fall into 237,675 different equivalence classes.

57. With Type 1 only, 480 vertices are isolated, namely those of classes D, F, G in the previous answer. With Type 2 only, the graph has 384 components, 288 of which are isolated vertices of classes F and G. There are 64 components of size 9, each containing 3 vertices from E and 6 from A; 16 components of size 30, each with 6 from H and 24 from C; and 16 components of size 84, each with 12 from D, 24 from B, 48 from I. With Type 3 (or Type 4) only, the entire graph is connected. [Similarly, all 91,392 of the 4-bit Gray *paths* are connected if path $\alpha\beta$ is considered adjacent to path $\alpha^R\beta$. Vickers and Silverman, *IEEE Trans.* **C-29** (1980), 329–331, have conjectured that Type 3 changes will suffice to connect the graph of n-bit Gray codes for all $n\ge 3$.]

58. If some nonempty substring of $\beta\beta$ involves each coordinate an even number of times, that substring cannot have length $|\beta|$, so some cyclic shift of β has a prefix γ

with the same evenness property. But then α doesn't define a Gray code, because we could change each n of γ back to 0.

59. If α is nonlocal in exercise 58, so is $\beta\beta$, provided that $q > 1$ and that 0 occurs more than $q+1$ times in α. Therefore, starting with the α of (30) but with 0 and 1 interchanged, we obtain nonlocal codes for $n \ge 5$ in which coordinate 0 changes exactly 6 times. [Mark Ramras, *Discrete Math.* **85** (1990), 329–331.] On the other hand, a 4-bit Gray code cannot be nonlocal because it always has a run of length 2; if $\delta_k = \delta_{k+2}$, elements $\{v_{k-1}, v_k, v_{k+1}, v_{k+2}\}$ form a 2-subcube.

60. Use the construction of exercise 58 with $q = 1$.

61. The idea is to interleave an m-bit code $U = (u_0, u_1, u_2, \dots)$ with an n-bit code $V = (v_0, v_1, v_2, \dots)$, by forming concatenations

$$W = (u_{i_0}v_{j_0},\ u_{i_1}v_{j_1},\ u_{i_2}v_{j_2},\ \dots), \qquad i_k = \overline{a}_0 + \cdots + \overline{a}_{k-1}, \quad j_k = a_0 + \cdots + a_{k-1},$$

where $a_0a_1a_2\dots$ is a periodic string of control bits $\alpha\alpha\alpha\dots$; we advance to the next element of U when $a_k = 0$, otherwise to the next element of V.

If α is any string of length $2^m \le 2^n$, containing s bits that are 0 and $t = 2^m - s$ bits that are 1, W will be an $(m+n)$-bit Gray code if s and t are odd. For we have $i_{k+l} \equiv i_k$ (modulo 2^m) and $j_{k+l} \equiv j_k$ (modulo 2^n) only if l is a multiple of 2^m, since $i_k + j_k = k$. Suppose $l = 2^m c$; then $j_{k+l} = j_k + tc$, so c is a multiple of 2^n.

(a) Let $\alpha = 0111$; then runs of length 8 occur in the left 2 bits and runs of length $\ge \lfloor \frac{4}{3} r(n) \rfloor$ occur in the right n bits.

(b) Let s be the largest odd number $\le 2^m r(m)/(r(m)+r(n))$. Also let $t = 2^m - s$ and $a_k = \lfloor (k+1)t/2^m \rfloor - \lfloor kt/2^m \rfloor$, so that $i_k = \lceil ks/2^m \rceil$ and $j_k = \lfloor kt/2^m \rfloor$. If a run of length l occurs in the left m bits, we have $i_{k+l+1} \ge i_k + r(m) + 1$, hence $l + 1 > 2^m r(m)/s \ge r(m) + r(n)$. And if it occurs in the right n bits we have $j_{k+l+1} \ge j_k + r(n) + 1$, hence

$$\begin{aligned} l + 1 &> 2^m r(n)/t > 2^m r(n)/\big(2^m r(n)/(r(m)+r(n)) + 2\big) \\ &= r(m) + r(n) - \frac{2(r(m)+r(n))^2}{2^m r(n) + 2(r(m)+r(n))} > r(m) + r(n) - 1 \end{aligned}$$

because $r(m) \le r(n)$.

The construction often works also in less restricted cases. See the paper that introduced the study of Gray code runs: L. Goddyn, G. M. Lawrence, and E. Nemeth, *Utilitas Math.* **34** (1988), 179–192.

63. Set $a_k \leftarrow k \bmod 4$ for $0 \le k < 2^{10}$, except that $a_k = 4$ when $k \bmod 16 = 15$ or $k \bmod 64 = 42$ or $k \bmod 256 = 133$. Also set $(j_0, j_1, j_2, j_3, j_4) \leftarrow (0, 2, 4, 6, 8)$. Then for $k = 0$, 1, ..., 1023, set $\delta_k \leftarrow j_{a_k}$ and $j_{a_k} \leftarrow 1 + 4a_k - j_{a_k}$. (This construction generalizes the method of exercise 61.)

64. (a) Each element u_k appears together with $\{v_k, v_{k+2^m}, \dots, v_{k+2^m(2^{n-1}-1)}\}$ and $\{v_{k+1}, v_{k+1+2^m}, \dots, v_{k+1+2^m(2^{n-1}-1)}\}$. Thus the permutation $\sigma_0 \dots \sigma_{2^m-1}$ must be a 2^{n-1}-cycle containing the n-bit vertices of even parity, times an arbitrary permutation of the other vertices. This condition is also sufficient.

(b) Let τ_j be the permutation that takes $v \mapsto v \oplus 2^j$, and let $\pi_j(u, w)$ be the permutation $(uw)\tau_j$. If $u \oplus w = 2^i + 2^j$ then $\pi_j(u, w)$ takes $u \mapsto u \oplus 2^i$ and $w \mapsto w \oplus 2^i$, while $v \mapsto v \oplus 2^j$ for all other vertices v, so it takes each vertex to a neighbor.

If S is any set $\subseteq \{0, \dots, n-1\}$, let $\sigma(S)$ be the stream of all permutations τ_j for all $j \in \{0, \dots, n-1\} \setminus S$, in increasing order of j, repeated twice; for example, if $n = 5$

we have $\sigma(\{1,2\}) = \tau_0\tau_3\tau_4\tau_0\tau_3\tau_4$. Then the Gray stream

$$\Sigma(i,j,u) = \sigma(\{i,j\})\,\pi_j(u, u\oplus 2^i\oplus 2^j)\,\sigma(\{i,j\})\,\tau_j\,\sigma(\{j\})$$

consists of $6n-8$ permutations whose product is the transposition $(u\ \ u\oplus 2^i\oplus 2^j)$. Moreover, when this stream is applied to any n-bit vertex v, its runs all have length $\ge n-2$.

We may assume that $n \ge 5$. Let $\delta_0 \ldots \delta_{2^n-1}$ be the delta sequence for an n-bit Gray code $(v_0, v_1, \ldots, v_{2^n-1})$ with all runs of length 3 or more. Then the product of all permutations in

$$\Sigma = \prod_{k=1}^{2^{n-1}-1} \big(\Sigma(\delta_{2k-1}, \delta_{2k}, v_{2k-1})\,\Sigma(\delta_{2k}, \delta_{2k+1}, v_{2k})\big)$$

is $(v_1\,v_3)(v_2\,v_4)\ldots(v_{2^n-3}\,v_{2^n-1})(v_{2^n-2}\,v_0) = (v_{2^n-1}\ldots v_1)(v_{2^n-2}\ldots v_0)$, so it satisfies the cycle condition of (a).

Moreover, all powers $(\sigma(\emptyset)\Sigma)^t$ produce runs of length $\ge n-2$ when applied to any vertex v. By repeating individual factors $\sigma(\{i,j\})$ or $\sigma(\{j\})$ in Σ as many times as we wish, we can adjust the length of $\sigma(\emptyset)\Sigma$, obtaining $2n+(2^{n-1}-1)(12n-16)+2(n-2)a+2(n-1)b$ for any integers $a, b \ge 0$; thus we can increase its length to exactly 2^m, provided that $2^m \ge 2n+(2^{n-1}-1)(12n-16)+2(n^2-5n+6)$, by exercise 5.2.1–21.

(c) The bound $r(n) \ge n - 4\lg n + 8$ can be proved for $n \ge 5$ as follows. First we observe that it holds for $5 \le n < 33$ by the methods of exercises 60–63. Then we observe that every integer $N \ge 33$ can be written as $N = m+n$ or $N = m+n+1$, for some $m \ge 20$, where

$$n = m - \lfloor 4\lg m \rfloor + 10.$$

If $m \ge 20$, 2^m is sufficiently large for the construction in part (b) to be valid; so we have

$$\begin{aligned} r(N) \ge r(m+n) \ge 2\min\big(r(m), n-2\big) &\ge 2\big(m - \lfloor 4\lg m\rfloor + 8\big) \\ &= m+n+1-\lfloor 4\lg(m+n) - 1 + \epsilon\rfloor + 8 \\ &\ge N - 4\lg N + 8 \end{aligned}$$

where $\epsilon = 4\lg\big(2m/(m+n)\big) < 1$. [To appear.] Recursive use of (b) gives, in fact, $r(1024) \ge 1000$.

65. A computer search reveals that eight essentially different patterns (and their reverses) are possible. One of them has the delta sequence 0102031420302404123 4214103234103, and it is close to two of the others.

66. (Solution by Mark Cooke.) One suitable delta sequence is 012345607012132435 657607102135346267015374123625670173142620657013421465605731024645375710204353761407363046427370356402713275054121027564150240365425013602541615604312576032572043157624321760452041751635476703564757062543724213262416152341751436714316431 4.

67. Let $v_{2k+1} = \overline{v}_{2k}$ and $v_{2k} = 0u_k$, where $(u_0, u_1, \ldots, u_{2^n-1})$ is any $(n-1)$-bit Gray code. [See Robinson and Cohn, *IEEE Trans.* **C-30** (1981), 17–23.]

68. Yes. The simplest way is probably to take $(n-1)$-trit modular Gray ternary code and add $0\ldots0$, $1\ldots1$, $2\ldots2$ to each string (modulo 3). For example, when $n=3$ the code is 000, 111, 222, 001, 112, 220, 002, 110, 221, 012, 120, 201, ..., 020, 101, 212.

69. (a) We need only verify the change in h when bits $b_{j-1}\dots b_0$ are simultaneously complemented, for $j = 1, 2, \dots$; and these changes are respectively $(1110)_2$, $(1101)_2$, $(0111)_2$, $(1011)_2$, $(10011)_2$, $(100011)_2$, ... To prove that every n-tuple occurs, note that $0 \le h(k) < 2^n$ when $0 \le k < 2^n$ and $n > 3$; also $h^{[-1]}((a_{n-1}\dots a_0)_2) = (b_{n-1}\dots b_0)_2$, where $b_0 = a_0 \oplus a_1 \oplus a_2 \oplus \cdots$, $b_1 = a_0$, $b_2 = a_2 \oplus a_3 \oplus a_4 \oplus \cdots$, $b_3 = a_0 \oplus a_1 \oplus a_3 \oplus \cdots$, and $b_j = a_j \oplus a_{j+1} \oplus \cdots$ for $j \ge 4$.

(b) Let $h(k) = (\dots a_2a_1a_0)_2$ where $a_j = b_j \oplus b_{j+1} \oplus b_0[j \le t] \oplus b_{t-1}[t-1 \le j \le t]$.

70. As in (32) and (33), we can remove a factor of $n!$ by assuming that the strings of weight 1 occur in order. Then there are 14 solutions for $n = 5$ starting with 00000, and 21 starting with 00001. When $n = 6$ there are 46,935 of each type (related by reversal and complementation). When $n = 7$ the number is much, much larger, yet very small by comparison with the total number of 7-bit Gray paths.

71. Suppose that $\alpha_{n(j+1)}$ differs from α_{nj} in coordinate t_j, for $0 \le j < n-1$. Then $t_j = j\pi_n$, by (44) and (38). Now Eq. (34) tells us that $t_0 = n-1$; and if $0 < j < n-1$ we have $t_j = ((j-1)\pi_{n-1})\pi_{n-1}$ by (40). Thus $t_j = j\sigma_n\pi_{n-1}^2$ for $0 \le j < n-1$, and the value of $(n-1)\pi_n$ is whatever is left. (Notations for permutations are notoriously confusing, so it is always wise to check a few small cases carefully.)

72. The delta sequence is 0102132430201234012313041021323.

73. Let $Q_{nj} = P_{nj}^R$ and denote the sequences (41), (42) by S_n and T_n. Thus $S_n = P_{n0}Q_{n1}P_{n2}\dots$ and $T_n = Q_{n0}P_{n1}Q_{n2}\dots$, if we omit the commas; and we have

$$S_{n+1} = 0P_{n0}\ 0Q_{n1}\ 1Q_{n0}^{\pi}\ 1P_{n1}^{\pi}\ 0P_{n2}\ 0Q_{n3}\ 1Q_{n2}^{\pi}\ 1P_{n3}^{\pi}\ 0P_{n4}\ \dots,$$
$$T_{n+1} = 0Q_{n0}\ 1P_{n0}^{\pi}\ 0P_{n1}\ 0Q_{n2}\ 1Q_{n1}^{\pi}\ 1P_{n2}^{\pi}\ 0P_{n3}\ 0Q_{n4}\ 1Q_{n3}^{\pi}\ \dots,$$

where $\pi = \pi_n$, revealing a reasonably simple joint recursion between the delta sequences Δ_n and E_n of S_n and T_n. Namely, if we write

$$\Delta_n = \phi_1\, a_1\, \phi_2\, a_2 \dots \phi_{n-1}\, a_{n-1}\, \phi_n, \qquad E_n = \psi_1\, b_1\, \psi_2\, b_2 \dots \psi_{n-1}\, b_{n-1}\, \psi_n,$$

where each ϕ_j and ψ_j is a string of length $2\binom{n-1}{j-1} - 1$, the next sequences are

$$\Delta_{n+1} = \phi_1\ a_1\ \phi_2\ n\ \psi_1\pi\ b_1\pi\ \psi_2\pi\ n\ \phi_3\ a_3\ \phi_4\ n\ \psi_3\pi\ b_3\pi\ \psi_4\pi\ n\ \dots$$
$$E_{n+1} = \psi_1\ n\ \phi_1\pi\ n\ \psi_2\ b_2\ \psi_3\ n\ \phi_2\pi\ a_2\pi\ \phi_3\pi\ n\ \psi_4\ b_4\ \psi_5\ n\ \phi_4\pi\ a_4\pi\ \phi_5\pi\ n\ \dots$$

For example, we have $\Delta_3 = 0\,\underline{1}\,0\,2\,1\,\underline{0}\,1$ and $E_3 = 0\,\underline{2}\,1\,2\,0\,\underline{2}\,1$, if we underline the a's and b's to distinguish them from the ϕ's and ψ's; and

$$\Delta_4 = 0\ 1\ 0\ 2\ 1\ 3\ 0\pi\ 2\pi\ 1\pi\ 2\pi\ 0\pi\ 3\ 1\ 3\ 1\pi = 0\ \underline{1}\ 0\ 2\ 1\ 3\ 2\ \underline{1}\ 0\ 1\ 2\ 3\ 1\ \underline{3}\ 0,$$
$$E_4 = 0\ 3\ 0\pi\ 3\ 1\ 2\ 0\ 2\ 1\ 3\ 0\pi\ 2\pi\ 1\pi\ 0\pi\ 1\pi = 0\ \underline{3}\ 2\ 3\ 1\ 2\ 0\ \underline{2}\ 1\ 3\ 2\ 1\ 0\ \underline{2}\ 0;$$

here $a_3\phi_4$ and $b_3\psi_4$ are empty. Elements have been underlined for the next step.

Thus we can compute the delta sequences in memory as follows. Here $p[j] = j\pi_n$ for $1 \le j < n$; $s_k = \delta_k$, $t_k = \varepsilon_k$, and $u_k = [\delta_k$ and ε_k are underlined], for $0 \le k < 2^n - 1$.

R1. [Initialize.] Set $n \leftarrow 1$, $p[0] \leftarrow 0$, $s_0 \leftarrow t_0 \leftarrow u_0 \leftarrow 0$.

R2. [Advance n.] Perform Algorithm S below, which computes the arrays s', t', and u' for the next value of n; then set $n \leftarrow n+1$.

R3. [Ready?] If n is sufficiently large, the desired delta sequence Δ_n is in array s'; terminate. Otherwise keep going.

R4. [Compute π_n.] Set $p'[0] = n-1$, and $p'[j] = p[p[j-1]]$ for $1 \le j < n$.

R5. [Prepare to advance.] Set $p[j] \leftarrow p'[j]$ for $0 \le j < n$; set $s_k \leftarrow s'_k$, $t_k \leftarrow t'_k$, and $u_k \leftarrow u'_k$ for $0 \le k < 2^n - 1$. Return to R2. ∎

In the following steps, "Transmit stuff(l,j) while $u_j=0$" is an abbreviation for "If $u_j=0$, repeatedly stuff(l,j), $l\leftarrow l+1$, $j\leftarrow j+1$, until $u_j\neq 0$."

S1. [Prepare to compute Δ_{n+1}.] Set $j\leftarrow k\leftarrow l\leftarrow 0$ and $u_{2^n-1}\leftarrow -1$.

S2. [Advance j.] Transmit $s'_l\leftarrow s_j$ and $u'_l\leftarrow 0$ while $u_j=0$. Then go to S5 if $u_j<0$.

S3. [Advance j and k.] Set $s'_l\leftarrow s_j$, $u'_l\leftarrow 1$, $l\leftarrow l+1$, $j\leftarrow j+1$. Then transmit $s'_l\leftarrow s_j$ and $u'_l\leftarrow 0$ while $u_j=0$. Then set $s'_l\leftarrow n$, $u'_l\leftarrow 0$, $l\leftarrow l+1$. Then transmit $s'_l\leftarrow p[t_k]$ and $u'_l\leftarrow 0$ while $u_k=0$. Then set $s'_l\leftarrow p[t_k]$, $u'_l\leftarrow 1$, $l\leftarrow l+1$, $k\leftarrow k+1$. And once again transmit $s'_l\leftarrow p[t_k]$ and $u'_l\leftarrow 0$ while $u_k=0$.

S4. [Done with Δ_{n+1}?] If $u_k<0$, go to S6. Otherwise set $s'_l\leftarrow n$, $u'_l\leftarrow 0$, $l\leftarrow l+1$, $j\leftarrow j+1$, $k\leftarrow k+1$, and return to S2.

S5. [Finish Δ_{n+1}.] Set $s'_l\leftarrow n$, $u'_l\leftarrow 1$, $l\leftarrow l+1$. Then transmit $s'_l\leftarrow p[t[k]]$ and $u'_l\leftarrow 0$ while $u_k=0$.

S6. [Prepare to compute E_{n+1}.] Set $j\leftarrow k\leftarrow l\leftarrow 0$. Transmit $t'_l\leftarrow t_k$ while $u_k=0$. Then set $t'_l\leftarrow n$, $l\leftarrow l+1$.

S7. [Advance j.] Transmit $t'_l\leftarrow p[s_j]$ while $u_j=0$. Then terminate if $u_j<0$; otherwise set $t'_l\leftarrow n$, $l\leftarrow l+1$, $j\leftarrow j+1$, $k\leftarrow k+1$.

S8. [Advance k.] Transmit $t'_l\leftarrow t_k$ while $u_k=0$. Then go to S10 if $u_k<0$.

S9. [Advance k and j.] Set $t'_l\leftarrow t_k$, $l\leftarrow l+1$, $k\leftarrow k+1$. Then transmit $t'_l\leftarrow t_k$ while $u_k=0$. Then set $t'_l\leftarrow n$, $l\leftarrow l+1$. Then transmit $t'_l\leftarrow p[s_j]$ while $u_j=0$. Then set $t'_l\leftarrow p[s_j]$, $l\leftarrow l+1$, $j\leftarrow j+1$. Return to S7.

S10. [Finish E_{n+1}.] Set $t'_l\leftarrow n$, $l\leftarrow l+1$. Then transmit $t'_l\leftarrow p[s_j]$ while $u_j=0$. ∎

To generate the monotonic Savage–Winkler path for fairly large n, one can first generate Δ_{10} and E_{10}, say, or even Δ_{20} and E_{20}. Using these tables, a suitable recursive procedure will then be able to reach higher values of n with very little computational overhead per step, on the average.

74. If the monotonic path is $v_0,\ldots,v_{2^n-1}$ and if v_k has weight j, we have

$$2\sum_{t>0}\binom{n}{j-2t}+\big((j+\nu(v_0))\bmod 2\big)\le k\le 2\sum_{t\ge 0}\binom{n}{j-2t}+\big((j+\nu(v_0))\bmod 2\big)-2.$$

Therefore the maximum distance between vertices of respective weights j and $j+1$ is $2\big(\binom{n-1}{j-1}+\binom{n-1}{j}+\binom{n-1}{j+1}\big)-1$. The maximum value, approximately $3\cdot 2^n/\sqrt{2\pi n}$, occurs when j is approximately $n/2$. [This is only about three times the smallest value achievable in *any* ordering of the vertices, which is $\sum_{j=0}^{n-1}\binom{j}{\lfloor j/2\rfloor}$ by exercise 7.10–00.]

75. There are only five essentially distinct solutions, all of which turn out in fact to be Gray *codes*. The delta sequences are

$$0\,1\,2\,3\,0\,1\,2\,4\,2\,1\,0\,3\,2\,1\,0\,1\,2\,1\,0\,3\,2\,1\,0\,4\,0\,1\,2\,3\,0\,1\,2\ (1)$$
$$0\,1\,2\,3\,0\,1\,2\,4\,2\,1\,0\,3\,2\,1\,0\,1\,3\,0\,1\,2\,3\,0\,1\,4\,1\,0\,3\,2\,1\,0\,3\ (1)$$
$$0\,1\,2\,3\,0\,1\,2\,4\,2\,1\,0\,3\,2\,1\,0\,2\,0\,3\,2\,1\,0\,3\,2\,4\,2\,3\,0\,1\,2\,3\,0\ (2)$$
$$0\,1\,2\,3\,0\,1\,2\,4\,2\,3\,0\,1\,2\,3\,0\,2\,0\,1\,2\,3\,0\,1\,2\,4\,2\,3\,0\,1\,2\,3\,0\ (2)$$
$$0\,1\,2\,3\,4\,1\,0\,1\,2\,1\,0\,3\,0\,1\,4\,3\,2\,1\,0\,3\,0\,1\,4\,1\,0\,1\,2\,3\,4\,1\,0\ (3)$$

76. If $v_0, \ldots, v_{2^n-1}$ is trend-free, so is the $(n+1)$-bit code $0v_0$, $1v_0$, $1v_1$, $0v_1$, $0v_2$, $1v_2$, $\ldots$, $1v_{2^n-1}$, $0v_{2^n-1}$. Fig. 14(g) shows a somewhat more interesting construction, which generalizes the first solution of exercise 75 to an $(n+2)$-bit code

$$00\Gamma''^R,\ 01\Gamma'^R,\ 11\Gamma',\ 10\Gamma'',\ 10\Gamma,\ 11\Gamma''',\ 01\Gamma'''^R,\ 00\Gamma^R$$

where Γ is the n-bit sequences $g(1), \ldots, g(2^{n-1})$ and $\Gamma' = \Gamma \oplus g(1)$, $\Gamma'' = \Gamma \oplus g(2^{n-1})$, $\Gamma''' = \Gamma \oplus g(2^{n-1}+1)$. [An n-bit trend-free design that is *almost* a Gray code, having just four steps in which $\nu(v_k \oplus v_{k+1}) = 2$, was found for all $n \geq 3$ by C. S. Cheng, *Proc. Berkeley Conf. Neyman and Kiefer* **2** (Hayward, Calif.: Inst. of Math. Statistics, 1985), 619–633.]

77. Replace the array $(d_{n-1}, \ldots, d_0)$ by an array of sentinel values $(s_{n-1}, \ldots, s_0)$, with $s_j \leftarrow m_j - 1$ in step H1. Set $a_j \leftarrow (a_j + 1) \bmod m_j$ in step H4. If $a_j = s_j$ in step H5, set $s_j \leftarrow (s_j - 1) \bmod m_j$, $f_j \leftarrow f_{j+1}$, $f_{j+1} \leftarrow j+1$.

78. For (50), notice that B_{j+1} is the number of times reflection has occurred in coordinate j, because we bypass coordinate j on steps that are multiples of $m_j \ldots m_0$. Hence, if $b_j < m_j$, an increase of b_j by 1 causes a_j to increase or decrease by 1 as appropriate. Furthermore, if $b_i = m_i - 1$ for $0 \leq i < j$, changing all these b_i to 0 when incrementing b_j will increase each of $B_0, \ldots, B_j$ by 1, thereby leaving the values $a_0, \ldots, a_{j-1}$ unchanged in (50).

For (51), note that $B_j = m_j B_{j+1} + b_j \equiv m_j B_{j+1} + a_j + (m_j - 1)B_{j+1} \equiv a_j + B_{j+1}$ (modulo 2); hence $B_j \equiv a_j + a_{j+1} + \cdots$, and (51) is obviously equivalent to (50).

In the modular Gray code for general radices $(m_{n-1}, \ldots, m_0)$, let

$$mg(k) = \begin{bmatrix} a_{n-1}, & \ldots, & a_2, & a_1, & a_0 \\ m_{n-1}, & \ldots, & m_2, & m_1, & m_0 \end{bmatrix}$$

when k is given by (46). Then $a_j = (b_j - B_{j+1}) \bmod m_j$, because coordinate j has increased modulo m_j exactly $B_j - B_{j+1}$ times if we start at $(0, \ldots, 0)$. The inverse function, which determines the b's from the modular Gray a's, is $b_j = (a_j + a_{j+1} + a_{j+2} + \cdots) \bmod m_j$ in the special case that each m_j is a divisor of m_{j+1} (for example, if all m_j are equal). But the inverse has no simple form in general; it can be computed by using the recurrences $b_j = (a_j + B_{j+1}) \bmod m_j$, $B_j = m_j B_{j+1} + b_j$ for $j = n-1$, $\ldots$, 0, starting with $B_n = 0$.

[Reflected Gray codes for radix $m > 2$ were introduced by Ivan Flores in *IRE Trans.* **EC-5** (1956), 79–82; he derived (50) and (51) in the case that all m_j are equal. Modular Gray codes with general mixed radices were implicitly discussed by Joseph Rosenbaum in *AMM* **45** (1938), 694–696, but without the conversion formulas; conversion formulas when all m_j have a common value m were published by Martin Cohn, *Info. and Control* **6** (1963), 70–78.]

79. (a) The last n-tuple always has $a_{n-1} = m_{n-1} - 1$, so it is one step from $(0, \ldots, 0)$ only if $m_{n-1} = 2$. And this condition suffices to make the final n-tuple $(1, 0, \ldots, 0)$. [Similarly, the final subforest output by Algorithm K is adjacent to the initial one if and only if the leftmost tree is an isolated vertex.]

(b) The last n-tuple is $(m_{n-1}-1, 0, \ldots, 0)$ if and only if $m_{n-1} \ldots m_{j+1} \bmod m_j = 0$ for $0 \leq j < n-1$, because $b_j = m_j - 1$ and $B_j = m_{n-1} \ldots m_j - 1$.

80. Run through $p_1^{a_1} \ldots p_t^{a_t}$ using reflected Gray code with radices $m_j = e_j + 1$.

81. The first cycle contains the edge from (x, y) to $\big(x, (y+1) \bmod m\big)$ if and only if $(x+y) \bmod m \neq m-1$ if and only if the second cycle contains the edge from (x, y) to $\big((x+1) \bmod m, y\big)$.

82. There are two 4-bit Gray codes $(u_0, \ldots, u_{15})$ and $(v_0, \ldots, v_{15})$ that cover all edges of the 4-cube. (Indeed, the non-edges of classes A, B, D, H, and I in exercise 56 form Gray codes, belonging to the same class as their complement.) Therefore with 16-ary modular Gray code we can form the four desired cycles $(u_0u_0, u_0u_1, \ldots, u_0u_{15}, u_1u_{15}, \ldots, u_{15}u_0)$, $(u_0u_0, u_1u_0, \ldots, u_{15}u_0, u_{15}u_1, \ldots, u_0u_{15})$, $(v_0v_0, \ldots, v_{15}u_0)$, $(v_0v_0, \ldots, v_0v_{15})$.

In a similar way we can show that $n/2$ edge-disjoint n-bit Gray codes exist when n is 16, 32, 64, etc. [*Abhandlungen Math. Sem. Hamburg* **20** (1956), 13–16.] J. Aubert and B. Schneider [*Discrete Math.* **38** (1982), 7–16] have proved that the same property holds for *all* even values of $n \geq 4$, but no simple construction is known.

84. Calling the initial position $(2, 2)$, the 8-step solution in Fig. A-1 shows how the sequence progresses down to $(0, 0)$. In the first move, for example, the front half of the cord passes around and behind the right comb, then through the large right loop. The middle line should be read from right to left. The generalization to n pairs of loops would, similarly, take $3^n - 1$ steps.

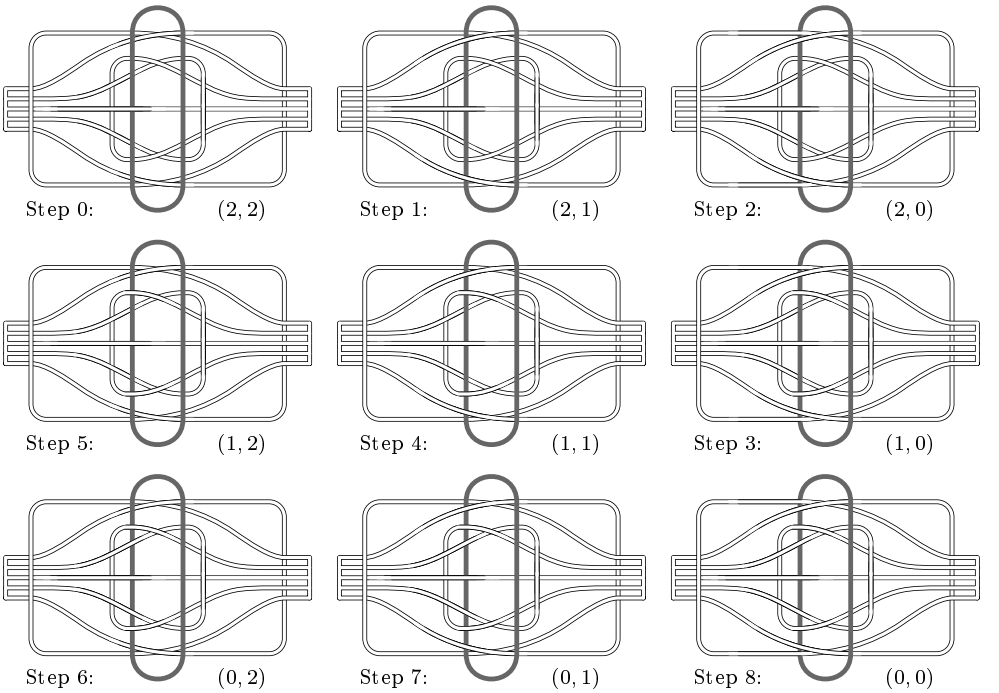

Fig. A-1.

[The origin of this delightful puzzle is obscure. *The Book of Ingenious & Diabolical Puzzles* by Jerry Slocum and Jack Botermans (1994) shows a 2-loop version carved from horn, probably made in China about 1850 [page 101], and a modern 6-loop version made in Malaysia about 1988 [page 93]. Slocum also owns a 4-loop version made from bamboo in England about 1884. He has found it listed in Henry Novra's *Catalogue of Conjuring Tricks and Puzzles* (1858 or 1859) and W. H. Cremer's *Games, Amusements, Pastimes and Magic* (1867), as well as in Hamleys' catalog of 1895, under the name "Marvelous Canoe Puzzle." Dyckman noted its connection to reflected Gray ternary in a letter to Martin Gardner, dated 2 August 1972.]

85. By (50), element $\left[\begin{smallmatrix} b, & b' \\ t, & t' \end{smallmatrix}\right]$ of $\Gamma \boxtimes \Gamma'$ is $\alpha_a \alpha'_{a'}$ if $rg(\left[\begin{smallmatrix} b, & b' \\ t, & t' \end{smallmatrix}\right]) = \left[\begin{smallmatrix} a, & a' \\ t, & t' \end{smallmatrix}\right]$ in the reflected Gray code for radices (t, t'). We can now show that element $\left[\begin{smallmatrix} b, & b', & b'' \\ t, & t', & t'' \end{smallmatrix}\right]$ of both $(\Gamma \boxtimes \Gamma') \boxtimes \Gamma''$ and $\Gamma \boxtimes (\Gamma' \boxtimes \Gamma'')$ is $\alpha_a \alpha'_{a'} \alpha''_{a''}$ if $rg(\left[\begin{smallmatrix} b, & b', & b'' \\ t, & t', & t'' \end{smallmatrix}\right]) = \left[\begin{smallmatrix} a, & a', & a'' \\ t, & t', & t'' \end{smallmatrix}\right]$ in the reflected Gray code for radices (t, t', t''). See exercise 4.1–10, and note also the mixed-radix law

$$m_1 \ldots m_n - 1 - \begin{bmatrix} x_1, & \ldots, & x_n \\ m_1, & \ldots, & m_n \end{bmatrix} = \begin{bmatrix} m_1 - 1 - x_1, & \ldots, & m_n - 1 - x_n \\ m_1, & \ldots, & m_n \end{bmatrix}.$$

In general, the reflected Gray code for radices $(m_1, \ldots, m_n)$ is $(0, \ldots, m_1 - 1) \boxtimes \cdots \boxtimes (0, \ldots, m_n - 1)$. [*Information Processing Letters* **22** (1986), 201–205.]

86. Let Γ_{mn} be the reflected m-ary Gray path, which can be defined by $\Gamma_{m0} = \epsilon$ and

$$\Gamma_{m(n+1)} = (0, 1, \ldots, m-1) \boxtimes \Gamma_{mn}, \qquad n \geq 0.$$

This path runs from $(0, 0, \ldots, 0)$ to $(m-1, 0, \ldots, 0)$ when m is even. Consider the Gray path Π_{mn} defined by $\Pi_{m0} = \emptyset$ and

$$\Pi_{m(n+1)} = \begin{cases} (0, 1, \ldots, m-1) \boxtimes \Pi_{mn},\ m\Gamma^R_{(m+1)n}, & \text{if } m \text{ is odd;} \\ (0, 1, \ldots, m) \boxtimes \Pi_{mn},\ m\Gamma^R_{mn}, & \text{if } m \text{ is even.} \end{cases}$$

This path traverses all of the $(m+1)^n - m^n$ nonnegative integer n-tuples for which $\max(a_1, \ldots, a_n) = m$, starting with $(0, \ldots, 0, m)$ and ending with $(m, 0, \ldots, 0)$. The desired infinite Gray path is Π_{0n}, Π^R_{1n}, Π_{2n}, Π^R_{3n}, ...

87. This is impossible when n is odd, because the n-tuples with $\max(|a_1|, \ldots, |a_n|) = 1$ include $\frac{1}{2}(3^n + 1)$ with odd parity and $\frac{1}{2}(3^n - 3)$ with even parity. When $n = 2$ we can use a spiral Σ_0, Σ_1, Σ_2, ..., where Σ_m winds clockwise from $(m, 1-m)$ to $(m, -m)$ when $m > 0$. For even values of $n \geq 2$, if T_m is a path of n-tuples from $(m, 1-m, m-1, 1-m, \ldots, m-1, 1-m)$ to $(m, -m, m, -m, \ldots, m, -m)$, we can use $\Sigma_m \boxtimes (T_0, \ldots, T_{m-1}), (\Sigma_0, \ldots, \Sigma_m)^R \,\overline{\boxtimes}\, T_m$ for $(n+2)$-tuples with the same property, where $\overline{\boxtimes}$ is the dual operation

$$\Gamma \,\overline{\boxtimes}\, \Gamma' = (\alpha_0\alpha'_0, \ldots, \alpha_{t-1}\alpha'_0, \alpha_{t-1}\alpha'_1, \ldots, \alpha_0\alpha'_1, \alpha_0\alpha'_2, \ldots, \alpha_{t-1}\alpha'_2, \alpha_{t-1}\alpha'_3, \ldots).$$

[Infinite n-dimensional Gray paths *without* the magnitude constraint were first constructed by E. Vázsonyi, *Acta Litterarum ac Scientiarum*, sectio Scientiarum Mathematicarum **9** (Szeged: 1938), 163–173.]

88. It would visit all the subforests again, but in reverse order, ending with $(0, \ldots, 0)$ and returning to the state it had after the initialization step K1. (This reflection principle is, in fact, the key to understanding how Algorithm K works.)

89. (a) Let $M_0 = \epsilon$, $M_1 = \bullet$, and $M_{n+2} = \bullet\, M^R_{n+1}$, $-M^R_n$. This construction works because the last element of M^R_{n+1} is the first element of M_{n+1}, namely a dot followed by the first element of M^R_n.

(b) Given a string $d_1 \ldots d_l$ where each d_j is $\bullet$ or $-$, we can find its successor by letting $k = l - [d_l = \bullet]$ and proceeding as follows: If k is odd and $d_k = \bullet$, change $d_k d_{k+1}$ to $-$; if k is even and $d_k = -$, change d_k to $\bullet\bullet$; otherwise decrease k by 1 and repeat until either making a change or reaching $k = 0$. The successor of the given word is $\bullet - - \bullet\bullet\bullet - \bullet - \bullet$.

90. A cycle can exist only when the number of code words is even, since the number of dashes changes by ± 1 at each step. Thus we must have $n \bmod 3 = 2$. The Gray paths M_n of exercise 89 are not suitable; they begin with $(\bullet -)^{\lfloor n/3 \rfloor} \bullet^{n \bmod 3}$ and end

with $(\mathit{—}\bullet)^{\lfloor n/3\rfloor}\bullet^{[n \bmod 3=1]}\mathit{—}^{[n \bmod 3=2]}$. But $M_{3k+1}\bullet$, $M_{3k}^R\mathit{—}$ is a Hamiltonian circuit in the Morse code graph when $n = 3k+2$.

91. Equivalently, the n-tuples $a_1\bar{a}_2a_3\bar{a}_4\ldots$ have no two consecutive 1s. Such n-tuples correspond to Morse code sequences of length $n+1$, if we append 0 and then represent $\bullet$ and $\bullet\mathit{—}$ respectively by 0 and 10. Under this correspondence we can convert the path M_{n+1} of exercise 89 into a procedure like Algorithm K, with the fringe containing the indices where each dot or dash begins (except for a final dot).

Q1. [Initialize.] Set $a_j \leftarrow \lfloor((j-1) \bmod 6)/3\rfloor$ and $f_j \leftarrow j$ for $1 \le j \le n$. Also set $f_0 \leftarrow 0$, $r_0 \leftarrow 1$, $l_1 \leftarrow 0$, $r_j \leftarrow j+(j \bmod 3)$ and $l_{j+(j \bmod 3)} \leftarrow j$ for $1 \le j \le n$, except if $j+(j \bmod 3) > n$ set $r_j \leftarrow 0$ and $l_0 \leftarrow j$. (The "fringe" now contains 1, 2, 4, 5, 7, 8, ...)

Q2. [Visit.] Visit the n-tuple $(a_1, \ldots, a_n)$.

Q3. [Choose p.] Set $q \leftarrow l_0$, $p \leftarrow f_q$, $f_q \leftarrow q$.

Q4. [Check a_p.] Terminate the algorithm if $p = 0$. Otherwise set $a_p \leftarrow 1 - a_p$ and go to Q6 if $a_p + p$ is now even.

Q5. [Insert $p+1$.] If $p < n$, set $q \leftarrow r_p$, $l_q \leftarrow p+1$, $r_{p+1} \leftarrow q$, $r_p \leftarrow p+1$, $l_{p+1} \leftarrow p$. Go to Q7.

Q6. [Delete $p+1$.] If $p < n$, set $q \leftarrow r_{p+1}$, $r_p \leftarrow q$, $l_q \leftarrow p$.

Q7. [Make p passive.] Set $f_p \leftarrow f_{l_p}$ and $f_{l_p} \leftarrow l_p$. Return to Q2. ∎

This algorithm can also be derived as a special case of a considerably more general method due to Gang Li, Frank Ruskey, and D. E. Knuth, which extends Algorithm K by allowing the user to specify either $a_p \ge a_q$ or $a_p \le a_q$ for each (parent, child) pair (p, q). [See Knuth and Ruskey, "Deconstructing coroutines," to appear.] A generalization in another direction, which produces all strings of length n that do not contain certain substrings, has been discovered by M. B. Squire, *Electronic J. Combinatorics* **3** (1996), #R17, 1–29.

92. Yes, because the digraph of all $(n-1)$-tuples $(x_1, \ldots, x_{n-1})$ with $x_1, \ldots, x_{n-1} \le m$ and with arcs $(x_1, \ldots, x_{n-1}) \to (x_2, \ldots, x_n)$ whenever $\max(x_1, \ldots, x_n) = m$ is connected and balanced; see Theorem 2.3.4.2G. Indeed, we get such a sequence from Algorithm F if we note that the final k^n elements of the prime strings of length dividing n, when subtracted from $m-1$, are the same for all $m \ge k$. When $n = 4$, for example, the first 81 digits of the sequence Φ_4 are $2 - \alpha^R = 0\,0001\,01\,0011\ldots$, where α is the string (62). [There also are infinite m-ary sequences whose first m^n elements are de Bruijn cycles for all n, given any fixed $m \ge 3$. See L. J. Cummings and D. Wiedemann, *Cong. Numerantium* **53** (1986), 155–160.]

93. The cycle generated by $f()$ is a cyclic permutation of $\alpha 1$, where α has length $m^n - 1$ and ends with 1^{n-1}. The cycle generated by Algorithm R is a cyclic permutation of $\gamma = c_0 \ldots c_{m^{n+1}-1}$, where $c_k = (c_0 + b_0 + \cdots + b_{k-1}) \bmod m$ and $b_0 \ldots b_{m^{n+1}-1} = \beta = \alpha^m 1^m$.

If $x_0 \ldots x_n$ occurs in γ, say $x_j = c_{k+j}$ for $0 \le j \le n$, then $y_j = b_{k+j}$ for $0 \le j < n$, where $y_j = (x_{j+1} - x_j) \bmod m$. [This is the connection with modular m-ary Gray code; see exercise 78.] Now if $y_0 \ldots y_{n-1} = 1^n$ we have $m^{n+1} - m - n < k \le m^{n+1} - n$; otherwise there is an index k' such that $-n < k' < m^n - n$ and $y_0 \ldots y_{n-1}$ occurs in β at positions $k = (k' + r(m^n - 1)) \bmod m^{n+1}$ for $0 \le r < m$. In both cases the m choices of k have different values of x_0, because the sum of all elements in α is $m-1$

(modulo m) when $n \geq 2$. [Algorithm R is valid also for $n = 1$ if $m \bmod 4 \neq 2$, because $m \perp \sum \alpha$ in that case.]

94. 0<u>01</u>0<u>2</u>03041<u>12</u>1<u>3</u>142<u>2</u>3243344. (The underlined digits are effectively inserted into the interleaving of 00112234 with 34. Algorithm D can be used in general when $n = 1$ and $r = m - 2 \geq 0$; but it is pointless to do so, in view of (54).)

95. (a) Let $c_0 c_1 c_2 \ldots$ have period r. If r is odd we have $p = q = r$, so $r = pq$ only in the trivial case when $p = q = 1$ and $a_0 = b_0$. Otherwise $r/2 = \operatorname{lcm}(p, q) = pq/\gcd(p, q)$ by 4.5.2–(10), hence $\gcd(p, q) = 2$. In the latter case the $2n$-tuples $c_l c_{l+1} \ldots c_{l+2n-1}$ that occur are $a_j b_k \ldots a_{j+n-1} b_{k+n-1}$ for $0 \leq j < p$, $0 \leq k < q$, $j \equiv k$ (modulo 2), and $b_k a_j \ldots b_{k+n-1} a_{j+n-1}$ for $0 \leq j < p$, $0 \leq k < q$, $j \not\equiv k$ (modulo 2).

(b) The output would interleave two sequences $a_0 a_1 \ldots$ and $b_0 b_1 \ldots$ whose periods are respectively $m^n + r$ and $m^n - r$; the a's are the cycle of $f()$ with x^n changed to x^{n+1} and the b's are the cycle of $g()$ with x^n changed to x^{n-1}, for $0 \leq x < r$. By (58) and part (a), the period length is $m^{2n} - r^2$, and every $2n$-tuple occurs with the exception of $(xy)^n$ for $0 \leq x, y < r$.

(c) The real step D6 alters the behavior of (b) by going to D3 when $t \geq n$ and $0 \leq x' = x < r$; this emits an extra x at the time when x^{2n-1} has just been output and b is about to be emitted, where b is the digit following x^n in g's cycle. D6 also allows control to pass to D7 and then D3 with $t' = n$ in the case that $t \geq n$ and $x < x' < r$; this emits an extra $x'x$ at the time when $(xx')^{n-1}x$ has just been output and b will be next. These r^2 extra bits provide the r^2 missing $2n$-tuples of (b).

96. (a) The recurrences $S_2 = 1$, $S_{2n+1} = S_{2n} = 2S_n$, $R_2 = 0$, $R_{2n+1} = 1 + R_{2n}$, $R_{2n} = 2R_n$, $D_2 = 0$, $D_{2n+1} = D_{2n} = 1 + 2D_n$ have the solution $S_n = 2^{\lfloor \lg n \rfloor - 1}$, $R_n = n - 2S_n$, $D_n = S_n - 1$. Thus $S_n + R_n + D_n = n - 1$.

(b) Each top-level output usually involves $\lfloor \lg n \rfloor - 1$ D-activations and $\nu(n) - 1$ R-activations, plus one basic activation at the bottom level. But there are exceptions: Algorithm R might invoke its $f()$ twice, if the first activation completed a sequence 1^n; and sometimes Algorithm R doesn't need to invoke $f()$ at all. Algorithm D might invoke its $g()$ twice, if the first activation completed a sequence $(x')^n$; but sometimes Algorithm D doesn't need to invoke either $f()$ or $g()$.

Algorithm R completes a sequence x^{n+1} if and only if its child $f()$ has just completed a sequence 0^n. Algorithm D completes a sequence x^{2n} for $x < r$ if and only if it has just jumped from D6 to D3 without invoking any child.

From these observations we can conclude that at most $\lfloor \lg n \rfloor + \nu(n) + 1$ activations are possible per top-level output, if $r > 1$; such a case happens when Algorithm D for $n = 6$ goes from D6 to D4. But when $r = 1$ we can have as many as $2\lfloor \lg n \rfloor + 3$ activations, for example when Algorithm R for $n = 25$ goes from R4 to R2.

97. (a) (0011), (00011101), (0000101001111011), and (0000011000101101111 1001110101001). Thus $j_2 = 2$, $j_3 = 3$, $j_4 = 9$, $j_5 = 15$.

(b) We obviously have $f_{n+1}(k) = \Sigma f_n(k) \bmod 2$ for $0 \leq k < j_n + n$. The next value, $f_{n+1}(j_n + n)$, depends on whether step R4 jumps to R2 after computing $y = f_n(j_n + n - 1)$. If it does (namely, if $f_{n+1}(j_n + n - 1) \neq 0$), we have $f_{n+1}(k) \equiv 1 + \Sigma(k+1)$ for $j_n + n \leq k < 2^n + j_n + n$; otherwise we have $f_{n+1}(k) \equiv 1 + \Sigma(k-1)$ for those values of k. In particular, $f_{n+1}(k) = 1$ when $2^n \leq k + \delta_n \leq 2^n + n$. The stated formula, which has simpler ranges for the index k, holds because $1 + \Sigma(k \pm 1) \equiv \Sigma(k)$ when $j_n < k < j_n + n$ or $2^n + j_n < k < 2^n + j_n + n$.

(c) The interleaved cycle has $c_n(2k) = f_n^+(k)$ and $c_n(2k+1) = f_n^-(k)$, where

$$f_n^+(k) = \begin{cases} f_n(k-1), & \text{if } 0 < k \le j_n+1; \\ f_n(k-2), & \text{if } j_n+1 < k \le 2^n+2; \end{cases} \qquad f_n^-(k) = \begin{cases} f_n(k+1), & \text{if } 0 \le k < j_n; \\ f_n(k+2), & \text{if } j_n \le k < 2^n-2; \end{cases}$$

$f_n^+(k) = f_n^+\big(k \bmod (2^n+2)\big)$, $f_n^-(k) = f_n^-\big(k \bmod (2^n-2)\big)$. Therefore the subsequence 1^{2n-1} begins at position $k_n = (2^{n-1}-2)(2^n+2) + 2j_n + 2$ in the c_n cycle; this will make j_{2n} odd. The subsequence $(01)^{n-1}0$ begins at position $l_n = (2^{n-1}+1)(j_n-1)$ if $j_n \bmod 4 = 1$, at $l_n = (2^{n-1}+1)(2^n+j_n-3)$ if $j_n \bmod 4 = 3$. Also $k_2 = 6$, $l_2 = 2$.

(d) Algorithm D inserts four elements into the c_n cycle; hence

$$f_{2n}(k) = \begin{cases} c_n(k-1), & \text{if } 0 < k \le l_n+2; \\ c_n(k-3), & \text{if } l_n+2 < k \le k_n+3; \\ c_n(k-4), & \text{if } k_n+3 < k \le 2^{2n}; \end{cases} \quad \text{when } j_n \bmod 4 < 3 \ (l_n < k_n);$$

$$= \begin{cases} c_n(k-1), & \text{if } 0 < k \le k_n+1; \\ c_n(k-2), & \text{if } k_n+1 < k \le l_n+3; \\ c_n(k-4), & \text{if } l_n+3 < k \le 2^{2n}. \end{cases} \quad \text{when } j_n \bmod 4 = 3 \ (k_n < l_n);$$

(e) Consequently $j_{2n} = k_n + 1 + 2[j_n \bmod 4 < 3]$. Indeed, the elements preceding 1^{2n} consist of $2^{n-2}-1$ complete periods of $f_n^+()$ interleaved with 2^{n-2} complete periods of $f_n^-()$, with one 0 inserted and also with 10 inserted if $l_n < k_n$, followed by $f_n(1)f_n(1)f_n(2)f_n(2)\ldots f_n(j_n-1)f_n(j_n-1)$. The sum of all these elements is odd, unless $l_n < k_n$; therefore $\delta_{2n} = 1 - 2[j_n \bmod 4 = 3]$.

Let $n = 2^t q$, where q is odd and $n > 2$. The recurrences imply that, if $q = 1$, we have $j_n = 2^{n-1} + b_t$ where $b_t = 2^t/3 - (-1)^t/3$. And if $q > 1$ we have $j_n = 2^{n-1} \pm b_{t+2}$, where the $+$ sign is chosen if and only if $\lfloor \lg q \rfloor + [\lfloor 4q/2^{\lfloor \lg q \rfloor} \rfloor = 5]$ is even.

98. If $f(k) = g(k)$ when k lies in a certain range, there's a constant C such that $\Sigma f(k) = C + \Sigma g(k)$ for k in that range. We can therefore continue almost mindlessly to derive additional recurrences: If $n > 1$ we have

$$\Sigma f_{2n}(k), \text{ when } j_n \bmod 4 < 3 \ (l_n < k_n): \quad \equiv \begin{cases} \Sigma c_n(k-1), & \text{if } 0 < k \le l_n+2; \\ 1+\Sigma c_n(k-3), & \text{if } l_n+2 < k \le k_n+3; \\ \Sigma c_n(k-4), & \text{if } k_n+3 < k \le 2^{2n}; \end{cases}$$

$$\text{when } j_n \bmod 4 = 3 \ (k_n < l_n): \quad \equiv \begin{cases} \Sigma c_n(k-1), & \text{if } 0 < k \le k_n+1; \\ 1+\Sigma c_n(k-2), & \text{if } k_n+1 < k \le l_n+3; \\ \Sigma c_n(k-4), & \text{if } l_n+3 < k \le 2^{2n}. \end{cases}$$

$$\Sigma c_n(k) \equiv \Sigma f_n^+\big(\lceil k/2 \rceil\big) + \Sigma f_n^-\big(\lfloor k/2 \rfloor\big).$$

$$\Sigma f_n^+(k) \equiv \begin{cases} \Sigma f_n(k-1), & \text{if } 0 < k \le j_n+1; \\ 1+\Sigma f_n(k-2), & \text{if } j_n+1 < k \le 2^n+2; \end{cases} \qquad \Sigma f_n^-(k) \equiv \begin{cases} \Sigma f_n(k+1), & \text{if } 0 \le k < j_n; \\ 1+\Sigma f_n(k+2), & \text{if } j_n \le k < 2^n-2; \end{cases}$$

$$\Sigma f_n^\pm(k) \equiv \lfloor k/(2^n \pm 2) \rfloor + \Sigma f_n^\pm\big(k \bmod (2^n \pm 2)\big); \quad \Sigma f_n(k) = \Sigma f_n(k \bmod 2^n).$$

$$\Sigma f_{2n+1}(k) \equiv \begin{cases} \Sigma\Sigma f_{2n}(k), & \text{if } 0 < k \le j_{2n} \text{ or } 2^{2n}+j_{2n} < k \le 2^{2n+1}; \\ 1+k+\Sigma\Sigma f_{2n}(k+\delta_{2n}), & \text{if } j_{2n} < k \le 2^{2n}+j_{2n}. \end{cases}$$

$$\Sigma\Sigma f_{2n}(k), \text{ when } j_n \bmod 4 < 3 \ (l_n < k_n): \quad \equiv \begin{cases} \Sigma\Sigma c_n(k-1), & \text{if } 0 < k \le l_n+2; \\ 1+k+\Sigma\Sigma c_n(k-3), & \text{if } l_n+2 < k \le k_n+3; \\ \Sigma\Sigma c_n(k-4), & \text{if } k_n+3 < k \le 2^{2n}; \end{cases}$$

$$\text{when } j_n \bmod 4 = 3 \ (k_n < l_n): \quad \equiv \begin{cases} \Sigma\Sigma c_n(k-1), & \text{if } 0 < k \le k_n+1; \\ 1+k+\Sigma c_n(k-2), & \text{if } k_n+1 < k \le l_n+3; \\ 1+\Sigma\Sigma c_n(k-4), & \text{if } l_n+3 < k \le 2^{2n}. \end{cases}$$

$$\Sigma\Sigma f_{2n}(k) \equiv [j_n \bmod 4 < 3]\lfloor k/2^{2n} \rfloor + \Sigma\Sigma f_{2n}(k \bmod 2^{2n}).$$

And then, aha, there is closure:

$$\Sigma\Sigma c_n(2k) = \Sigma f_n^+(k), \qquad \Sigma\Sigma c_n(2k+1) = \Sigma f_n^-(k).$$

If $n = 2^t q$ where q is odd, the running time to evaluate $f_n(k)$ by this system of recursive formulas is $O(t + S(q))$, where $S(1) = 1$, $S(2k) = 1 + 2S(k)$, and $S(2k+1) = 1 + S(k)$. Clearly $S(k) < 2k$, so the evaluations involve at most $O(n)$ simple operations on n-bit numbers. In fact, the method is often significantly faster: If we average $S(k)$ over all k with $\lfloor \lg k \rfloor = s$ we get $(3^{s+1} - 2^{s+1})/2^s$, which is less than $3k^{\lg(3/2)} < 3k^{0.59}$. (Incidentally, if $k = 2^{s+1} - 1 - (2^{s-e_1} + 2^{s-e_2} + \cdots + 2^{s-e_t})$ we have $S(k) = s + 1 + e_t + 2e_{t-1} + 4e_{t-2} + \cdots + 2^t e_1$.)

99. A string that starts at position k in $f_n()$ starts at position $k^+ = k + 1 + [k > j_n]$ in $f_n^+()$ and at position $k^- = k - 1 - [k > j_n]$ in $f_n^-()$, except that 0^n and 1^n occur twice in $f_n^+()$ but not at all in $f_n^-()$.

To find $\gamma = a_0 b_0 \ldots a_{n-1} b_{n-1}$ in the cycle $f_{2n}()$, let $\alpha = a_0 \ldots a_{n-1}$ and $\beta = b_0 \ldots b_{n-1}$. Suppose α starts at position j and β at position k in $f_n()$, and assume that neither α nor β is 0^n or 1^n. If $j^+ \equiv k^+$ (modulo 2), let $l/2$ be a solution to the equation $j^+ + (2^n + 2)x = k^- + (2^n - 2)y$; we may take $l/2 = k + (2^n - 2)\big(2^{n-3}(j-k) \bmod (2^{n-1}+1)\big)$ if $j \geq k$, otherwise $l/2 = j + (2^n + 2)\big(2^{n-3}(k-j) \bmod (2^{n-1}-1)\big)$. Otherwise let $(l-1)/2 = k^+ + (2^n + 2)x = j^- + (2^n - 2)y$. Then γ starts at position l in the cycle $c_n()$; hence it starts at position $l + 1 + [l \geq k_n] + 2[l \geq l_n]$ in the cycle $f_{2n}()$. Similar formulas hold when $\alpha \in \{0^n, 1^n\}$ or $\beta \in \{0^n, 1^n\}$ (but not both). Finally, 0^{2n}, 1^{2n}, $(01)^n$, and $(10)^n$ start respectively in positions 0, j_{2n}, $l_n + 1 + [k_n < l_n]$, and $l_n + 2 + [k_n < l_n]$.

To find $\beta = b_0 b_1 \ldots b_n$ in $f_{n+1}()$ when n is even, suppose that the n-bit string $(b_0 \oplus b_1) \ldots (b_{n-1} \oplus b_n)$ starts at position j in $f_n()$. Then β starts at position $k = j - \delta_n[j \geq j_n] + 2^n[j = j_n][\delta_n = 1]$ if $f_{n+1}(k) = b_0$, otherwise at position $k + (2^n - \delta_n, \delta_n, 2^n + \delta_n)$ according as $(j < j_n, j = j_n, j > j_n)$.

The running time of this recursion satisfies $T(n) = O(n) + 2T\big(\lfloor n/2 \rfloor\big)$, so it is $O(n \log n)$. [Exercises 97–99 are based on the work of J. Tuliani, who also has developed methods for certain larger values of m; see *Discrete Math.* **226** (2001), 313–336.]

100. No obvious defects are apparent, but extensive testing should be done before any sequence can be recommended. By contrast, the de Bruijn cycle produced implicitly by Algorithm F is a terrible source of supposedly random bits, even though it is n-distributed in the sense of Definition 3.5D, because 0s predominate at the beginning. Indeed, when n is prime, bits $tn + 1$ of that sequence are zero for $0 \leq t < (2^n - 2)/n$.

101. (a) Let β be a proper suffix of $\lambda\lambda'$ with $\beta \leq \lambda\lambda'$. Either β is a suffix of λ', whence $\lambda < \lambda' \leq \beta$, or $\beta = \alpha\lambda'$ and we have $\lambda < \alpha < \beta$.

Now $\lambda < \beta \leq \lambda\lambda'$ implies that $\beta = \lambda\gamma$ for some $\gamma \leq \lambda'$. But γ is a suffix of β with $1 \leq |\gamma| = |\beta| - |\lambda| < |\lambda'|$; hence γ is a proper suffix of λ', and $\lambda' < \gamma$. Contradiction.

(b) Any string of length 1 is prime. Combine adjacent primes by (a), in any order, until no further combination is possible. [See the more general results of M. P. Schützenberger, *Proc. Amer. Math. Soc.* **16** (1965), 21–24.]

(c) If $t \neq 0$, let λ be the smallest suffix of $\lambda_1 \ldots \lambda_t$. Then λ is prime by definition, and it has the form $\beta\gamma$ where β is a nonempty suffix of some λ_j. Therefore $\lambda_t \leq \lambda_j \leq \beta \leq \beta\gamma = \lambda \leq \lambda_t$, so we must have $\lambda = \lambda_t$. Remove λ_t and repeat until $t = 0$.

(d) True. For if we had $\alpha = \lambda\beta$ for some prime λ with $|\lambda| > |\lambda_1|$, we could append the factors of β to obtain another factorization of α.

(e) $3 \cdot 14159265358979323846264338327 95 \cdot 02884197$. (Knowing more digits of π would not change the first two factors. The infinite decimal expansion of any number that is "normal" in the sense of Borel (see Section 3.5) factors into primes of finite length.)

102. We must have $1/(1-mz) = 1/\prod_{n=1}^{\infty}(1-z^n)^{L_m(n)}$. This implies (6o) as in exercise 4.6.2–4.

103. When $n = p$ is prime, (59) tells us that $L_m(1) + pL_m(p) = m^p$, and we also have $L_m(1) = m$. [This combinatorial proof provides an interesting contrast to the traditional algebraic proof of Theorem 1.2.4F.]

104. The 4483 nonprimes are `abaca`, `agora`, `ahead`, ...; the 1274 primes are ..., `rusts`, `rusty`, `rutty`. (Since `prime` isn't prime, we should perhaps call prime strings `lowly`.)

105. (a) Let α' be α with its last letter increased, and suppose $\alpha' = \beta\gamma'$ where $\alpha = \beta\gamma$ and $\beta \neq \epsilon$, $\gamma \neq \epsilon$. Let θ be the prefix of α with $|\theta| = |\gamma|$. By hypothesis there is a string ω such that $\alpha\omega$ is prime; hence $\theta \le \alpha\omega < \gamma\omega$, so we must have $\theta \le \gamma$. Consequently $\theta < \gamma'$, and we have $\alpha' < \gamma'$.

(b) Let $\alpha = \lambda_1\beta = a_1 \ldots a_n$ where $\lambda_1\beta\omega$ is prime. The condition $\lambda_1\beta\omega < \beta\omega$ implies that $a_j \le a_{j+r}$ for $1 \le j \le n-r$, where $r = |\lambda_1|$. But we cannot have $a_j < a_{j+r}$; otherwise α would begin with a prime longer than λ_1, contradicting exercise 101(d).

(c) If α is the n-extension of both λ and λ', where $|\lambda| > |\lambda'|$, we must have $\lambda = (\lambda')^q\theta$ where θ is a proper prefix of λ'. But then $\theta < \lambda' < \lambda < \theta$.

106. **B1.** [Initialize.] Set $a_1 \leftarrow \cdots \leftarrow a_n \leftarrow m-1$, $a_{n+1} \leftarrow -1$, and $j \leftarrow 1$.

B2. [Visit.] Visit $(a_1, \ldots, a_n)$ with index j.

B3. [Subtract one.] Terminate if $a_j = 0$. Otherwise set $a_j \leftarrow a_j - 1$, and $a_k \leftarrow m-1$ for $j < k \le n$.

B4. [Prepare to factor.] (According to exercise 105(b), we now want to find the first prime factor λ_1 of $a_1 \ldots a_n$.) Set $j \leftarrow 1$ and $k \leftarrow 2$.

B5. [Find the new j.] (Now $a_1 \ldots a_{k-1}$ is the $(k-1)$-extension of the prime $a_1 \ldots a_j$.) If $a_{k-j} > a_k$, return to B2. Otherwise, if $a_{k-j} < a_k$, set $j \leftarrow k$. Then increase k by 1 and repeat this step. ∎

The efficient factoring algorithm in steps B4 and B5 is due to J. P. Duval, *J. Algorithms* **4** (1983), 363–381. For further information, see Cattell, Ruskey, Sawada, Serra, and Miers, *J. Algorithms* **37** (2000), 267–282.

107. The number of n-tuples visited is $P_m(n) = \sum_{j=1}^{n} L_m(j)$. Since $L_m(n) = \frac{1}{n}m^n + O(m^{n/2}/n)$, we have $P_m(n) = Q(m,n) + O\big(Q(\sqrt{m}, n)\big)$, where

$$Q(m,n) = \sum_{k=1}^{n} \frac{m^k}{k} = \frac{m^n}{n}\, R(m,n);$$

$$R(m,n) = \sum_{k=0}^{n-1} \frac{m^{-k}}{1-k/n} = \sum_{k=0}^{n/2} \frac{m^{-k}}{1-k/n} + O(nm^{-n/2})$$

$$= \frac{m}{m-1} \sum_{j=0}^{t-1} \frac{1}{n^j} \sum_{l} \left\langle {j \atop l} \right\rangle \frac{m^l}{(m-1)^j} + O(n^{-t}).$$

The main contributions to the running time come from the loops in steps F3 and F5, which cost $n-j$ for each prime of length j, hence a total of $nP(n) - \sum_{j=1}^{n} jL_m(j) = m^{n+1}/((m-1)^2 n) + O(1/(mn^2))$. This is less than the time needed to output the m^n individual digits of the de Bruijn cycle.

108. (a) If $\alpha \neq 9 \ldots 9$, we have $\lambda_{k+1} \le \beta 9^{|\alpha|}$, because the latter is prime.

(b) We can assume that β is not all 0s, since 9^j0^{n-j} is a substring of $\lambda_{t-1}\lambda_t\lambda_1\lambda_2 = 89^n0^n1$. Let k be maximal with $\beta \le \lambda_k$; then $\lambda_k \le \beta\alpha$, so β is a prefix of λ_k. Since β is a preprime, it is the $|\beta|$-extension of some prime $\beta' \le \beta$. The preprime visited by Algorithm F just before β' is $(\beta'-1)9^{n-|\beta'|}$, by exercise 106, where $\beta'-1$ denotes the decimal number that is one less than β'. Thus, if β' is not λ_{k-1}, the hint (which also follows from exercise 106) implies that λ_{k-1} ends with at least $n-|\beta'| \ge n-|\beta|$ 9s, and α is a suffix of λ_{k-1}. On the other hand if $\beta' = \lambda_{k-1}$, α is a suffix of λ_{k-2}, and β is a prefix of $\lambda_{k-1}\lambda_k$.

(c) If $\alpha \ne 9\ldots9$, we have $\lambda_{k+1} \le (\beta\alpha)^{d-1}\beta9^{|\alpha|}$, because the latter is prime. Otherwise λ_{k-1} ends with at least $(d-1)|\beta\alpha|$ 9s, and $\lambda_{k+1} \le (\beta\alpha)^{d-1}9^{|\beta\alpha|}$, so $(\alpha\beta)^d$ is a substring of $\lambda_{k-1}\lambda_k\lambda_{k+1}$.

(d) Within the primes 135899 135914, 787899 787979, 129999 13 131314, 09 090911, 089999 09 090911, 089999 119 119122.

[In all cases, the position of $a_1\ldots a_n$ precedes the position of $a_1\ldots a_{n-1}(a_n+1)$, if $0 \le a_n < 9$ (and if we assume that strings like 9^j0^{n-j} occur at the beginning). Furthermore 9^j0^{n-j-1} occurs only after $9^{j-1}0^{n-j}a$ has appeared for $1 \le a \le 9$, so we must not place 0 after 9^j0^{n-j-1}. Therefore no m-ary de Bruijn cycle of length m^n can be lexicographically smaller than $\lambda_1\ldots\lambda_t$.]

109. Suppose we want to locate the submatrix

$$\begin{pmatrix} (w_{n-1}\ldots w_1w_0)_2 & (x_{n-1}\ldots x_1x_0)_2 \\ (y_{n-1}\ldots y_1y_0)_2 & (z_{n-1}\ldots z_1z_0)_2 \end{pmatrix}.$$

The binary case $n=1$ is the given example, and if $n>1$ we can assume by induction that we only need to determine the leading bits a_{2n-1}, a_{2n-2}, b_{2n-1}, and b_{2n-2}. The case $n=3$ is typical: We must solve

$$\begin{aligned}
b_5 &= w_2, & b_4 &= x_2, & a_5\oplus b_5 &= y_2, & a_4\oplus b_4 &= z_2, & &\text{if } a_0=0,\ b_0=0;\\
b_4 &= w_2, & b'_5 &= x_2, & a_4\oplus b_4 &= y_2, & a_5\oplus b'_5 &= z_2, & &\text{if } a_0=0,\ b_0=1;\\
a_5\oplus b_5 &= w_2, & a_4\oplus b_4 &= x_2, & b_5 &= y_2, & b_4 &= z_2, & &\text{if } a_0=1,\ b_0=0;\\
a_4\oplus b_4 &= w_2, & a_5\oplus b'_5 &= x_2, & b_4 &= y_2, & b'_5 &= z_2, & &\text{if } a_0=1,\ b_0=1;
\end{aligned}$$

here $b'_5 = b_5 \oplus b_4b_3b_2b_1$ takes account of carrying when j becomes $j+1$.

110. Let $a_0a_1\ldots a_{m^2-1}$ be an m-ary de Bruijn cycle, such as the first m^2 elements of (54). If m is odd, let $a_{ij} = a_j$ when i is even, $a_{ij} = a_{(j+(i-1)/2) \bmod m^2}$ when i is odd. [The first of many people to discover this construction seems to have been John C. Cock, who also constructed de Bruijn toruses of other shapes and sizes in *Discrete Math.* **70** (1988), 209–210.]

If $m = m'm''$ where $m' \perp m''$, we use the Chinese remainder theorem to define

$$a_{ij} \equiv a'_{ij} \text{ (modulo } m') \qquad \text{and} \qquad a_{ij} \equiv a''_{ij} \text{ (modulo } m'')$$

in terms of matrices that solve the problem for m' and m''. Thus the previous exercise leads to a solution for arbitrary m.

Another interesting solution for even values of m was found by Zoltán Tóth [*2nd Conf. Automata, Languages, and Programming Systems* (1988), 165–172; see also Hurlbert and Isaak, *Contemp. Math.* **178** (1994), 153–160]. The first m^2 elements a_j of the infinite sequence

0011 021331203223 041524355342514054450617263746577564 . . . 07667 08 . . .

define a de Bruijn cycle with the property that the distance between the appearances of ab and ba is always even. Then we can let $a_{ij} = a_j$ if $i + j$ is even, $a_{ij} = a_i$ if $i + j$ is odd. For example, when $m = 4$ we have

$$\begin{pmatrix}
0&0&1&0&0&2&1&2&2&0&3&0&2&2&3&2\\
0&0&0&1&0&2&0&3&2&0&2&1&2&2&2&3\\
0&1&1&1&0&3&1&3&2&1&3&1&2&3&3&3\\
1&0&1&1&1&2&1&3&3&0&3&1&3&2&3&3\\
0&0&1&0&0&2&1&2&2&0&3&0&2&2&3&2\\
0&2&0&3&0&0&0&1&2&2&2&3&2&0&2&1\\
0&1&1&1&0&3&1&3&2&1&3&1&2&3&3&3\\
1&2&1&3&1&0&1&1&3&2&3&3&3&0&3&1\\
0&0&1&0&0&2&1&2&2&0&3&0&2&2&3&2\\
2&0&2&1&2&2&2&3&0&0&0&1&0&2&0&3\\
0&1&1&1&0&3&1&3&2&1&3&1&2&3&3&3\\
3&0&3&1&3&2&3&3&1&0&1&1&1&2&1&3\\
0&0&1&0&0&2&1&2&2&0&3&0&2&2&3&2\\
2&2&2&3&2&0&2&1&0&2&0&3&0&0&0&1\\
0&1&1&1&0&3&1&3&2&1&3&1&2&3&3&3\\
3&2&3&3&3&0&3&1&1&2&1&3&1&0&1&1
\end{pmatrix}$$ (exercise 109);

$$\begin{pmatrix}
0&0&1&0&0&0&1&0&3&0&2&0&3&0&2&0\\
0&0&0&1&0&2&0&3&0&1&0&0&0&2&0&3\\
0&1&1&1&0&1&1&1&3&1&2&1&3&1&2&1\\
1&0&1&1&1&2&1&3&1&1&1&0&1&2&1&3\\
0&0&1&0&0&0&1&0&3&0&2&0&3&0&2&0\\
2&0&2&1&2&2&2&3&2&1&2&0&2&2&2&3\\
0&1&1&1&0&1&1&1&3&1&2&1&3&1&2&1\\
3&0&3&1&3&2&3&3&3&1&3&0&3&2&3&3\\
0&3&1&3&0&3&1&3&3&3&2&3&3&3&2&3\\
1&0&1&1&1&2&1&3&1&1&1&0&1&2&1&3\\
0&2&1&2&0&2&1&2&3&2&2&2&3&2&2&2\\
0&0&0&1&0&2&0&3&0&1&0&0&0&2&0&3\\
0&3&1&3&0&3&1&3&3&3&2&3&3&3&2&3\\
2&0&2&1&2&2&2&3&2&1&2&0&2&2&2&3\\
0&2&1&2&0&2&1&2&3&2&2&2&3&2&2&2\\
3&0&3&1&3&2&3&3&3&1&3&0&3&2&3&3
\end{pmatrix}$$ (Tóth).

111. (a) Let $d_j = j$ and $0 \le a_j < 3$ for $1 \le j \le 9$, $a_9 \ne 0$. Form sequences s_j, t_j by the rules $s_1 = 0$, $t_1 = d_1$; $t_{j+1} = d_{j+1} + 10t_j[a_j = 0]$ for $1 \le j < 9$; $s_{j+1} = s_j + (0, t_j, -t_j)$ for $a_j = (0, 1, 2)$ and $1 \le j \le 9$. Then s_{10} is a possible result; we need only remember the smallish values that occur. More than half the work is saved by disallowing $a_k = 2$ when $s_k = 0$, then using $|s_{10}|$ instead of s_{10}. Since fewer than $3^8 = 6561$ possibilities need to be tried, brute force via the ternary version of Algorithm M works well; fewer than 24,000 mems and 1600 multiplications are needed to deduce that all integers less than 211 are representable, but 211 is not.

Another approach, using Gray code to vary the signs after breaking the digits into blocks in 2^8 possible ways, reduces the number of multiplications to 255, but at the cost of about 500 additional mems. Therefore Gray code is not advantageous in this application.

(b) Now (with 73,000 mems and 4900 multiplications) we can reach all numbers less than 241, but not 241. There are 46 ways to represent 100, including the remarkable $9 - 87 + 6 + 5 - 43 + 210$.

[H. E. Dudeney introduced his "century" problem in *The Weekly Dispatch* (4 and 18 June 1899); see also *The Numerology of Dr. Matrix* by Martin Gardner, Chapter 6.]

112. The method of exercise 111 now needs more than 167 million mems and 10 million multiplications, because 3^{16} is so much larger than 3^8. We can do much better (10.4 million mems, 1100 mults) by first tabulating the possibilities obtainable from the first k and last k digits, for $1 \le k < 9$, then considering all blocks of digits that use the 9. There are 60,318 ways to represent 100, and the first unreachable number is 16,040.

INDEX AND GLOSSARY

When an index entry refers to a page containing a relevant exercise, see also the *answer* to that exercise for further information. An answer page is not indexed here unless it refers to a topic not included in the statement of the exercise.

PREFACE

I thought it worth a Dayes labour,
to write something on this Art or Science,
that the Rules thereof might not be lost and obscured.
— RICHARD DUCKWORTH, *Tintinnalogia* (1668)

THIS BOOKLET contains draft material that I'm circulating to experts in the field, in hopes that they can help remove its most egregious errors before too many other people see it. I am also, however, posting it on the Internet for courageous and/or random readers who don't mind the risk of reading a few pages that have not yet reached a very mature state. *Beware:* This material has not yet been proofread as thoroughly as the manuscripts of Volumes 1, 2, and 3 were at the time of their first printings. Those volumes, alas, were subsequently found to contain thousands of mistakes.

Given this caveat, I hope that my errors this time will not be so numerous and/or obtrusive that you will be discouraged from reading the material carefully. I did try to make it both interesting and authoritative, as far as it goes. But the field is so vast, I cannot hope to have surrounded it enough to corral it completely. Therefore I beg you to let me know about any deficiencies you discover.

To put the material in context, this is Section 7.2.1.2 of a long, long chapter on combinatorial algorithms. Chapter 7 will eventually fill three volumes (namely Volumes 4A, 4B, and 4C), assuming that I'm able to remain healthy. It will begin with a short review of graph theory, with emphasis on some highlights of significant graphs in The Stanford GraphBase (from which I will be drawing many examples). Then comes Section 7.1, which deals with the topic of bitwise manipulations. (I drafted about 60 pages about that subject in 1977, but those pages need extensive revision; meanwhile I've decided to work for awhile on the material that follows it, so that I can get a better feel for how much to cut.) Section 7.2 is about generating all possibilities, and it begins with Section 7.2.1: Generating Basic Combinatorial Patterns—which, in turn, begins with Section 7.2.1.1, "Generating all n-tuples." (Readers of the present booklet should have already looked at Section 7.2.1.1, a draft of which is available as Prefascicle 2A.) That sets the stage for the main contents of this booklet, Section 7.2.1.2: "Generating all permutations." Then will come Section 7.2.1.3 (about combinations), etc. Section 7.2.2 will deal with backtracking in general. And so it will go on, if all goes well; an outline of the entire Chapter 7 as currently envisaged appears on the `taocp` webpage that is cited on page ii.

Even the apparently lowly topic of permutation generation turns out to be surprisingly rich, with ties to Sections 1.2.9, 1.3.3, 2.2.3, 2.3.4.2, 3.4.2, 4.1, 5.1.1, 5.1.2, 5.1.4, 5.2.1, 5.2.2, 5.3.1, and 6.1 of the first three volumes. There also is material related to the `MMIX` computer, defined in Section 1.3.1′ of Fascicle 1. I strongly believe in building up a firm foundation, so I have discussed this topic much more thoroughly than I will be able to do with material that is newer or less basic. To my surprise, I came up with 111 exercises, even though — believe it or not — I had to eliminate quite a bit of the interesting material that appears in my files.

Some of the things presented are new, to the best of my knowledge, although I will not be at all surprised to learn that my own little "discoveries" have been discovered before. Please look, for example, at the exercises that I've classed as research problems (rated with difficulty level 46 or higher), namely exercises 108 and 111; I've also implicitly posed additional unsolved questions in the answers to exercises 28, 58, 63, 67, 88, 99, 105, and 111. Are those problems still open? Please let me know if you know of a solution to any of these intriguing questions. And of course if no solution is known today but you do make progress on any of them in the future, I hope you'll let me know.

I urgently need your help also with respect to some exercises that I made up as I was preparing this material. I certainly don't like to get credit for things that have already been published by others, and most of these results are quite natural "fruits" that were just waiting to be "plucked." Therefore please tell me if you know who I should have credited, with respect to the ideas found in exercises 6, 7, 20, 25, 41, 55, 60, 65, 66, 67, 69, 70, 75, 88, 98, and/or 103.

I shall happily pay a finder's fee of \$2.56 for each error in this draft when it is first reported to me, whether that error be typographical, technical, or historical. The same reward holds for items that I forgot to put in the index. And valuable suggestions for improvements to the text are worth 32¢ each. (Furthermore, if you find a better solution to an exercise, I'll actually reward you with immortal glory instead of mere money, by publishing your name in the eventual book:–)

Happy reading!

— DOROTHY L. SAYERS, *The Nine Tailors* (1934)

A permutation on the ten decimal digits is simply a 10 digit decimal number in which all digits are distinct. Hence all we need to do is to produce all 10 digit numbers and select only those whose digits are distinct. Isn't it wonderful how high speed computing saves us from the drudgery of thinking! We simply program $k + 1 \rightarrow k$ *and examine the digits of* k *for undesirable equalities. This gives us the permutations in dictionary order too! On second sober thought . . . we do need to think of something else.*

— D. H. LEHMER (1957)

7.2.1.2. Generating all permutations. After n-tuples, the next most important item on nearly everybody's wish list for combinatorial generation is the task of visiting all *permutations* of some given set or multiset. Many different ways have been devised to solve this problem. In fact, almost as many different algorithms have been published for unsorting as for sorting! We will study the most important permutation generators in this section, beginning with a classical method that is both simple and flexible:

Algorithm L (*Lexicographic permutation generation*). Given a sequence of n elements $a_1 a_2 \dots a_n$, initially sorted so that

$$a_1 \le a_2 \le \cdots \le a_n, \tag{1}$$

this algorithm generates all permutations of $\{a_1, a_2, \dots, a_n\}$, visiting them in lexicographic order. (For example, the permutations of $\{1, 2, 2, 3\}$ are

1223, 1232, 1322, 2123, 2132, 2213, 2231, 2312, 2321, 3122, 3212, 3221,

ordered lexicographically.) An auxiliary element a_0 is assumed to be present for convenience; a_0 must be strictly less than the largest element a_n.

L1. [Visit.] Visit the permutation $a_1 a_2 \dots a_n$.

L2. [Find j.] Set $j \leftarrow n-1$. If $a_j \geq a_{j+1}$, decrease j by 1 repeatedly until $a_j < a_{j+1}$. Terminate the algorithm if $j = 0$. (At this point j is the largest subscript such that we have already visited all permutations beginning with $a_1 \ldots a_j$. Therefore the lexicographically next permutation will increase the value of a_j.)

L3. [Increase a_j.] Set $l \leftarrow n$. If $a_j \geq a_l$, decrease l by 1 repeatedly until $a_j < a_l$. Then interchange $a_j \leftrightarrow a_l$. (Since $a_{j+1} \geq \cdots \geq a_n$, element a_l is the smallest element greater than a_j that can legitimately follow $a_1 \ldots a_{j-1}$ in a permutation. Before the interchange we had $a_{j+1} \geq \cdots \geq a_{l-1} \geq a_l > a_j \geq a_{l+1} \geq \cdots \geq a_n$; after the interchange, we have $a_{j+1} \geq \cdots \geq a_{l-1} \geq a_j > a_l \geq a_{l+1} \geq \cdots \geq a_n$.)

L4. [Reverse $a_{j+1} \ldots a_n$.] Set $k \leftarrow j+1$ and $l \leftarrow n$. Then, if $k < l$, interchange $a_k \leftrightarrow a_l$, set $k \leftarrow k+1$, $l \leftarrow l-1$, and repeat until $k \geq l$. Return to L1. ∎

This algorithm goes back at least to the 18th century, in C. F. Hindenburg's preface to *Specimen Analyticum de Lineis Curvis Secundi Ordinis* by C. F. Rüdiger (Leipzig: 1784), xlvi–xlvii, and it has been frequently rediscovered ever since. The parenthetical remarks in steps L2 and L3 explain why it works.

In general, the lexicographic successor of any combinatorial pattern $a_1 \ldots a_n$ is obtainable by a three-step procedure:

1) Find the largest j such that a_j can be increased.
2) Increase a_j by the smallest feasible amount.
3) Find the lexicographically least way to extend the new $a_1 \ldots a_j$ to a complete pattern.

Algorithm L follows this general procedure in the case of permutation generation, just as Algorithm 7.2.1.1M followed it in the case of n-tuple generation; we will see numerous further instances later, as we consider other kinds of combinatorial patterns. Notice that we have $a_{j+1} \geq \cdots \geq a_n$ at the beginning of step L4. Therefore the first permutation beginning with the current prefix $a_1 \ldots a_j$ is $a_1 \ldots a_j a_n \ldots a_{j+1}$, and step L4 produces it by doing $\lfloor (n-j)/2 \rfloor$ interchanges.

In practice, step L2 finds $j = n-1$ half of the time when the elements are distinct, because exactly $n!/2$ of the $n!$ permutations have $a_{n-1} < a_n$. Therefore Algorithm L can be speeded up by recognizing this special case, without making it significantly more complicated. (See exercise 1.) Similarly, the probability that $j \leq n-t$ is only $1/t!$ when the a's are distinct; hence the loops in steps L2–L4 usually go very fast. Exercise 6 analyzes the running time in general, showing that Algorithm L is reasonably efficient even when equal elements are present, unless some values appear much more often than others do in the multiset $\{a_1, a_2, \ldots, a_n\}$.

Adjacent interchanges. We saw in Section 7.2.1.1 that Gray codes are advantageous for generating n-tuples, and similar considerations apply when we want to generate permutations. The simplest possible change to a permutation is to interchange adjacent elements, and we know from Chapter 5 that any permutation can be sorted into order if we make a suitable sequence of such

interchanges. (For example, Algorithm 5.2.2B works in this way.) Hence we can go backward and obtain any desired permutation, by starting with all elements in order and then exchanging appropriate pairs of adjacent elements.

A natural question now arises: Is it possible to run through *all* permutations of a given multiset in such a way that only two adjacent elements change places at every step? If so, the overall program that is examining all permutations will often be simpler and faster, because it will only need to calculate the effect of an exchange instead of to reprocess an entirely new array $a_1 \ldots a_n$ each time.

Alas, when the multiset has repeated elements, we can't always find such a Gray-like sequence. For example, the six permutations of $\{1, 1, 2, 2\}$ are connected to each other in the following way by adjacent interchanges:

$$1122 \text{ —— } 1212 \begin{array}{l} \diagup \\ \diagdown \end{array} \begin{array}{c} 2112 \\ 1221 \end{array} \begin{array}{l} \diagdown \\ \diagup \end{array} 2121 \text{ —— } 2211; \tag{2}$$

this graph has no Hamiltonian path.

But most applications deal with permutations of *distinct* elements, and for this case there is good news: A simple algorithm makes it possible to generate all $n!$ permutations by making just $n! - 1$ adjacent interchanges. Furthermore, another such interchange returns to the starting point, so we have a Hamiltonian circuit analogous to Gray binary code.

The idea is to take such a sequence for $\{1, \ldots, n-1\}$ and to insert the number n into each permutation in all ways. For example, if $n = 4$ the sequence $(123, 132, 312, 321, 231, 213)$ leads to the columns of the array

$$\begin{array}{cccccc} 1234 & 1324 & 3124 & 3214 & 2314 & 2134 \\ 1243 & 1342 & 3142 & 3241 & 2341 & 2143 \\ 1423 & 1432 & 3412 & 3421 & 2431 & 2413 \\ 4123 & 4132 & 4312 & 4321 & 4231 & 4213 \end{array} \tag{3}$$

when 4 is inserted in all four possible positions. Now we obtain the desired sequence by reading downwards in the first column, upwards in the second, downwards in the third, ..., upwards in the last: $(1234, 1243, 1423, 4123, 4132, 1432, 1342, 1324, 3124, 3142, \ldots, 2143, 2134)$.

In Section 5.1.1 we studied the inversions of a permutation, namely the pairs of elements (not necessarily adjacent) that are out of order. Every interchange of adjacent elements changes the total number of inversions by ± 1. In fact, when we consider the so-called inversion table $c_1 \ldots c_n$ of exercise 5.1.1–7, where c_j is the number of elements lying to the right of j that are less than j, we find that the permutations in (3) have the following inversion tables:

$$\begin{array}{cccccc} 0000 & 0010 & 0020 & 0120 & 0110 & 0100 \\ 0001 & 0011 & 0021 & 0121 & 0111 & 0101 \\ 0002 & 0012 & 0022 & 0122 & 0112 & 0102 \\ 0003 & 0013 & 0023 & 0123 & 0113 & 0103 \end{array} \tag{4}$$

And if we read these columns alternately down and up as before, we obtain precisely the reflected Gray code for mixed radices $(1, 2, 3, 4)$, as in Eqs. (46)–(51)

of Section 7.2.1.1. The same property holds for all n, as noticed by E. W. Dijkstra [*Acta Informatica* **6** (1976), 357–359], and it leads us to the following formulation:

Algorithm P (*Plain changes*). Given a sequence $a_1a_2\ldots a_n$ of n distinct elements, this algorithm generates all of their permutations by repeatedly interchanging adjacent pairs. It uses an auxiliary array $c_1c_2\ldots c_n$, which represents inversions as described above, running through all sequences of integers such that

$$0 \le c_j < j \qquad \text{for } 1 \le j \le n. \tag{5}$$

Another array $d_1d_2\ldots d_n$ governs the directions by which the entries c_j change.

P1. [Initialize.] Set $c_j \leftarrow 0$ and $d_j \leftarrow 1$ for $1 \le j \le n$.

P2. [Visit.] Visit the permutation $a_1a_2\ldots a_n$.

P3. [Prepare for change.] Set $j \leftarrow n$ and $s \leftarrow 0$. (The following steps determine the coordinate j for which c_j is about to change, preserving (5); variable s is the number of indices $k > j$ such that $c_k = k - 1$.)

P4. [Ready to change?] Set $q \leftarrow c_j + d_j$. If $q < 0$, go to P7; if $q = j$, go to P6.

P5. [Change.] Interchange $a_{j-c_j+s} \leftrightarrow a_{j-q+s}$. Then set $c_j \leftarrow q$ and return to P2.

P6. [Increase s.] Terminate if $j = 1$; otherwise set $s \leftarrow s + 1$.

P7. [Switch direction.] Set $d_j \leftarrow -d_j$, $j \leftarrow j - 1$, and go back to P4. ∎

This procedure, which clearly works for all $n \ge 1$, originated in 17th-century England, when bell ringers began the delightful custom of ringing a set of bells in all possible permutations. They called Algorithm P the method of *plain changes*. Figure 18(a) illustrates the "Cambridge Forty-Eight," an irregular and ad hoc sequence of 48 permutations on 5 bells that had been used in the early 1600s, before the plain-change principle revealed how to achieve all $5! = 120$ possibilities. The venerable history of Algorithm P has been traced to a manuscript by Peter Mundy now in the Bodleian Library, written about 1653 and transcribed by Ernest Morris in *The History and Art of Change Ringing* (1931), 29–30. Shortly afterwards, a famous book called *Tintinnalogia*, published anonymously in 1668 but now known to have been written by Richard Duckworth and Fabian Stedman, devoted its first 60 pages to a detailed description of plain changes, working up from $n = 3$ to the case of arbitrarily large n.

> Cambridge Forty-eight, *for many years,*
> *was the greatest* Peal *that was* Rang *or invented; but now,*
> *neither* Forty-eight, *nor a* Hundred, *nor* Seven-hundred and twenty,
> *nor any Number can confine us; for we can* Ring Changes, Ad infinitum.
> . . . *On four Bells, there are* Twenty four several Changes,
> *in* Ringing *of which, there is one Bell called the* Hunt,
> *and the other three are* Extream *Bells;*
> *the* Hunt *moves, and* hunts *up and down continually . . . ;*
> *two of the* Extream *Bells makes a* Change
> *every time the* Hunt *comes before or behind them.*

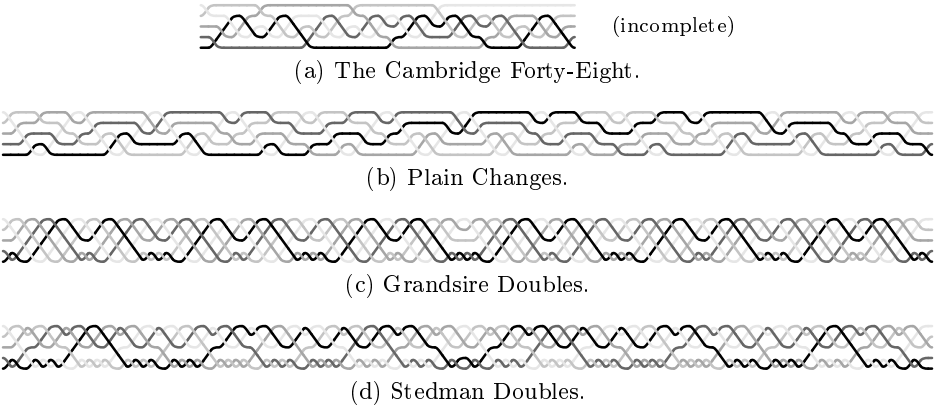
> — DUCKWORTH and STEDMAN (1668)



(a) The Cambridge Forty-Eight.

(b) Plain Changes.

(c) Grandsire Doubles.

(d) Stedman Doubles.

Fig. 18. Four patterns used to ring church-bells in 17th-century England. Pattern (b) corresponds to Algorithm P.

British bellringing enthusiasts soon went on to develop more complicated schemes in which two or more pairs of bells change places simultaneously. For example, they devised the pattern in Fig. 18(c) known as Grandsire Doubles, "the best and most ingenious Peal that ever was composed, to be rang on five bells" [*Tintinnalogia*, page 95]. Such fancier methods are more interesting than Algorithm P from a musical or mathematical standpoint, but they are less useful in computer applications, so we shall not dwell on them here. Interested readers can learn more by reading W. G. Wilson's book, *Change Ringing* (1965); see also A. T. White, *AMM* **103** (1996), 771–778.

H. F. Trotter published the first computer implementation of plain changes in *CACM* **5** (1962), 434–435. The algorithm is quite efficient, especially when it is streamlined as in exercise 16, because $n-1$ out of every n permutations are generated without using steps P6 and P7. By contrast, Algorithm L enjoys its best case only about half of the time.

The fact that Algorithm P does exactly one interchange per visit means that the permutations it generates are alternately even and odd (see exercise 5.1.1–13). Therefore we can generate all the even permutations by simply bypassing the odd ones. In fact, the c and d tables make it easy to keep track of the current total number of inversions, $c_1 + \cdots + c_n$, as we go.

Many programs need to generate the same permutations repeatedly, and in such cases we needn't run through the steps of Algorithm P each time. We can simply prepare a list of suitable transitions, using the following method:

Algorithm T (*Plain change transitions*). This algorithm computes a table $t[1]$, $t[2]$, $\ldots$, $t[n!-1]$ such that the actions of Algorithm P are equivalent to the successive interchanges $a_{t[k]} \leftrightarrow a_{t[k]+1}$ for $1 \le k < n!$. We assume that $n \ge 2$.

T1. [Initialize.] Set $N \leftarrow n!$, $d \leftarrow N/2$, $t[d] \leftarrow 1$, and $m \leftarrow 2$.

T2. [Loop on m.] Terminate if $m = n$. Otherwise set $m \leftarrow m+1$, $d \leftarrow d/m$, and $k \leftarrow 0$. (We maintain the condition $d = n!/m!$.)

T3. [Hunt down.] Set $k \leftarrow k+d$ and $j \leftarrow m-1$. Then while $j > 0$, set $t[k] \leftarrow j$, $j \leftarrow j-1$, and $k \leftarrow k+d$, until $j = 0$.

T4. [Offset.] Set $t[k] \leftarrow t[k]+1$ and $k \leftarrow k+d$.

T5. [Hunt up.] While $j < m-1$, set $j \leftarrow j+1$, $t[k] \leftarrow j$, and $k \leftarrow k+d$. Return to T3 if $k < N$, otherwise return to T2. ∎

For example, if $n = 4$ we get the table $(t[1], t[2], \ldots, t[23]) = (3,2,1,3,1,2,3,1,3,2,1,3,1,2,3,1,3,2,1,3,1,2,3)$.

Alphametics. Now let's consider a simple kind of puzzle in which permutations are useful: How can the pattern

$$\begin{array}{r} \texttt{SEND} \\ +\,\texttt{MORE} \\ \hline \texttt{MONEY} \end{array} \tag{6}$$

represent a correct sum, if every letter stands for a different decimal digit? [H. E. Dudeney, *Strand* **68** (1924), 97, 214.] Such puzzles are often called "alphametics," a word coined by J. A. H. Hunter [*Globe and Mail* (Toronto: 27 October 1955), 27]; another term, "cryptarithm," has also been suggested by S. Vatriquant [*Sphinx* **1** (May 1931), 50].

The classic alphametic (6) can easily be solved by hand (see exercise 21). But let's suppose we want to deal with a large set of complicated alphametics, some of which may be unsolvable while others may have dozens of solutions. Then we can save time by programming a computer to try out all permutations of digits that match a given pattern, seeing which permutations yield a correct sum. [A computer program for solving alphametics was published by John Beidler in *Creative Computing* **4**, 6 (November–December 1978), 110–113.]

We might as well raise our sights slightly and consider additive alphametics in general, dealing not only with simple sums like (6) but also with examples like

$$\texttt{VIOLIN} + \texttt{VIOLIN} + \texttt{VIOLA} \;=\; \texttt{TRIO} + \texttt{SONATA}.$$

Equivalently, we want to solve puzzles such as

$$2(\texttt{VIOLIN}) + \texttt{VIOLA} - \texttt{TRIO} - \texttt{SONATA} \;=\; 0, \tag{7}$$

where a sum of terms with integer coefficients is given and the goal is to obtain zero by substituting distinct decimal digits for the different letters. Each letter in such a problem has a "signature" obtained by substituting 1 for that letter and 0 for the others; for example, the signature for `I` in (7) is

$$2(010010) + 01000 - 0010 - 000000,$$

namely 21010. If we arbitrarily assign the codes $(1, 2, \ldots, 10)$ to the letters $(\texttt{V}, \texttt{I}, \texttt{O}, \texttt{L}, \texttt{N}, \texttt{A}, \texttt{T}, \texttt{R}, \texttt{S}, \texttt{X})$, the respective signatures corresponding to (7) are

$$\begin{array}{llllll} s_1 = 210000, & s_2 = 21010, & s_3 = -7901, & s_4 = 210, & s_5 = -998, \\ s_6 = -100, & s_7 = -1010, & s_8 = -100, & s_9 = -100000, & s_{10} = 0. \end{array} \tag{8}$$

The problem then is to find all permutations $a_1 \ldots a_{10}$ of $\{0, 1, \ldots, 9\}$ such that

$$a \cdot s \;=\; \sum_{j=1}^{10} a_j s_j \;=\; 0. \tag{9}$$

There also is a side condition, because the numbers in alphametics should not have zero as a leading digit. For example, the sums

$$\begin{array}{r} 7316 \\ +\,0823 \\ \hline 08139 \end{array} \quad \text{and} \quad \begin{array}{r} 5731 \\ +\,0647 \\ \hline 06378 \end{array} \quad \text{and} \quad \begin{array}{r} 6524 \\ +\,0735 \\ \hline 07259 \end{array} \quad \text{and} \quad \begin{array}{r} 2817 \\ +\,0368 \\ \hline 03185 \end{array}$$

and numerous others are *not* considered to be valid solutions of (6). In general there is a set F of first letters such that we must have

$$a_j \neq 0 \qquad \text{for all } j \in F; \tag{10}$$

the set F corresponding to (7) and (8) is $\{1, 7, 9\}$.

One way to tackle a family of additive alphametics is to start by using Algorithm T to prepare a table of $10! - 1$ transitions $t[j]$. Then, for each problem defined by a signature sequence $(s_1, \ldots, s_{10})$ and a first-letter set F, we can exhaustively look for solutions as follows:

A1. [Initialize.] Set $a_1 a_2 \ldots a_{10} \leftarrow 01 \ldots 9$, $v \leftarrow \sum_{j=1}^{10} (j-1)s_j$, $k \leftarrow 1$, and $\delta_j \leftarrow s_{j+1} - s_j$ for $1 \le j < 10$.

A2. [Test.] If $v = 0$ and if (10) holds, output the solution $a_1 \ldots a_{10}$.

A3. [Swap.] Stop if $k = 10!$. Otherwise set $j \leftarrow t[k]$, $v \leftarrow v - (a_{j+1} - a_j)\delta_j$, $a_{j+1} \leftrightarrow a_j$, $k \leftarrow k + 1$, and return to A2. ∎

Step A3 is justified by the fact that swapping a_j with a_{j+1} simply decreases $a \cdot s$ by $(a_{j+1} - a_j)(s_{j+1} - s_j)$. Even though 10! is 3,628,800, a fairly large number, the operations in step A3 are so simple that the whole job takes only a fraction of a second on a modern computer.

An alphametic is said to be *pure* if it has a unique solution. Unfortunately (7) is not pure; the permutations 1764802539 and 3546281970 both solve (9) and (10), hence we have both

$$176478 + 176478 + 17640 \;=\; 2576 + 368020$$

and

$$354652 + 354652 + 35468 \;=\; 1954 + 742818.$$

Furthermore $s_6 = s_8$ in (8), so we can obtain two more solutions by interchanging the digits assigned to `A` and `R`.

On the other hand (6) *is* pure, yet the method we have described will find two different permutations that solve it. The reason is that (6) involves only eight distinct letters, hence we will set it up for solution by using two dummy signatures $s_9 = s_{10} = 0$. In general, an alphametic with m distinct letters will have $10 - m$ dummy signatures $s_{m+1} = \cdots = s_{10} = 0$, and each of its solutions will be found $(10 - m)!$ times unless we insist that, say, $a_{m+1} < \cdots < a_{10}$.

A general framework. A great many algorithms have been proposed for generating permutations of distinct objects, and the best way to understand them is to apply the multiplicative properties of permutations that we studied in Section 1.3.3. For this purpose we will change our notation slightly, by using 0-origin indexing and writing $a_0\,a_1\ldots a_{n-1}$ for permutations of $\{0,1,\ldots,n-1\}$ instead of writing $a_1a_2\ldots a_n$ for permutations of $\{1,2,\ldots,n\}$. More importantly, we will consider schemes for generating permutations in which most of the action takes place at the *left*, so that all permutations of $\{0,1,\ldots,k-1\}$ will be generated during the first $k!$ steps, for $1\le k\le n$. For example, one such scheme for $n=4$ is

$$\begin{aligned}&0123, 1023, 0213, 2013, 1203, 2103, 0132, 1032, 0312, 3012, 1302, 3102,\\ &0231, 2031, 0321, 3021, 2301, 3201, 1230, 2130, 1320, 3120, 2310, 3210;\end{aligned}\qquad(11)$$

this is called "reverse colex order," because if we reflect the strings from right to left we get 3210, 3201, 3120, ..., 0123, the reverse of lexicographic order. Another way to think of (11) is to view the entries as $(n-a_n)\ldots(n-a_2)(n-a_1)$, where $a_1a_2\ldots a_n$ runs lexicographically through the permutations of $\{1,2,\ldots,n\}$.

Let's recall that a permutation like $\alpha=250143$ can be written either in the two-line form

$$\alpha=\begin{pmatrix}012345\\250143\end{pmatrix}$$

or in the more compact cycle form

$$\alpha=(0\ 2)(1\ 5\ 3),$$

with the meaning that α takes $0\mapsto 2$, $1\mapsto 5$, $2\mapsto 0$, $3\mapsto 1$, $4\mapsto 4$, and $5\mapsto 3$; a 1-cycle like '(4)' need not be indicated. Since 4 is a fixed point of this permutation we say that "α fixes 4." We also write $0\alpha=2$, $1\alpha=5$, and so on, saying that $j\alpha$ is "the image of j under α." Multiplication of permutations, like α times β where $\beta=543210$, is readily carried out either in the two-line form

$$\alpha\beta=\begin{pmatrix}012345\\250143\end{pmatrix}\begin{pmatrix}012345\\543210\end{pmatrix}=\begin{pmatrix}012345\\250143\end{pmatrix}\begin{pmatrix}250143\\305412\end{pmatrix}=\begin{pmatrix}012345\\305412\end{pmatrix}$$

or in the cycle form

$$\alpha\beta=(0\ 2)(1\ 5\ 3)\ \cdot\ (0\ 5)(1\ 4)(2\ 3)\ =\ (0\ 3\ 4\ 1)(2\ 5).$$

Notice that the image of 1 under $\alpha\beta$ is $1(\alpha\beta)=(1\alpha)\beta=5\beta=0$, etc. *Warning:* About half of all books that deal with permutations multiply them the other way (from right to left), imagining that $\alpha\beta$ means that β should be applied before α. The reason is that traditional functional notation, in which one writes $\alpha(1)=5$, makes it natural to think that $\alpha\beta(1)$ should mean $\alpha(\beta(1))=\alpha(4)=4$. However, the present book subscribes to the other philosophy, and we shall always multiply permutations from left to right.

The order of multiplication needs to be understood carefully when permutations are represented by arrays of numbers. For example, if we "apply" the reflection $\beta=543210$ to the permutation $\alpha=250143$, the result 341052 is not $\alpha\beta$

but $\beta\alpha$. In general, the operation of replacing a permutation $\alpha = a_0 a_1 \dots a_{n-1}$ by some rearrangement $a_{0\beta} a_{1\beta} \dots a_{(n-1)\beta}$ takes $k \mapsto a_{k\beta} = k\beta\alpha$. Permuting the *positions* by β corresponds to *premultiplication* by β, changing α to $\beta\alpha$; permuting the *values* by β corresponds to *postmultiplication* by β, changing α to $\alpha\beta$. Thus, for example, a permutation generator that interchanges $a_1 \leftrightarrow a_2$ is premultiplying the current permutation by (1 2), postmultiplying it by $(a_1\ a_2)$.

Following a proposal made by Évariste Galois in 1830, a nonempty set G of permutations is said to form a *group* if it is closed under multiplication, that is, if the product $\alpha\beta$ is in G whenever α and β are elements of G [see *Écrits et Mémoires Mathématiques d'Évariste Galois* (Paris: 1962), 47]. Consider, for example, the 4-cube represented as a 4×4 torus

$$\begin{array}{|cccc|}\hline 0 & 1 & 3 & 2 \\ 4 & 5 & 7 & 6 \\ c & d & f & e \\ 8 & 9 & b & a \\ \hline\end{array} \tag{12}$$

as in exercise 7.2.1.1–17, and let G be the set of all permutations of the vertices $\{0, 1, \dots, f\}$ that preserve adjacency: A permutation α is in G if and only if u — v implies $u\alpha$ — $v\alpha$ in the 4-cube. (Here we are using hexadecimal digits $(0, 1, \dots, f)$ to stand for the integers $(0, 1, \dots, 15)$. The labels in (12) are chosen so that u — v if and only if u and v differ in only one bit position.) This set G is obviously a group, and its elements are called the symmetries or "automorphisms" of the 4-cube.

Groups of permutations G are conveniently represented inside a computer by means of a *Sims table*, introduced by Charles C. Sims [*Computational Methods in Abstract Algebra* (Oxford: Pergamon, 1970), 169–183], which is a family of subsets S_1, S_2, ... of G having the following property: S_k contains exactly one permutation σ_{kj} that takes $k \mapsto j$ and fixes the values of all elements greater than k, whenever G contains such a permutation. We let σ_{kk} be the identity permutation, which is always present in G; but when $0 \le j < k$, any suitable permutation can be selected to play the role of σ_{kj}. The main advantage of a Sims table is that it provides a convenient representation of the entire group:

Lemma S. *Let S_1, S_2, ..., S_{n-1} be a Sims table for a group G of permutations on $\{0, 1, \dots, n-1\}$. Then every element α of G has a unique representation*

$$\alpha = \sigma_1 \sigma_2 \dots \sigma_{n-1}, \qquad \text{where } \sigma_k \in S_k \text{ for } 1 \le k < n. \tag{13}$$

Proof. If α has such a representation and if σ_{n-1} is the permutation $\sigma_{(n-1)j} \in S_{n-1}$, then α takes $n-1 \mapsto j$, because all elements of $S_1 \cup \dots \cup S_{n-2}$ fix the value of $n-1$. Conversely, if α takes $n-1 \mapsto j$ we have $\alpha = \alpha' \sigma_{(n-1)j}$, where

$$\alpha' = \alpha\, \sigma^{-}_{(n-1)j}$$

is a permutation of G that fixes $n-1$. The set G' of all such permutations is a group, and S_1, ..., S_{n-2} is a Sims table for G'; therefore the result follows by induction on n. ∎

For example, a bit of calculation shows that one possible Sims table for the automorphism group of the 4-cube is

$$\begin{aligned}
S_{\mathtt{f}} &= \{(),\ (\mathtt{01})(\mathtt{23})(\mathtt{45})(\mathtt{67})(\mathtt{89})(\mathtt{ab})(\mathtt{cd})(\mathtt{ef}),\ \ldots,\\
&\qquad\qquad (\mathtt{0f})(\mathtt{1e})(\mathtt{2d})(\mathtt{3c})(\mathtt{4b})(\mathtt{5a})(\mathtt{69})(\mathtt{78})\};\\
S_{\mathtt{e}} &= \{(),\ (\mathtt{12})(\mathtt{56})(\mathtt{9a})(\mathtt{de}),\ (\mathtt{14})(\mathtt{36})(\mathtt{9c})(\mathtt{be}),\ (\mathtt{18})(\mathtt{3a})(\mathtt{5c})(\mathtt{7e})\};\\
S_{\mathtt{d}} &= \{(),\ (\mathtt{24})(\mathtt{35})(\mathtt{ac})(\mathtt{bd}),\ (\mathtt{28})(\mathtt{39})(\mathtt{6c})(\mathtt{7d})\};\\
S_{\mathtt{c}} &= \{()\};\\
S_{\mathtt{b}} &= \{(),\ (\mathtt{48})(\mathtt{59})(\mathtt{6a})(\mathtt{7b})\};\\
S_{\mathtt{a}} &= S_{\mathtt{9}} = \cdots = S_{\mathtt{1}} = \{()\};
\end{aligned} \tag{14}$$

here $S_{\mathtt{f}}$ contains 16 permutations $\sigma_{\mathtt{f}j}$ for $0 \le j \le 15$, which respectively take $i \mapsto i \oplus (15 - j)$ for $0 \le i \le 15$. The set $S_{\mathtt{e}}$ contains only four permutations, because an automorphism that fixes `f` must take `e` into a neighbor of `f`; thus the image of `e` must be either `e` or `d` or `b` or `7`. The set $S_{\mathtt{c}}$ contains only the identity permutation, because an automorphism that fixes `f`, `e`, and `d` must also fix `c`. Most groups have $S_k = \{()\}$ for all small values of k, as in this example; hence a Sims table usually needs to contain only a fairly small number of permutations although the group itself might be quite large.

The Sims representation (13) makes it easy to test if a given permutation α lies in G: First we determine $\sigma_{n-1} = \sigma_{(n-1)j}$, where α takes $n-1 \mapsto j$, and we let $\alpha' = \alpha\sigma_{n-1}^-$; then we determine $\sigma_{n-2} = \sigma_{(n-2)j'}$, where α' takes $n-2 \mapsto j'$, and we let $\alpha'' = \alpha'\sigma_{n-2}^-$; and so on. If at any stage the required σ_{kj} does not exist in S_k, the original permutation α does not belong to G. In the case of (14), this process must reduce α to the identity after finding $\sigma_{\mathtt{f}}$, $\sigma_{\mathtt{e}}$, $\sigma_{\mathtt{d}}$, $\sigma_{\mathtt{c}}$, and $\sigma_{\mathtt{b}}$.

For example, let α be the permutation $(\mathtt{14})(\mathtt{28})(\mathtt{3c})(\mathtt{69})(\mathtt{7d})(\mathtt{be})$, which corresponds to transposing (12) about its main diagonal $\{\mathtt{0},\mathtt{5},\mathtt{f},\mathtt{a}\}$. Since α fixes `f`, $\sigma_{\mathtt{f}}$ will be the identity permutation (), and $\alpha' = \alpha$. Then $\sigma_{\mathtt{e}}$ is the member of $S_{\mathtt{e}}$ that takes $\mathtt{e} \mapsto \mathtt{b}$, namely $(\mathtt{14})(\mathtt{36})(\mathtt{9c})(\mathtt{be})$, and we find $\alpha'' = (\mathtt{28})(\mathtt{39})(\mathtt{6c})(\mathtt{7d})$. This permutation belongs to $S_{\mathtt{d}}$, so α is indeed an automorphism of the 4-cube.

Conversely, (13) also makes it easy to generate all elements of the corresponding group. We simply run through all permutations of the form

$$\sigma(1, c_1)\sigma(2, c_2)\ldots\sigma(n-1, c_{n-1}),$$

where $\sigma(k, c_k)$ is the $(c_k + 1)$st element of S_k for $0 \le c_k < s_k = \|S_k\|$ and $1 \le k < n$, using any algorithm of Section 7.2.1.1 that runs through all $(n-1)$-tuples $(c_1, \ldots, c_{n-1})$ for the respective radices $(s_1, \ldots, s_{n-1})$.

Using the general framework. Our chief concern is the group of *all* permutations on $\{0, 1, \ldots, n-1\}$, and in this case every set S_k of a Sims table will contain $k+1$ elements $\{\sigma(k,0), \sigma(k,1), \ldots, \sigma(k,k)\}$, where $\sigma(k,0)$ is the identity and the others take k to the values $\{0, \ldots, k-1\}$ in some order (fixing all elements greater than k). Every such Sims table leads to a permutation generator, according to the following outline:

Algorithm G (*General permutation generator*). Given a Sims table $(S_1, S_2, \ldots, S_{n-1})$ where each S_k has $k+1$ elements $\sigma(k,j)$ as just described, this algorithm generates all permutations $a_0 a_1 \ldots a_{n-1}$ of $\{0, 1, \ldots, n-1\}$, using an auxiliary control table $c_n \ldots c_2 c_1$.

G1. [Initialize.] Set $a_j \leftarrow j$ and $c_{j+1} \leftarrow 0$ for $0 \le j < n$.

G2. [Visit.] (At this point the mixed-radix number $\left[\begin{smallmatrix} c_{n-1}, \ldots, c_2, c_1 \\ n, \ \ldots, \ 3, \ 2 \end{smallmatrix}\right]$ is the number of permutations visited so far.) Visit the permutation $a_0 a_1 \ldots a_{n-1}$.

G3. [Add 1 to $c_n \ldots c_2 c_1$.] Set $k \leftarrow 1$. If $c_k = k$, set $c_k \leftarrow 0$, $k \leftarrow k+1$, and repeat until $c_k < k$. Terminate the algorithm if $k = n$; otherwise set $c_k \leftarrow c_k + 1$.

G4. [Permute.] Apply the permutation $\tau(k, c_k)\omega(k-1)^-$ to $a_0 a_1 \ldots a_{n-1}$, as explained below, and return to G2. ∎

Applying a permutation π to $a_0 a_1 \ldots a_{n-1}$ means replacing a_j by $a_{j\pi}$ for $0 \le j < n$; this corresponds to premultiplication by π as explained earlier. Let us define

$$\tau(k,j) = \sigma(k,j)\sigma(k,j-1)^- \qquad \text{for } 1 \le j \le k; \tag{15}$$

$$\omega(k) = \sigma(1,1)\ldots\sigma(k,k). \tag{16}$$

Then steps G3 and G4 maintain the property that

$$a_0 a_1 \ldots a_{n-1} \text{ is the permutation } \sigma(1,c_1)\sigma(2,c_2)\ldots\sigma(n-1,c_{n-1}), \tag{17}$$

and Lemma S proves that every permutation is visited exactly once.

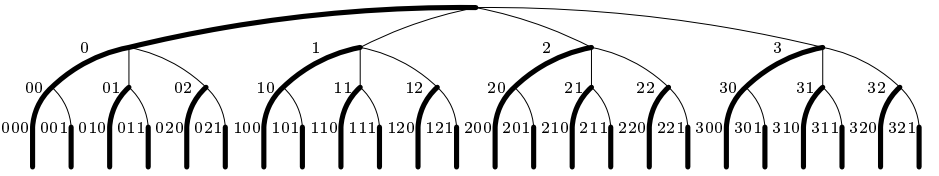


Fig. 19. Algorithm G implicitly traverses this tree when $n = 4$.

The tree in Fig. 19 illustrates Algorithm G in the case $n = 4$. According to (17), every permutation $a_0 a_1 a_2 a_3$ of $\{0,1,2,3\}$ corresponds to a three-digit control string $c_3 c_2 c_1$, with $0 \le c_3 \le 3$, $0 \le c_2 \le 2$, and $0 \le c_1 \le 1$. Some nodes of the tree are labeled by a single digit c_3; these correspond to the permutations $\sigma(3, c_3)$ of the Sims table being used. Other nodes, labeled with two digits $c_3 c_2$, correspond to the permutations $\sigma(2,c_2)\sigma(3,c_3)$. A heavy line connects node c_3 to node $c_3 0$ and node $c_3 c_2$ to node $c_3 c_2 0$, because $\sigma(2,0)$ and $\sigma(1,0)$ are the identity permutation and these nodes are essentially equivalent. Adding 1 to the mixed-radix number $c_3 c_2 c_1$ in step G3 corresponds to moving from one node of Fig. 19 to its successor in preorder, and the transformation in step G4 changes the permutations accordingly. For example, when $c_3 c_2 c_1$ changes from 121 to 200, step G4 premultiplies the current permutation by

$$\tau(3,2)\omega(2)^- = \tau(3,2)\,\sigma(2,2)^-\sigma(1,1)^-;$$

premultiplying by $\sigma(1,1)^-$ takes us from node 121 to node 12, premultiplying by $\sigma(2,2)^-$ takes us from node 12 to node 1, and premultiplying by $\tau(3,2) = \sigma(3,2)\sigma(3,1)^-$ takes us from node 1 to node $2 \equiv 200$, which is the preorder successor of node 121. Stating this another way, premultiplication by $\tau(3,2)\omega(2)^-$ is exactly what is needed to change $\sigma(1,1)\sigma(2,2)\sigma(3,1)$ to $\sigma(1,0)\sigma(2,0)\sigma(3,2)$, preserving (17).

Algorithm G defines a huge number of permutation generators (see exercise 37), so it is no wonder that many of its special cases have appeared in the literature. Of course some of its variants are much more efficient than others, and we want to find examples where the operations are particularly well suited to the computer we are using.

We can, for instance, obtain permutation in reverse colex order as a special case of Algorithm G (see (11)), by letting $\sigma(k,j)$ be the $(j+1)$-cycle

$$\sigma(k,j) \;=\; (k{-}j \;\; k{-}j{+}1 \;\; \ldots \;\; k). \tag{18}$$

The reason is that $\sigma(k,j)$ should be the permutation that corresponds to $c_n \ldots c_1$ in reverse colex order when $c_k = j$ and $c_i = 0$ for $i \neq k$, and this permutation $a_0 a_1 \ldots a_{n-1}$ is $01\ldots(k{-}j{-}1)(k{-}j{+}1)\ldots(k)(k{-}j)(k{+}1)\ldots(n{-}1)$. For example, when $n = 8$ and $c_n \ldots c_1 = 00030000$ the corresponding reverse colex permutation is 01345267, which is $(2\,3\,4\,5)$ in cycle form. When $\sigma(k,j)$ is given by (18), Eqs. (15) and (16) lead to the formulas

$$\tau(k,j) = (k{-}j \;\; k); \tag{19}$$

$$\omega(k) = (0\,1)(0\,1\,2)\ldots(0\,1\,\ldots\,k) = (0\,k)(1\,k{-}1)(2\,k{-}2)\ldots = \phi(k); \tag{20}$$

here $\phi(k)$ is the "$(k+1)$-flip" that changes $a_0 \ldots a_k$ to $a_k \ldots a_0$. In this case $\omega(k)$ turns out to be the same as $\omega(k)^-$, because $\phi(k)^2 = ()$.

Equations (19) and (20) are implicitly present behind the scenes in Algorithm L and in its reverse colex equivalent (exercise 2), where step L3 essentially applies a transposition and step L4 does a flip. Step G4 actually does the flip first; but the identity

$$(k{-}j\;\,k)\phi(k-1) \;=\; \phi(k-1)(j{-}1\;\,k) \tag{21}$$

shows that a flip followed by a transposition is the same as a (different) transposition followed by the flip.

In fact, equation (21) is a special case of the important identity

$$\pi^-(j_1\;j_2\;\ldots\;j_t)\,\pi \;=\; (j_1\pi\;\,j_2\pi\;\ldots\;\,j_t\pi) \tag{22}$$

valid for *any* permutation π and any t-cycle $(j_1\;j_2\;\ldots\;j_t)$. On the left of (22) we have, for example, $j_1\pi \mapsto j_1 \mapsto j_2 \mapsto j_2\pi$, in agreement with the cycle on the right. Therefore if α and π are any permutations whatever, the permutation $\pi^-\alpha\,\pi$ (called the *conjugate* of α by π) has exactly the same cycle structure as α; we simply replace each element j in each cycle by $j\pi$.

Another significant special case of Algorithm G was introduced by R. J. Ord-Smith [*CACM* **10** (1967), 452; **12** (1969), 638; see also *Comp. J.* **14** (1971),

136–139], whose algorithm is obtained by setting

$$\sigma(k,j) = (k\ \ldots\ 1\ 0)^j. \tag{23}$$

Now it is clear from (15) that

$$\tau(k,j) = (k\ \ldots\ 1\ 0); \tag{24}$$

and once again we have

$$\omega(k) = (0\ k)(1\ k{-}1)(2\ k{-}2)\ldots = \phi(k), \tag{25}$$

because $\sigma(k,k) = (0\ 1\ \ldots\ k)$ is the same as before. The nice thing about this method is that the permutation needed in step G4, namely $\tau(k,c_k)\omega(k-1)^-$, does not depend on c_k:

$$\tau(k,j)\omega(k-1)^- = (k\ \ldots\ 1\ 0)\phi(k-1)^- = \phi(k). \tag{26}$$

Thus, Ord-Smith's algorithm is the special case of Algorithm G in which step G4 simply interchanges $a_0 \leftrightarrow a_k$, $a_1 \leftrightarrow a_{k-1}$, ...; this operation is usually quick, because k is small, and it saves some of the work of Algorithm L. (See exercise 38.)

We can do even better by rigging things so that step G4 needs to do only a single transposition each time, somewhat as in Algorithm P but not necessarily on adjacent elements. Many such schemes are possible. The best is probably to let

$$\tau(k,j)\omega(k-1)^- = \begin{cases} (k\ 0), & \text{if } k \text{ is even,} \\ (k\ j{-}1), & \text{if } k \text{ is odd,} \end{cases} \tag{27}$$

as suggested by B. R. Heap [*Comp. J.* **6** (1963), 293–294]. Notice that Heap's method always transposes $a_k \leftrightarrow a_0$ except when $k = 3, 5, \ldots$; and the value of k, in 5 of every 6 steps, is either 1 or 2. Exercise 40 proves that Heap's method does indeed generate all permutations.

Bypassing unwanted blocks. One noteworthy advantage of Algorithm G is that it runs through all permutations of $a_0 \ldots a_{k-1}$ before touching a_k; then it performs another $k!$ cycles before changing a_k again, and so on. Therefore if at any time we reach a setting of the final elements $a_k \ldots a_{n-1}$ that is unimportant to the problem we're working on, we can skip quickly over all permutations that end with the undesirable suffix. More precisely, we could replace step G2 by the following substeps:

G2.0. [Acceptable?] If $a_k \ldots a_{n-1}$ is not an acceptable suffix, go to G2.1. Otherwise set $k \leftarrow k-1$. Then if $k > 0$, repeat this step; if $k = 0$, proceed to step G2.2.

G2.1. [Skip this suffix.] If $c_k = k$, apply $\sigma(k,k)^-$ to $a_0 \ldots a_{n-1}$, set $c_k \leftarrow 0$, $k \leftarrow k+1$, and repeat until $c_k < k$. Terminate if $k = n$; otherwise set $c_k \leftarrow c_k + 1$, apply $\tau(k,c_k)$ to $a_0 \ldots a_{n-1}$, and return to G2.0.

G2.2. [Visit.] Visit the permutation $a_0 \ldots a_{n-1}$. ∎

Step G1 should also set $k \leftarrow n-1$. Notice that the new steps are careful to preserve condition (17). The algorithm has become more complicated, because

we need to know the permutations $\tau(k,j)$ and $\sigma(k,k)$ in addition to the permutations $\tau(k,j)\omega(k-1)^-$ that appear in G4. But the additional complications are often worth the effort, because the resulting program might run significantly faster.

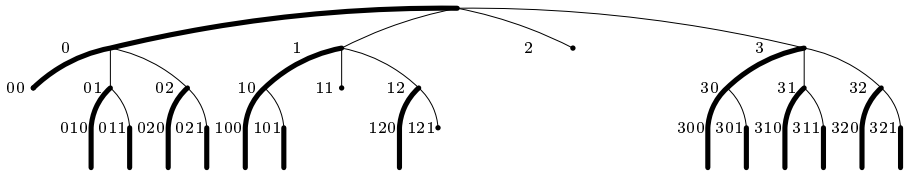

Fig. 20. Unwanted branches can be pruned from the tree of Fig. 19, if Algorithm G is suitably extended.

For example, Fig. 20 shows what happens to the tree of Fig. 19 when the suffixes of $a_0a_1a_2a_3$ that correspond to nodes 00, 11, 121, and 2 are not acceptable. (Each suffix $a_k\ldots a_{n-1}$ of the permutation $a_0\ldots a_{n-1}$ corresponds to a *prefix* $c_n\ldots c_k$ of the control string $c_n\ldots c_1$, because the permutations $\sigma(1,c_1)\ldots\sigma(k-1,c_{k-1})$ do not affect $a_k\ldots a_{n-1}$.) Step G2.1 premultiplies by $\tau(k,j)$ to move from node $c_{n-1}\ldots c_{k+1}j$ to its right sibling $c_{n-1}\ldots c_{k+1}(j{+}1)$, and it premultiplies by $\sigma(k,k)^-$ to move up from node $c_{n-1}\ldots c_{k+1}k$ to its parent $c_{n-1}\ldots c_{k+1}$. Thus, to get from the rejected prefix 121 to its preorder successor, the algorithm premultiplies by $\sigma(1,1)^-$, $\sigma(2,2)^-$, and $\tau(3,2)$, thereby moving from node 121 to 12 to 1 to 2. (This is a somewhat exceptional case, because a prefix with $k=1$ is rejected only if we don't want to visit the unique permutation $a_0a_1\ldots a_{n-1}$ that has suffix $a_1\ldots a_{n-1}$.) After node 2 is rejected, $\tau(3,3)$ takes us to node 3, etc.

Notice, incidentally, that bypassing a suffix $a_k\ldots a_{n-1}$ in this extension of Algorithm G is essentially the same as bypassing a prefix $a_1\ldots a_j$ in our original notation, if we go back to the idea of generating permutations $a_1\ldots a_n$ of $\{1,\ldots,n\}$ and doing most of the work at the right-hand end. Our original notation corresponds to choosing a_1 first, then a_2, ..., then a_n; the notation in Algorithm G essentially chooses a_{n-1} first, then a_{n-2}, ..., then a_0. Algorithm G's conventions may seem backward, but they make the formulas for Sims table manipulation a lot simpler. A good programmer soon learns to switch without difficulty from one viewpoint to another.

We can apply these ideas to alphametics, because it is clear for example that most choices of the values for the letters `D`, `E`, and `Y` will make it impossible for `SEND` plus `MORE` to equal `MONEY`: We need to have $(\mathtt{D}+\mathtt{E}-\mathtt{Y}) \bmod 10 = 0$ in that problem. Therefore many permutations can be eliminated from consideration.

In general, if r_k is the maximum power of 10 that divides the signature value s_k, we can sort the letters and assign codes $\{0,1,\ldots,9\}$ so that $r_0 \ge r_1 \ge \cdots \ge r_9$. For example, to solve the trio sonata problem (7), we could use $(0,1,\ldots,9)$ respectively for $(\mathtt{X},\mathtt{S},\mathtt{V},\mathtt{A},\mathtt{R},\mathtt{I},\mathtt{L},\mathtt{T},\mathtt{O},\mathtt{N})$, obtaining the signatures

$$s_0=0,\quad s_1=-100000,\quad s_2=210000,\quad s_3=-100,\quad s_4=-100,$$
$$s_5=21010,\quad s_6=210,\quad s_7=-1010,\quad s_8=-7901,\quad s_9=-998;$$

hence $(r_0,\ldots,r_9)=(\infty,5,4,2,2,1,1,1,0,0)$. Now if we get to step G2.0 for a value of k with $r_{k-1}\neq r_k$, we can say that the suffix $a_k\ldots a_9$ is unacceptable unless $a_k s_k+\cdots+a_9 s_9$ is a multiple of $10^{r_{k-1}}$. Also, (10) tells us that $a_k\ldots a_9$ is unacceptable if $a_k=0$ and $k\in F$; the first-letter set F is now $\{1,2,7\}$.

Our previous approach to alphametics with steps A1–A3 above used brute force to run through 10! possibilities. It operated rather fast under the circumstances, since the adjacent-transposition method allowed it to get by with only 6 memory references per permutation; but still, 10! is 3,628,800, so the entire process cost almost 22 megamems, regardless of the alphametic being solved. By contrast, the extended Algorithm G with Heap's method and the cutoffs just described will find all four solutions to (7) with fewer than 128 *kilo*mems! Thus the suffix-skipping technique runs more than 170 times faster than the previous method, which simply blasted away blindly.

Most of the 128 kilomems in the new approach are spent applying $\tau(k,c_k)$ in step G2.1. The other memory references come primarily from applications of $\sigma(k,k)^-$ in that step, but τ is needed 7812 times while σ^- is needed only 2162 times. The reason is easy to understand from Fig. 20, because the "shortcut move" $\tau(k,c_k)\omega(k-1)^-$ in step G4 hardly ever applies; in this case it is used only four times, once for each solution. Thus, preorder traversal of the tree is accomplished almost entirely by τ steps that move to the right and σ^- steps that move upward. The τ steps dominate in a problem like this, where very few complete permutations are actually visited, because each step $\sigma(k,k)^-$ is preceded by k steps $\tau(k,1)$, $\tau(k,2)$, $\ldots$, $\tau(k,k)$.

This analysis reveals that Heap's method—which goes to great lengths to optimize the permutations $\tau(k,j)\omega(k-1)^-$ so that each transition in step G4 is a simple transposition—is not especially good for the extended Algorithm G unless comparatively few suffixes are rejected in step G2.0. The simpler reverse colex order, for which $\tau(k,j)$ itself is always a simple transposition, is now much more attractive (see (19)). Indeed, Algorithm G with reverse colex order solves the alphametic (7) with only 97 kilomems.

Similar results occur with respect to other alphametic problems. For example, if we apply the extended Algorithm G to the alphametics in exercise 24, parts (a) through (h), the computations involve respectively

$$\begin{array}{l}(551,\ 110,\ 14,\ 8,\ 350,\ 84,\ 153,\ 1598)\ \text{kilomems with Heap's method;}\\ (429,\ \ 84,\ 10,\ 5,\ 256,\ 63,\ 117,\ 1189)\ \text{kilomems with reverse colex.}\end{array}\qquad(28)$$

The speedup factor for reverse colex in these examples, compared to brute force with Algorithm T, ranges from 18 in case (h) to 4200 in case (d), and it is about 80 on the average; Heap's method gives an average speedup of about 60.

We know from Algorithm L, however, that lexicographic order is easily handled *without* the complication of the control table $c_n\ldots c_1$ used by Algorithm G. And a closer look at Algorithm L shows that we can improve its behavior when permutations are frequently being skipped, by using a linked list instead of a sequential array. The improved algorithm is well-suited to a wide variety of algorithms that wish to generate restricted classes of permutations:

Algorithm X (*Lexicographic permutations with restricted prefixes*). This algorithm generates all permutations $a_1 a_2 \dots a_n$ of $\{1, 2, \dots, n\}$ that pass a given sequence of tests

$$t_1(a_1), \quad t_2(a_1, a_2), \quad \dots, \quad t_n(a_1, a_2, \dots, a_n),$$

visiting them in lexicographic order. It uses an auxiliary table of links l_0, l_1, $\dots$, l_n to maintain a cyclic list of unused elements, so that if the currently available elements are

$$\{1, \dots, n\} \setminus \{a_1, \dots, a_k\} = \{b_1, \dots, b_{n-k}\}, \qquad \text{where } b_1 < \cdots < b_{n-k}, \tag{29}$$

then we have

$$l_0 = b_1, \quad l_{b_j} = b_{j+1} \quad \text{for } 1 \le j < n-k, \quad \text{and} \quad l_{b_{n-k}} = 0. \tag{30}$$

It also uses an auxiliary table $u_1 \dots u_n$ to undo operations that have been performed on the l array.

X1. [Initialize.] Set $l_k \leftarrow k+1$ for $0 \le k < n$, and $l_n \leftarrow 0$. Then set $k \leftarrow 1$.

X2. [Enter level k.] Set $p \leftarrow 0$, $q \leftarrow l_0$.

X3. [Test $a_1 \dots a_k$.] Set $a_k \leftarrow q$. If $t_k(a_1, \dots, a_k)$ is false, go to X5. Otherwise, if $k = n$, visit $a_1 \dots a_n$ and go to X6.

X4. [Increase k.] Set $u_k \leftarrow p$, $l_p \leftarrow l_q$, $k \leftarrow k+1$, and return to X2.

X5. [Increase a_k.] Set $p \leftarrow q$, $q \leftarrow l_p$. If $q \neq 0$ return to X3.

X6. [Decrease k.] Set $k \leftarrow k-1$, and terminate if $k = 0$. Otherwise set $p \leftarrow u_k$, $q \leftarrow a_k$, $l_p \leftarrow q$, and go to X5. ∎

The basic idea of this elegant algorithm is due to M. C. Er [*Comp. J.* **30** (1987), 282]. We can apply it to alphametics by changing notation slightly, obtaining permutations $a_0 \dots a_9$ of $\{0, \dots, 9\}$ and letting l_{10} play the former role of l_0. The resulting algorithm needs only 49 kilomems to solve the trio-sonata problem (7), and it solves the alphametics of exercise 24(a)–(h) in

$$(248,\ 38,\ 4,\ 3,\ 122,\ 30,\ 55,\ 553) \text{ kilomems}, \tag{31}$$

respectively. Thus it runs about 165 times faster than the brute-force approach.

Another way to apply Algorithm X to alphametics is often faster yet (see exercise 49).

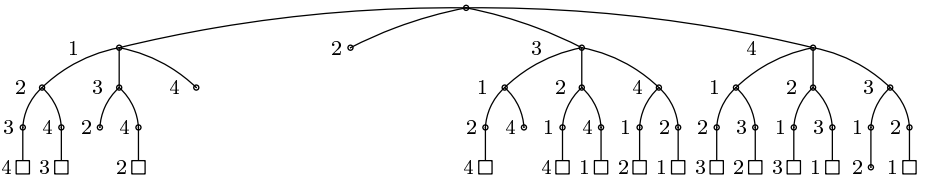

Fig. 21. The tree implicitly traversed by Algorithm X when $n = 4$, if all permutations are visited except those beginning with 132, 14, 2, 314, or 4312.

***Dual methods.** If $S_1, \ldots, S_{n-1}$ is a Sims table for a permutation group G, we learned in Lemma S that every element of G can be expressed uniquely as a product $\sigma_1 \ldots \sigma_{n-1}$, where $\sigma_k \in S_k$; see (13). Exercise 50 shows that every element α can also be expressed uniquely in the dual form

$$\alpha = \sigma_{n-1}^- \ldots \sigma_2^- \sigma_1^-, \qquad \text{where } \sigma_k \in S_k \text{ for } 1 \le k < n, \tag{32}$$

and this fact leads to another large family of permutation generators. In particular, when G is the group of all $n!$ permutations, every permutation can be written

$$\sigma(n-1, c_{n-1})^- \ldots \sigma(2, c_2)^- \sigma(1, c_1)^-, \tag{33}$$

where $0 \le c_k \le k$ for $1 \le k < n$ and the permutations $\sigma(k, j)$ are the same as in Algorithm G. Now, however, we want to vary c_{n-1} most rapidly and c_1 least rapidly, so we arrive at an algorithm of a different kind:

Algorithm H (*Dual permutation generator*). Given a Sims table as in Algorithm G, this algorithm generates all permutations $a_0 \ldots a_{n-1}$ of $\{0, \ldots, n-1\}$, using an auxiliary table $c_0 \ldots c_{n-1}$.

H1. [Initialize.] Set $a_j \leftarrow j$ and $c_j \leftarrow 0$ for $0 \le j < n$.

H2. [Visit.] (At this point the mixed-radix number $\left[\begin{smallmatrix} c_1, & c_2, & \ldots, & c_{n-1} \\ 2, & 3, & \ldots, & n \end{smallmatrix}\right]$ is the number of permutations visited so far.) Visit the permutation $a_0 a_1 \ldots a_{n-1}$.

H3. [Add 1 to $c_0 c_1 \ldots c_{n-1}$.] Set $k \leftarrow n-1$. If $c_k = k$, set $c_k \leftarrow 0$, $k \leftarrow k-1$, and repeat until $k = 0$ or $c_k < k$. Terminate the algorithm if $k = 0$; otherwise set $c_k \leftarrow c_k + 1$.

H4. [Permute.] Apply the permutation $\tau(k, c_k)\omega(k+1)^-$ to $a_0 a_1 \ldots a_{n-1}$, as explained below, and return to H2. ∎

Although this algorithm looks almost identical to Algorithm G, the permutations τ and ω that it needs in step H4 are quite different from those needed in step G4. The new rules, which replace (15) and (16), are

$$\tau(k, j) = \sigma(k, j)^- \sigma(k, j-1), \qquad \text{for } 1 \le j \le k, \tag{34}$$

$$\omega(k) = \sigma(n-1, n-1)^- \sigma(n-2, n-2)^- \ldots \sigma(k, k)^-. \tag{35}$$

The number of possibilities is just as vast as it was for Algorithm G, so we will confine our attention to a few cases that have special merit. One natural case to try is, of course, the Sims table that makes Algorithm G produce reverse colex order, namely

$$\sigma(k, j) \;=\; (k{-}j \;\; k{-}j{+}1 \;\; \ldots \;\; k) \tag{36}$$

as in (18). The resulting permutation generator turns out to be very nearly the same as the method of plain changes; so we can say that Algorithms L and P are essentially dual to each other. (See exercise 52.)

Another natural idea is to construct a Sims table for which step H4 always makes a single transposition of two elements, by analogy with the construction of (27) that achieves maximum efficiency in step G4. But such a mission now turns out to be impossible: We cannot achieve it even when $n = 4$. For if

we start with the identity permutation $a_0a_1a_2a_3 = 0123$, the transitions that take us from control table $c_0c_1c_2c_3 = 0000$ to 0001 to 0002 to 0003 must move the 3; so, if they are transpositions, they must be $(3\,a)$, $(a\,b)$, and $(b\,c)$ for some permutation abc of $\{0,1,2\}$. The permutation corresponding to $c_0c_1c_2c_3 = 0003$ is now $\sigma(3,3)^- = (b\,c)(a\,b)(3\,a) = (3\,a\,b\,c)$; and the next permutation, which corresponds to $c_0c_1c_2c_3 = 0010$, will be $\sigma(2,1)^-$, which must fix the element 3. The only suitable transposition is $(3\,c)$, hence $\sigma(2,1)^-$ must be $(3\,c)(3\,a\,b\,c) = (a\,b\,c)$. Similarly we find that $\sigma(2,2)^-$ must be $(a\,c\,b)$, and the permutation corresponding to $c_0c_1c_2c_3 = 0023$ will be $(3\,a\,b\,c)(a\,c\,b) = (3\,c)$. Step H4 is now supposed to convert this to the permutation $\sigma(1,1)^-$, which corresponds to the control table 0100 that follows 0023. But the only transposition that will convert $(3\,c)$ into a permutation that fixes 2 and 3 is $(3\,c)$; and the resulting permutation also fixes 1, so it cannot be $\sigma(1,1)^-$.

The proof in the preceding paragraph shows that we cannot use Algorithm H to generate all permutations with the minimum number of transpositions. But it also suggests a simple generation scheme that comes very close to the minimum, and the resulting algorithm is quite attractive because it needs to do extra work only once per $n(n-1)$ steps. (See exercise 53.)

Finally, let's consider the dual of Ord-Smith's method, when

$$\sigma(k,j) = (k\ \ldots\ 1\ 0)^j \tag{37}$$

as in (23). Once again the value of $\tau(k,j)$ is independent of j,

$$\tau(k,j) = (0\ 1\ \ldots\ k), \tag{38}$$

and this fact is particularly advantageous in Algorithm H because it allows us to dispense with the control table $c_0c_1\ldots c_{n-1}$. The reason is that $c_{n-1} = 0$ in step H3 if and only if $a_{n-1} = n-1$, because of (32); and indeed, when $c_j = 0$ for $k < j < n$ in step H3 we have $c_k = 0$ if and only if $a_k = k$. Therefore we can reformulate this variant of Algorithm H as follows.

Algorithm C (*Permutation generation by cyclic shifts*). This algorithm visits all permutations $a_1\ldots a_n$ of the distinct elements $\{x_1,\ldots,x_n\}$.

C1. [Initialize.] Set $a_j \leftarrow x_j$ for $1 \le j \le n$.

C2. [Visit.] Visit the permutation $a_1\ldots a_n$, and set $k \leftarrow n$.

C3. [Shift.] Replace $a_1a_2\ldots a_k$ by the cyclic shift $a_2\ldots a_ka_1$, and return to C2 if $a_k \neq x_k$.

C4. [Decrease k.] Set $k \leftarrow k-1$, and go back to C3 if $k > 1$. ∎

For example, the successive permutations of $\{1,2,3,4\}$ generated when $n = 4$ are

1234, 2341, 3412, 4123, (1234),
2314, 3142, 1423, 4231, (2314),
3124, 1243, 2431, 4312, (3124), (1234),
2134, 1342, 3421, 4213, (2134),
1324, 3241, 2413, 4132, (1324),
3214, 2143, 1432, 4321, (3214), (2134), (1234),

with unvisited intermediate permutations shown in parentheses. This algorithm may well be the simplest permutation generator of all, in terms of minimum program length. It is due to G. G. Langdon, Jr. [*CACM* **10** (1967), 298–299; **11** (1968), 392]; similar methods had been published previously by C. Tompkins [*Proc. Symp. Applied Math.* **6** (1956), 202–205] and, more explicitly, by R. Seitz [*Unternehmensforschung* **6** (1962), 2–15]. The procedure is particularly well suited to applications in which cyclic shifting is efficient, for example when successive permutations are being kept in a machine register instead of in an array.

The main disadvantage of dual methods is that they usually do not adapt well to situations where large blocks of permutations need to be skipped, because the set of all permutations with a given value of the first control entries $c_0 c_1 \ldots c_{k-1}$ is usually not of importance. The special case (36) is, however, sometimes an exception, because the $n!/k!$ permutations with $c_0 c_1 \ldots c_{k-1} = 00\ldots0$ in that case are precisely those $a_0 a_1 \ldots a_{n-1}$ in which 0 precedes 1, 1 precedes 2, ..., and $k-2$ precedes $k-1$.

***Ehrlich's swap method.** Gideon Ehrlich has discovered a completely different approach to permutation generation, based on yet another way to use a control table $c_1 \ldots c_{n-1}$. His method obtains each permutation from its predecessor by interchanging the leftmost element with another:

Algorithm E (*Ehrlich swaps*). This algorithm generates all permutations of the distinct elements $a_0 \ldots a_{n-1}$ by using auxiliary tables $b_0 \ldots b_{n-1}$ and $c_1 \ldots c_n$.

E1. [Initialize.] Set $b_j \leftarrow j$ and $c_{j+1} \leftarrow 0$ for $0 \le j < n$.

E2. [Visit.] Visit the permutation $a_0 \ldots a_{n-1}$.

E3. [Find k.] Set $k \leftarrow 1$. Then if $c_k = k$, set $c_k \leftarrow 0$, $k \leftarrow k+1$, and repeat until $c_k < k$. Terminate if $k = n$, otherwise set $c_k \leftarrow c_k + 1$.

E4. [Swap.] Interchange $a_0 \leftrightarrow a_{b_k}$.

E5. [Flip.] Set $j \leftarrow 1$, $k \leftarrow k-1$. If $j < k$, interchange $b_j \leftrightarrow b_k$, set $j \leftarrow j+1$, $k \leftarrow k-1$, and repeat until $j \ge k$. Return to E2. ∎

Notice that steps E2 and E3 are identical to steps G2 and G3 of Algorithm G. The most amazing thing about this algorithm, which Ehrlich communicated to Martin Gardner in 1987, is that it works; exercise 55 contains a proof. A similar method, which simplifies the operations of step E5, can be validated in the same way (see exercise 56). The average number of interchanges performed in step E5 is less than 0.18 (see exercise 57).

As it stands, Algorithm E isn't faster than other methods we have seen. But it has the nice property that it changes each permutation in a minimal way, using only $n-1$ different kinds of transpositions. Whereas Algorithm P used adjacent interchanges, $a_{t-1} \leftrightarrow a_t$, Algorithm E uses first-element swaps, $a_0 \leftrightarrow a_t$, also called *star transpositions*, for some well-chosen sequence of indices $t[1]$, $t[2]$, ..., $t[n!-1]$. And if we are generating permutations repeatedly for the same fairly small value of n, we can precompute this sequence, as we did in Algorithm T

for the index sequence of Algorithm P. Notice that star transpositions have an advantage over adjacent interchanges, because we always know the value of a_0 from the previous swap; we need not read it from memory.

Let E_n be the sequence of $n!-1$ indices t such that Algorithm E swaps a_0 with a_t in step E4. Since E_{n+1} begins with E_n, we can regard E_n as the first $n!-1$ elements of an infinite sequence

$$E_\infty = 1212132121231212132121243131321313121\ldots. \tag{39}$$

For example, if $n = 4$ and $a_0a_1a_2a_3 = 1234$, the permutations visited by Algorithm E are

$$\begin{aligned} &1234,\ 2134,\ 3124,\ 1324,\ 2314,\ 3214,\\ &4213,\ 1243,\ 2143,\ 4123,\ 1423,\ 2413,\\ &3412,\ 4312,\ 1342,\ 3142,\ 4132,\ 1432,\\ &2431,\ 3421,\ 4321,\ 2341,\ 3241,\ 4231. \end{aligned} \tag{40}$$

***Using fewer generators.** After seeing Algorithms P and E, we might naturally ask whether all permutations can be obtained by using just *two* basic operations, instead of $n-1$. For example, Nijenhuis and Wilf [*Combinatorial Algorithms* (1975), Exercise 6] noticed that all permutations can be generated for $n = 4$ if we replace $a_1a_2a_3\ldots a_n$ at each step by either $a_2a_3\ldots a_na_1$ or $a_2a_1a_3\ldots a_n$, and they wondered whether such a method exists for all n.

In general, if G is any group of permutations and if $\alpha_1, \ldots, \alpha_k$ are elements of G, the *Cayley graph* for G with generators $(\alpha_1, \ldots, \alpha_k)$ is the directed graph whose vertices are the permutations π of G and whose arcs go from π to $\alpha_1\pi, \ldots, \alpha_k\pi$. [Arthur Cayley, *American J. Math.* **1** (1878), 174–176.] The question of Nijenhuis and Wilf is equivalent to asking whether the Cayley graph for all permutations of $\{1, 2, \ldots, n\}$, with generators σ and τ where σ is the cyclic permutation $(1\ 2\ \ldots\ n)$ and τ is the transposition $(1\ 2)$, has a Hamiltonian path.

A basic theorem due to R. A. Rankin [*Proc. Cambridge Philos. Soc.* **44** (1948), 17–25] allows us to conclude in many cases that Cayley graphs with two generators do not have a Hamiltonian circuit:

Theorem R. *Let G be a group consisting of g permutations. If the Cayley graph for G with generators (α, β) has a Hamiltonian circuit, and if the permutations $(\alpha, \beta, \alpha\beta^-)$ are respectively of order (a, b, c), then either c is even or g/a and g/b are odd.*

(The *order* of a permutation α is the least positive integer a such that α^a is the identity.)

Proof. See exercise 72. ∎

In particular, when $\alpha = \sigma$ and $\beta = \tau$ as above, we have $g = n!$, $a = n$, $b = 2$, and $c = n-1$, because $\sigma\tau^- = (2\ \ldots\ n)$. Therefore we conclude that no Hamiltonian circuit is possible when $n \geq 4$ is even. However, a Hamiltonian *path* is easy to

construct when $n = 4$, because we can join up the 12-cycles

$$\begin{aligned} &1234 \to 2341 \to 3412 \to 4312 \to 3124 \to 1243 \to 2431 \\ &\qquad \to 4231 \to 2314 \to 3142 \to 1423 \to 4123 \to 1234, \\ &2134 \to 1342 \to 3421 \to 4321 \to 3214 \to 2143 \to 1432 \\ &\qquad \to 4132 \to 1324 \to 3241 \to 2413 \to 4213 \to 2134, \end{aligned} \tag{41}$$

by starting at 2341 and jumping from 1234 to 2134, ending at 4213.

Ruskey, Jiang, and Weston [*Discrete Applied Math.* **57** (1995), 75–83] undertook an exhaustive search in the σ–τ graph for $n = 5$ and discovered that it has five essentially distinct Hamiltonian circuits, one of which (the "most beautiful") is illustrated in Fig. 22(a). They also found a Hamiltonian path for $n = 6$; this was a difficult feat, because it is the outcome of a 720-stage binary decision tree. Unfortunately the solution they discovered has no apparent logical structure. A somewhat less complex path is described in exercise 70, but even that path cannot be called simple. Therefore a σ–τ approach will probably not be of practical interest for larger values of n unless a new construction is discovered. R. C. Compton and S. G. Williamson [*Linear and Multilinear Algebra* **35** (1993), 237–293] have proved that Hamiltonian circuits exist for all n if the three generators σ, σ^-, and τ are allowed instead of just σ and τ; their cycles have the interesting property that every nth transformation is τ, and the intervening $n-1$ transformations are either all σ or all σ^-. But their method is too complicated to explain in a short space.

Exercise 69 describes a general permutation algorithm that is reasonably simple and needs only three generators, each of order 2. Fig. 22(b) illustrates the case $n = 5$ of this method, which was motivated by examples of bell-ringing.

(a) Using only transitions (1 2 3 4 5) and (1 2).

(b) Using only transitions (1 2)(3 4), (2 3)(4 5), and (3 4).

Fig. 22. Hamiltonian circuits for 5! permutations.

Faster, faster. What is the fastest way to generate permutations? This question has often been raised in computer publications, because people who examine $n!$ possibilities want to keep the running time as small as possible. But the answers have generally been contradictory, because there are many different ways to formulate the question. Let's try to understand the related issues by studying how permutations might be generated most rapidly on the `MMIX` computer.

Suppose first that our goal is to produce permutations in an array of n consecutive memory words (octabytes). The fastest way to do this, of all those we've seen in this section, is to streamline Heap's method (27), as suggested by R. Sedgewick [*Computing Surveys* **9** (1977), 157–160].

The key idea is to optimize the code for the most common cases of steps G2 and G3, namely the cases in which all activity occurs at the beginning of the array. If registers u, v, and w contain the contents of the first three words, and if the next six permutations to be generated involve permuting those words in all six possible ways, we can clearly do the job as follows:

```
PUSHJ 0,Visit
STO v,A0;  STO u,A1;  PUSHJ 0,Visit
STO w,A0;  STO v,A2;  PUSHJ 0,Visit
STO u,A0;  STO w,A1;  PUSHJ 0,Visit
STO v,A0;  STO u,A2;  PUSHJ 0,Visit
STO w,A0;  STO v,A1;  PUSHJ 0,Visit
```
(42)

(Here `A0` is the address of octabyte a_0, etc.) A complete permutation program, which takes care of getting the right things into u, v, and w, appears in exercise 76, but the other instructions are less important because they need to be performed only $\frac{1}{6}$ of the time. The total cost per permutation, not counting the $4v$ needed for `PUSHJ` and `POP` on each call to `Visit`, comes to approximately $2.77\mu + 5.69v$ with this approach. If we use four registers u, v, w, x, and if we expand (42) to 24 calls on `Visit`, the running time per permutation drops to about $2.19\mu + 3.07v$. And with r registers and $r!$ `Visit`s, exercise 77 shows that the cost is $(2 + O(1/r!))(\mu + v)$, which is very nearly the cost of two `STO` instructions.

The latter is, of course, the minimum possible time for any method that generates all permutations in a sequential array. ... Or is it? We have assumed that the visiting routine wants to see permutations in consecutive locations, but perhaps that routine is able to read the permutations from different starting points. Then we can arrange to keep a_{n-1} fixed and to keep two copies of the other elements in its vicinity:

$$a_0 a_1 \ldots a_{n-2} a_{n-1} a_0 a_1 \ldots a_{n-2}. \tag{43}$$

If we now let $a_0 a_1 \ldots a_{n-2}$ run through $(n-1)!$ permutations, always changing both copies simultaneously by doing two `STO` commands instead of one, we can let every call to `Visit` look at the n permutations

$$a_0 a_1 \ldots a_{n-1}, \quad a_1 \ldots a_{n-1} a_0, \quad \ldots, \quad a_{n-1} a_0 \ldots a_{n-2}, \tag{44}$$

which all appear consecutively. The cost per permutation is now reduced to the cost of three simple instructions like `ADD`, `CMP`, `PBNZ`, plus $O(1/n)$. [See Varol and Rotem, *Comp. J.* **24** (1981), 173–176.]

Furthermore, we might not want to waste time storing permutations into memory at all. Suppose, for example, that our goal is to generate all permutations of $\{0, 1, \ldots, n-1\}$. The value of n will probably be at most 16, because $16! = 20{,}922{,}789{,}888{,}000$ and $17! = 355{,}687{,}428{,}096{,}000$. Therefore an entire permutation will fit in the 16 nybbles of an octabyte, and we can keep it in a single register. This will be advantageous only if the visiting routine doesn't need to unpack the individual nybbles; but let's suppose that it doesn't. How fast can we generate permutations in the nybbles of a 64-bit register?

One idea, suggested by a technique due to A. J. Goldstein [*U. S. Patent 3383661* (14 May 1968)], is to precompute the table $(t[1], \ldots, t[5039])$ of plain-change transitions for seven elements, using Algorithm T. These numbers $t[k]$ lie between 1 and 6, so we can pack 20 of them into a 64-bit word. It is convenient to put the number $\sum_{k=1}^{20} 2^{3k-1} t[20j+k]$ into word j of an auxiliary table, for $0 \le j < 252$, with $t[5040] = 1$; for example, the table begins with the codeword

00|001|010|011|100|101|110|100|110|101|100|011|010|001|110|001|010|011|100|101|110|00.

The following program reads such codes efficiently:

```
Perm  ⟨Set register a to the first permutation⟩
0H    LDA  p,T       p ← address of first codeword.
      JMP  3F
1H    ⟨Visit the permutation in register a⟩
      ⟨Swap the nybbles of a that lie t bits from the right⟩
      SRU  c,c,3     c ← c ≫ 3.
2H    AND  t,c,#1c   t ← c ∧ (11100)₂.
      PBNZ t,1B      Branch if t ≠ 0.
      ADD  p,p,8
3H    LDO  c,p,0     c ← next codeword.
      PBNZ c,2B      (The final codeword is followed by 0.)
      ⟨If not done, advance the leading n − 7 nybbles and return to 0B⟩
```
(45)

Exercise 78 shows how to ⟨Swap the nybbles ...⟩ with seven instructions, using bit manipulation operations that are found on most computers. Therefore the cost per permutation is just a bit more than $10v$. (The instructions that fetch new codewords cost only $(\mu + 5v)/20$; and the instructions that advance the leading $n-7$ nybbles are even more negligible since their cost is divided by 5040.) Notice that there is now no need for `PUSHJ` and `POP` as there was with (42); we ignored those instructions before, but they did cost $4v$.

We can, however, do even better by adapting Langdon's cyclic-shift method, Algorithm C. Suppose we start with the lexicographically largest permutation and operate as follows:

```
      GREG @
0H    OCTA #fedcba9876543210&(1<<(4*N)-1)
Perm  LDOU a,0B                          Set a ← #...3210.
      JMP  2F
1H    SRU  a,a,4*(16-N)                  a ← ⌊a/16^(16−n)⌋.
      OR   a,a,t                         a ← a ∨ t.
2H    ⟨Visit the permutation in register a⟩
      SRU  t,a,4*(N-1)                   t ← ⌊a/16^(n−1)⌋.
      SLU  a,a,4*(17-N)                  a ← 16^(17−n) a mod 16^16.
      PBNZ t,1B                          To 1B if t ≠ 0.
      ⟨Continue with Langdon's method⟩
```
(46)

The running time per permutation is now only $5v + O(1/n)$, again without the need for `PUSHJ` and `POP`. See exercise 80 for an interesting way to extend (46) to a complete program, obtaining a remarkably short and fast routine.

Fast permutation generators are amusing, but in practice we can usually save more time by streamlining the visiting routine than by speeding up the generator.

Topological sorting. Instead of working with all $n!$ permutations of $\{1,\ldots,n\}$, we often want to look only at permutations that obey certain restrictions. For example, we might be interested only in permutations for which 1 precedes 3, 2 precedes 3, and 2 precedes 4; there are five such permutations of $\{1,2,3,4\}$, namely

$$1234,\ 1243,\ 2134,\ 2143,\ 2413. \tag{47}$$

The problem of *topological sorting*, which we studied in Section 2.2.3 as a first example of nontrivial data structures, is the general problem of finding a permutation that satisfies m such conditions $x_1 \prec y_1, \ldots, x_m \prec y_m$, where $x \prec y$ means that x should precede y in the permutation. This problem arises frequently in practice, so it has several different names; for example, it is often called the *linear embedding* problem, because we want to arrange objects in a line while preserving certain order relationships. It is also the problem of extending a partial ordering to a total ordering (see exercise 2.2.3–14).

Our goal in Section 2.2.3 was to find a *single* permutation that satisfied all the relations. But now we want rather to find *all* such permutations, all topological sorts. Indeed, we will assume in the present section that the elements x and y on which the relations are defined are integers between 1 and n, and that we have $x < y$ whenever $x \prec y$. Consequently the permutation $12\ldots n$ will always be topologically correct. (If this simplifying assumption is not met, we can preprocess the data by using Algorithm 2.2.3T to rename the objects appropriately.)

Many important classes of permutations are special cases of this topological ordering problem. For example, the permutations of $\{1,\ldots,8\}$ such that

$$1 \prec 2, \quad 2 \prec 3, \quad 3 \prec 4, \quad 6 \prec 7, \quad 7 \prec 8$$

are equivalent to permutations of the multiset $\{1,1,1,1,2,3,3,3\}$, because we can map $\{1,2,3,4\} \mapsto 1$, $5 \mapsto 2$, and $\{6,7,8\} \mapsto 3$. We know how to generate permutations of a multiset using Algorithm L, but now we will learn another way.

Notice that x precedes y in a permutation $a_1\ldots a_n$ if and only if $a'_x < a'_y$ in the inverse permutation $a'_1\ldots a'_n$. Therefore the algorithm we are about to study will also find all permutations $a'_1\ldots a'_n$ such that $a'_j < a'_k$ whenever $j \prec k$. For example, we learned in Section 5.1.4 that a Young tableau is an arrangement of $\{1,\ldots,n\}$ in rows and columns so that each row is increasing from left to right and each column is increasing from top to bottom. The problem of generating all 3×3 Young tableaux is therefore equivalent to generating all $a'_1\ldots a'_9$ such that

$$\begin{aligned} &a'_1 < a'_2 < a'_3, \quad a'_4 < a'_5 < a'_6, \quad a'_7 < a'_8 < a'_9,\\ &a'_1 < a'_4 < a'_7, \quad a'_2 < a'_5 < a'_8, \quad a'_3 < a'_6 < a'_9, \end{aligned} \tag{48}$$

and this is a special kind of topological sorting.

We might also want to find all *matchings* of $2n$ elements, namely all ways to partition $\{1,\ldots,2n\}$ into n pairs. There are $(2n-1)(2n-3)\ldots(1) = (2n)!/(2^n n!)$ ways to do this, and they correspond to permutations that satisfy

$$a'_1 < a'_2, \quad a'_3 < a'_4, \quad \ldots, \quad a'_{2n-1} < a'_{2n}, \qquad a'_1 < a'_3 < \cdots < a'_{2n-1}. \tag{49}$$

An elegant algorithm for exhaustive topological sorting was discovered by Y. L. Varol and D. Rotem [*Comp. J.* **24** (1981), 83–84], who realized that a method analogous to plain changes (Algorithm P) can be used. Suppose we have found a way to arrange $\{1,\ldots,n-1\}$ topologically, so that $a_1\ldots a_{n-1}$ satisfies all the conditions that do not involve n. Then we can easily write down all the allowable ways to insert the final element n without changing the relative order of $a_1\ldots a_{n-1}$: We simply start with $a_1\ldots a_{n-1}\,n$, then shift n left one step at a time until it cannot move further. Applying this idea recursively yields the following straightforward procedure.

Algorithm V (*All topological sorts*). Given a relation $\prec$ on $\{1,\ldots,n\}$ with the property that $x \prec y$ implies $x < y$, this algorithm generates all permutations $a_1\ldots a_n$ and their inverses $a'_1\ldots a'_n$ with the property that $a'_j < a'_k$ whenever $j \prec k$. We assume for convenience that $a_0 = 0$ and that $0 \prec k$ for $1 \le k \le n$.

V1. [Initialize.] Set $a_j \leftarrow j$ and $a'_j \leftarrow j$ for $0 \le j \le n$.

V2. [Visit.] Visit the permutation $a_1\ldots a_n$ and its inverse $a'_1\ldots a'_n$. Then set $k \leftarrow n$.

V3. [Can k move left?] Set $j \leftarrow a'_k$ and $l \leftarrow a_{j-1}$. If $l \prec k$, go to V5.

V4. [Yes, move it.] Set $a_{j-1} \leftarrow k$, $a_j \leftarrow l$, $a'_k \leftarrow j-1$, and $a'_l \leftarrow j$. Go to V2.

V5. [No, put k back.] While $j < k$, set $l \leftarrow a_{j+1}$, $a_j \leftarrow l$, $a'_l \leftarrow j$, and $j \leftarrow j+1$. Then set $a_k \leftarrow a'_k \leftarrow k$. Decrease k by 1 and return to V3 if $k > 0$. ∎

For example, Theorem 5.1.4H tells us that there are exactly 42 Young tableaux of size 3×3. If we apply Algorithm V to the relations (48) and write the inverse permutation in array form

$$\begin{bmatrix} a'_1 & a'_2 & a'_3 \\ a'_4 & a'_5 & a'_6 \\ a'_7 & a'_8 & a'_9 \end{bmatrix}, \tag{50}$$

we get the following 42 results:

$$\begin{bmatrix}1&2&3\\4&5&6\\7&8&9\end{bmatrix}\quad\begin{bmatrix}1&2&3\\4&5&7\\6&8&9\end{bmatrix}\quad\begin{bmatrix}1&2&3\\4&5&8\\6&7&9\end{bmatrix}\quad\begin{bmatrix}1&2&3\\4&6&7\\5&8&9\end{bmatrix}\quad\begin{bmatrix}1&2&3\\4&6&8\\5&7&9\end{bmatrix}\quad\begin{bmatrix}1&2&4\\3&5&6\\7&8&9\end{bmatrix}\quad\begin{bmatrix}1&2&4\\3&5&7\\6&8&9\end{bmatrix}\quad\begin{bmatrix}1&2&4\\3&5&8\\6&7&9\end{bmatrix}\quad\begin{bmatrix}1&2&4\\3&6&7\\5&8&9\end{bmatrix}\quad\begin{bmatrix}1&2&4\\3&6&8\\5&7&9\end{bmatrix}\quad\begin{bmatrix}1&2&5\\3&6&7\\4&8&9\end{bmatrix}\quad\begin{bmatrix}1&2&5\\3&6&8\\4&7&9\end{bmatrix}\quad\begin{bmatrix}1&2&5\\3&6&7\\4&8&9\end{bmatrix}\quad\begin{bmatrix}1&2&5\\3&6&8\\4&7&9\end{bmatrix}$$

$$\begin{bmatrix}1&2&5\\3&4&8\\6&7&9\end{bmatrix}\quad\begin{bmatrix}1&2&6\\3&4&7\\5&8&9\end{bmatrix}\quad\begin{bmatrix}1&2&6\\3&4&8\\5&7&9\end{bmatrix}\quad\begin{bmatrix}1&2&7\\3&4&8\\5&6&9\end{bmatrix}\quad\begin{bmatrix}1&2&6\\3&5&7\\4&8&9\end{bmatrix}\quad\begin{bmatrix}1&2&6\\3&5&8\\4&7&9\end{bmatrix}\quad\begin{bmatrix}1&2&7\\3&5&8\\4&6&9\end{bmatrix}\quad\begin{bmatrix}1&2&6\\3&7&8\\4&5&9\end{bmatrix}\quad\begin{bmatrix}1&2&7\\3&6&8\\4&5&9\end{bmatrix}\quad\begin{bmatrix}1&2&7\\3&6&8\\4&5&9\end{bmatrix}\quad\begin{bmatrix}1&2&7\\3&6&8\\4&5&9\end{bmatrix}\quad\begin{bmatrix}1&2&8\\3&6&7\\4&5&9\end{bmatrix}$$

$$\begin{bmatrix}1&4&5\\2&6&7\\3&8&9\end{bmatrix}\quad\begin{bmatrix}1&4&5\\2&6&8\\3&7&9\end{bmatrix}\quad\begin{bmatrix}1&3&5\\2&6&7\\4&8&9\end{bmatrix}\quad\begin{bmatrix}1&3&5\\2&4&7\\6&8&9\end{bmatrix}\quad\begin{bmatrix}1&3&6\\2&4&7\\5&8&9\end{bmatrix}\quad\begin{bmatrix}1&3&6\\2&4&8\\5&7&9\end{bmatrix}\quad\begin{bmatrix}1&3&7\\2&4&8\\5&6&9\end{bmatrix}\quad\begin{bmatrix}1&3&6\\2&5&7\\4&8&9\end{bmatrix}\quad\begin{bmatrix}1&3&6\\2&5&8\\4&7&9\end{bmatrix}\quad\begin{bmatrix}1&3&7\\2&5&8\\4&6&9\end{bmatrix}\quad\begin{bmatrix}1&4&6\\2&5&7\\3&8&9\end{bmatrix}\quad\begin{bmatrix}1&4&6\\2&5&8\\3&7&9\end{bmatrix}\quad\begin{bmatrix}1&4&7\\2&5&8\\3&6&9\end{bmatrix}$$

Let t_r be the number of topological sorts for which the final $n-r$ elements are in their initial position $a_j = j$ for $r < j \le n$. Equivalently, t_r is the number of topological sorts $a_1 \dots a_r$ of $\{1, \dots, r\}$, when we ignore the relations involving elements greater than r. Then the recursive mechanism underlying Algorithm V shows that step V2 is performed N times and step V3 is performed M times, where

$$M = t_n + \cdots + t_1 \qquad \text{and} \qquad N = t_n. \tag{51}$$

Also, step V4 and the loop operations of V5 are performed $N-1$ times; the rest of step V5 is done $M - N + 1$ times. Therefore the total running time of the algorithm is a linear combination of M, N, and n.

If the element labels are chosen poorly, M might be much larger than N. For example, if the constraints input to Algorithm V are

$$2 \prec 3, \quad 3 \prec 4, \quad \dots, \quad n-1 \prec n, \tag{52}$$

then $t_j = j$ for $1 \le j \le n$ and we have $M = \frac{1}{2}(n^2 + n)$, $N = n$. But those constraints are also equivalent to

$$1 \prec 2, \quad 2 \prec 3, \quad \dots, \quad n-2 \prec n-1, \tag{53}$$

under renaming of the elements; then M is reduced to $2n - 1 = 2N - 1$.

Exercise 88 shows that a simple preprocessing step will find element labels so that a slight modification of Algorithm V is able to generate all topological sorts in $O(N+n)$ steps. Thus topological sorting can always be done efficiently.

Think twice before you permute. We have seen several attractive algorithms for permutation generation in this section, but many algorithms are known by which permutations that are optimum for particular purposes can be found *without* running through all possibilities. For example, Theorem 6.1S showed that we can find the best way to arrange records on a sequential storage simply by sorting them with respect to a certain cost criterion, and this process takes only $O(n \log n)$ steps. In Section 7.5.2 we will study the *assignment problem*, which asks how to permute the columns of a square matrix so that the sum of the diagonal elements is maximized. That problem can be solved in at most $O(n^3)$ operations, so it would be foolish to use a method of order $n!$ unless n is extremely small. Even in cases like the traveling salesrep problem, when no efficient algorithm is known, we can usually find a much better approach than to examine every possible solution. Permutation generation is best used when there is good reason to look at each permutation individually.

EXERCISES

▸ **1.** [*20*] Explain how to make Algorithm L run faster, by streamlining its operations when the value of j is near n.

2. [*20*] Rewrite Algorithm L so that it produces all permutations of $a_1 \dots a_n$ in reverse colex order. (In other words, the values of the reflections $a_n \dots a_1$ should be lexicographically decreasing, as in (11). This form of the algorithm is often simpler and faster than the original, because fewer calculations depend on the value of n.)

▸ **3.** [*M21*] The *rank* of a combinatorial arrangement X with respect to a generation algorithm is the number of other arrangements that the algorithm visits prior to X. Explain how to compute the rank of a given permutation $a_1 \dots a_n$ with respect to Algorithm L, if $\{a_1, \dots, a_n\} = \{1, \dots, n\}$. What is the rank of 314592687?

4. [*M23*] Generalizing exercise 3, explain how to compute the rank of $a_1 \dots a_n$ with respect to Algorithm L when $\{a_1, \dots, a_n\}$ is the multiset $\{n_1 \cdot x_1, \dots, n_t \cdot x_t\}$; here $n_1 + \cdots + n_t = n$ and $x_1 < \cdots < x_t$. (The total number of permutations is, of course, the multinomial coefficient

$$\binom{n}{n_1, \dots, n_t} = \frac{n!}{n_1! \dots n_t!};$$

see Eq. 5.1.2–(3).) What is the rank of 314159265?

5. [*HM25*] Compute the mean and variance of the number of comparisons made by Algorithm L in (a) step L2, (b) step L3, when the elements $\{a_1, \dots, a_n\}$ are distinct.

6. [*HM34*] Derive generating functions for the mean number of comparisons made by Algorithm L in (a) step L2, (b) step L3, when $\{a_1, \dots, a_n\}$ is a general multiset as in exercise 4. Also give the results in closed form when $\{a_1, \dots, a_n\}$ is the binary multiset $\{m \cdot 0, (n-m) \cdot 1\}$.

7. [*HM35*] What is the limit as $t \to \infty$ of the average number of comparisons made per permutation in step L2 when Algorithm L is being applied to the multiset (a) $\{2 \cdot 1, 2 \cdot 2, \dots, 2 \cdot t\}$? (b) $\{1 \cdot 1, 2 \cdot 2, \dots, t \cdot t\}$? (c) $\{2 \cdot 1, 4 \cdot 2, \dots, 2^t \cdot t\}$?

▸ **8.** [*21*] The *variations* of a multiset are the permutations of all its submultisets. For example, the variations of $\{1, 2, 2, 3\}$ are

ϵ, 1, 12, 122, 1223, 123, 1232, 13, 132, 1322,
2, 21, 212, 2123, 213, 2132, 22, 221, 2213, 223, 2231, 23, 231, 2312, 232, 2321,
3, 31, 312, 3122, 32, 321, 3212, 322, 3221.

Show that simple changes to Algorithm L will generate all variations of a given multiset $\{a_1, a_2, \dots, a_n\}$.

9. [*22*] Continuing the previous exercise, design an algorithm to generate all r-variations of a given multiset $\{a_1, a_2, \dots, a_n\}$, namely all permutations of its r-element submultisets. (For example, the solution to an alphametic with r distinct letters is an r-variation of $\{0, 1, \dots, 9\}$.)

10. [*20*] What are the values of $a_1 a_2 \dots a_n$, $c_1 c_2 \dots c_n$, and $d_1 d_2 \dots d_n$ at the end of Algorithm P, if $a_1 a_2 \dots a_n = 12 \dots n$ at the beginning?

11. [*M22*] How many times is each step of Algorithm P performed? (Assume that $n \geq 2$.)

▸ **12.** [*M23*] What is the 1000000th permutation visited by (a) Algorithm L, (b) Algorithm P, (c) Algorithm C, if $\{a_1, \dots, a_n\} = \{0, \dots, 9\}$? *Hint:* In mixed-radix notation we have $1000000 = \left[\begin{smallmatrix} 2, & 6, & 6, & 2, & 5, & 1, & 2, & 2, & 0, & 0 \\ 10, & 9, & 8, & 7, & 6, & 5, & 4, & 3, & 2, & 1 \end{smallmatrix}\right] = \left[\begin{smallmatrix} 0, & 0, & 1, & 2, & 3, & 0, & 2, & 7, & 1, & 0 \\ 1, & 2, & 3, & 4, & 5, & 6, & 7, & 8, & 9, & 10 \end{smallmatrix}\right]$.

13. [*M21*] (Martin Gardner, 1974.) True or false: If $a_1 a_2 \dots a_n$ is initially $12 \dots n$, Algorithm P begins by visiting all $n!/2$ permutations in which 1 precedes 2; then the next permutation is $n \dots 21$.

14. [*M22*] True or false: If $a_1 a_2 \dots a_n$ is initially $x_1 x_2 \dots x_n$ in Algorithm P, we always have $a_{j-c_j+s} = x_j$ at the beginning of step P5.

15. [*M23*] (Selmer Johnson, 1963.) Show that the offset variable s never exceeds 2 in Algorithm P.

16. [*21*] Explain how to make Algorithm P run faster, by streamlining its operations when the value of j is near n. (This problem is analogous to exercise 1.)

▶ **17.** [*20*] Extend Algorithm P so that the *inverse permutation* $a'_1 \ldots a'_n$ is available for processing when $a_1 \ldots a_n$ is visited in step P2. (The inverse satisfies $a'_k = j$ if and only if $a_j = k$.)

18. [*21*] (*Rosary permutations.*) Devise an efficient way to generate $(n-1)!/2$ permutations that represent all possible undirected cycles on the vertices $\{1, \ldots, n\}$; that is, no cyclic shift of $a_1 \ldots a_n$ or $a_n \ldots a_1$ will be generated if $a_1 \ldots a_n$ is generated. The permutations (1234, 1324, 3124) could, for example, be used when $n = 4$.

19. [*25*] Construct an algorithm that generates all permutations of n distinct elements *looplessly* in the spirit of Algorithm 7.2.1.1L.

▶ **20.** [*20*] The n-cube has $2^n n!$ symmetries, one for each way to permute and/or complement the coordinates. Such a symmetry is conveniently represented as a *signed permutation*, namely a permutation with optional signs attached to the elements. For example, $2\overline{3}1$ is a signed permutation that transforms the vertices of the 3-cube by changing $x_1x_2x_3$ to $x_2x_3\overline{x}_1$, so that $000 \mapsto 001$, $001 \mapsto 011$, $\ldots$, $111 \mapsto 110$. Design a simple algorithm that generates all signed permutations of $\{1, 2, \ldots, n\}$, where each step either interchanges two adjacent elements or negates the first element.

21. [*M21*] (E. P. McCravy, 1971.) How many solutions does the alphametic (6) have in radix b?

22. [*M15*] True or false: If an alphametic has a solution in radix b, it has a solution in radix $b + 1$.

23. [*M20*] True or false: A pure alphametic cannot have two identical signatures $s_j = s_k \neq 0$ when $j \neq k$.

24. [*25*] Solve the following alphametics by hand or by computer:

a) SEND + A + TAD + MORE = MONEY.

b) ZEROES + ONES = BINARY. (Peter Macdonald, 1977)

c) DCLIX + DLXVI = MCCXXV. (Willy Enggren, 1972)

d) COUPLE + COUPLE = QUARTET. (Michael R. W. Buckley, 1977)

e) FISH + N + CHIPS = SUPPER. (Bob Vinnicombe, 1978)

f) SATURN + URANUS + NEPTUNE + PLUTO = PLANETS. (Willy Enggren, 1968)

g) EARTH + AIR + FIRE + WATER = NATURE. (Herman Nijon, 1977)

h) AN + ACCELERATING + INFERENTIAL + ENGINEERING + TALE + ELITE + GRANT + FEE + ET + CETERA = ARTIFICIAL + INTELLIGENCE.

i) HARDY + NESTS = NASTY + HERDS.

▶ **25.** [*M21*] Devise a fast way to compute $\min(a \cdot s)$ and $\max(a \cdot s)$ over all valid permutations $a_1 \ldots a_{10}$ of $\{0, \ldots, 9\}$, given the signature vector $s = (s_1, \ldots, s_{10})$ and the first-letter set F of an alphametic problem. (Such a procedure makes it possible to rule out many cases quickly when a large family of alphametics is being considered, as in several of the exercises that follow, because a solution can exist only when $\min(a \cdot s) \leq 0 \leq \max(a \cdot s)$.)

26. [*25*] What is the unique alphametic solution to

$$\texttt{NIIHAU} \pm \texttt{KAUAI} \pm \texttt{OAHU} \pm \texttt{MOLOKAI} \pm \texttt{LANAI} \pm \texttt{MAUI} \pm \texttt{HAWAII} = 0?$$

27. [*30*] Construct pure additive alphametics in which all words have five letters.

28. [*M25*] A *partition* of the integer n is an expression of the form $n = n_1 + \cdots + n_t$ with $n_1 \geq \cdots \geq n_t > 0$. Such a partition is called *doubly true* if $\alpha(n) = \alpha(n_1) + \cdots + \alpha(n_t)$ is also a pure alphametic, where $\alpha(n)$ is the "name" of n in some language. Doubly true partitions were introduced by Alan Wayne in *AMM* **54** (1947), 38, 412–414, where he suggested solving TWENTY = SEVEN + SEVEN + SIX and a few others.

a) Find all partitions that are doubly true in English when $1 \leq n \leq 20$.

b) Wayne also gave the example EIGHTY = FIFTY + TWENTY + NINE + ONE. Find all doubly true partitions for $1 \leq n \leq 100$ in which the parts are *distinct*, using the names ONE, TWO, ..., NINETYNINE, ONEHUNDRED.

▸ **29.** [*M25*] Continuing the previous exercise, find all equations of the form $n_1 + \cdots + n_t = n'_1 + \cdots + n'_{t'}$ that are both mathematically and alphametically true in English, when $\{n_1, \ldots, n_t, n'_1, \ldots, n'_{t'}\}$ are distinct positive integers less than 20. For example,

$$\texttt{TWELVE} + \texttt{NINE} + \texttt{TWO} = \texttt{ELEVEN} + \texttt{SEVEN} + \texttt{FIVE};$$

the alphametics should all be pure.

30. [*25*] Solve these multiplicative alphametics by hand or by computer:

a) TWO × TWO = SQUARE. (H. E. Dudeney, 1929)

b) HIP × HIP = HURRAY. (Willy Enggren, 1970)

c) PI × R × R = AREA. (Brian Barwell, 1981)

d) NORTH/SOUTH = EAST/WEST. (Nob Yoshigahara, 1995)

31. [*M22*] (Nob Yoshigahara.) What is the unique solution to A/BC+D/EF+G/HI = 1, when {A, ..., I} = {1, ..., 9}?

32. [*M25*] (H. E. Dudeney, 1901.) Find all ways to represent 100 by inserting a plus sign and a slash into a permutation of the digits {1, ..., 9}. For example, $100 = 91 + 5742/638$. The plus sign should precede the slash.

33. [*25*] Continuing the previous exercise, find all positive integers less than 150 that (a) cannot be represented in such a fashion; (b) have a unique representation.

34. [*M26*] Make the equation EVEN + ODD + PRIME = x doubly true when (a) x is a perfect 5th power; (b) x is a perfect 7th power.

▸ **35.** [*M20*] The automorphisms of a 4-cube have many different Sims tables, only one of which is shown in (14). How many different Sims tables are possible for that group, when the vertices are numbered as in (12)?

36. [*M23*] Find a Sims table for the group of all automorphisms of the 4×4 tic-tac-toe board

0	1	2	3
4	5	6	7
8	9	a	b
c	d	e	f

,

namely the permutations that take lines into lines, where a "line" is a set of four elements that belong to a row, column, or diagonal.

▸ **37.** [*HM22*] How many Sims tables can be used with Algorithms G or H? Estimate the logarithm of this number as $n \to \infty$.

38. [*HM21*] Prove that the average number of transpositions per permutation when using Ord-Smith's algorithm (26) is approximately $\sinh 1 \approx 1.175$.

39. [*16*] Write down the 24 permutations generated for $n = 4$ by (a) Ord-Smith's method (26); (b) Heap's method (27).

40. [*M23*] Show that Heap's method (27) corresponds to a valid Sims table.

▸ **41.** [*M31*] Design an algorithm that generates all r-variations of $\{0, 1, \ldots, n-1\}$ by interchanging just two elements when going from one variation to the next. (See exercise 9.) *Hint:* Generalize Heap's method (27), obtaining the results in positions $a_{n-r} \ldots a_{n-1}$ of an array $a_0 \ldots a_{n-1}$. For example, one solution when $n = 5$ and $r = 2$ uses the final two elements of the respective permutations 01234, 31204, 30214, 30124, 40123, 20143, 24103, 24013, 34012, 14032, 13042, 13402, 23401, 03421, 02431, 02341, 12340, 42310, 41320, 41230.

42. [*M20*] Construct a Sims table for all permutations in which every $\sigma(k, j)$ and every $\tau(k, j)$ for $1 \le j \le k$ is a cycle of length ≤ 3.

43. [*M24*] Construct a Sims table for all permutations in which every $\sigma(k, k)$, $\omega(k)$, and $\tau(k, j)\omega(k-1)^-$ for $1 \le j \le k$ is a cycle of length ≤ 3.

44. [*20*] When blocks of unwanted permutations are being skipped by the extended Algorithm G, is the Sims table of Ord-Smith's method (23) superior to the Sims table of the reverse colex method (18)?

45. [*20*] (a) What are the indices $u_1 \ldots u_9$ when Algorithm X visits the permutation 314592687? (b) What permutation is visited when $u_1 \ldots u_9 = 314157700$?

46. [*20*] True or false: When Algorithm X visits $a_1 \ldots a_n$, we have $u_k > u_{k+1}$ if and only if $a_k > a_{k+1}$, for $1 \le k < n$.

▸ **47.** [*M21*] Express the number of times that each step of Algorithm X is performed in terms of the numbers N_0, N_1, ..., N_n, where N_k is the number of prefixes $a_1 \ldots a_k$ that satisfy $t_j(a_1, \ldots, a_j)$ for $1 \le j \le k$.

▸ **48.** [*M25*] Compare the running times of Algorithm X and Algorithm L, in the case when the tests $t_1(a_1)$, $t_2(a_1, a_2)$, ..., $t_n(a_1, a_2, \ldots, a_n)$ always are true.

▸ **49.** [*28*] The text's suggested method for solving additive alphametics with Algorithm X essentially chooses digits from right to left; in other words, it assigns tentative values to the least significant digits before considering digits that correspond to higher powers of 10.

Explore an alternative approach that chooses digits from left to right. For example, such a method will deduce immediately that $\texttt{M} = 1$ when $\texttt{SEND} + \texttt{MORE} = \texttt{MONEY}$. *Hint:* See exercise 25.

50. [*M15*] Explain why the dual formula (32) follows from (13).

51. [*M16*] True or false: If the sets $S_k = \{\sigma(k, 0), \ldots, \sigma(k, k)\}$ form a Sims table for the group of all permutations, so also do the sets $S_k^- = \{\sigma(k, 0)^-, \ldots, \sigma(k, k)^-\}$.

▸ **52.** [*M22*] What permutations $\tau(k, j)$ and $\omega(k)$ arise when Algorithm H is used with the Sims table (36)? Compare the resulting generator with Algorithm P.

▸ **53.** [*M26*] (F. M. Ives.) Construct a Sims table for which Algorithm H will generate all permutations by making only $n! + O((n-2)!)$ transpositions.

54. [*20*] Would Algorithm C work properly if step C3 did a right-cyclic shift, setting $a_1 \ldots a_{k-1} a_k \leftarrow a_k a_1 \ldots a_{k-1}$, instead of a left-cyclic shift?

55. [*M27*] Consider the *factorial ruler function*

$$\rho_!(m) = \max\{k \mid m \bmod k! = 0\}.$$

Let σ_k and τ_k be permutations of the nonnegative integers such that $\sigma_j \tau_k = \tau_k \sigma_j$ whenever $j \le k$. Let α_0 and β_0 be the identity permutation, and for $m > 0$ define

$$\alpha_m = \beta_{m-1}^- \tau_{\rho_!(m)} \beta_{m-1} \alpha_{m-1}, \qquad \beta_m = \sigma_{\rho_!(m)} \beta_{m-1}.$$

For example, if σ_k is the flip operation $(1\,k{-}1)(2\,k{-}2)\ldots = (0\,k)\phi(k)$ and if $\tau_k = (0\,k)$, and if Algorithm E is started with $a_j = j$ for $0 \le j < n$, then α_m and β_m are the contents of $a_0 \ldots a_{n-1}$ and $b_0 \ldots b_{n-1}$ after step E5 has been performed m times.

a) Prove that $\beta_{(n+1)!}\alpha_{(n+1)!} = \sigma_{n+1}\sigma_n^-\tau_{n+1}\tau_n^-(\beta_{n!}\alpha_{n!})^{n+1}$.

b) Use the result of (a) to establish the validity of Algorithm E.

56. [*M22*] Prove that Algorithm E remains valid if step E5 is replaced by

E5′. [Transpose pairs.] If $k > 2$, interchange $b_{j+1} \leftrightarrow b_j$ for $j = k-2, k-4, \ldots,$ (2 or 1). Return to E2. ▮

57. [*HM22*] What is the average number of interchanges made in step E5?

58. [*M21*] True or false: If Algorithm E begins with $a_0 \ldots a_{n-1} = x_1 \ldots x_n$ then the final permutation visited begins with $a_0 = x_n$.

59. [*M20*] Some authors define the arcs of a Cayley graph as running from π to $\pi\alpha_j$ instead of from π to $\alpha_j\pi$. Are the two definitions essentially different?

▸ **60.** [*21*] A *Gray code for permutations* is a cycle $(\pi_0, \pi_1, \ldots, \pi_{n!-1})$ that includes every permutation of $\{1, 2, \ldots, n\}$ and has the property that π_k differs from $\pi_{(k+1) \bmod n!}$ by an adjacent transposition. It can also be described as a Hamiltonian circuit on the Cayley graph for the group of all permutations on $\{1, 2, \ldots, n\}$, with the $n-1$ generators $\big((1\ 2), (2\ 3), \ldots, (n{-}1\ n)\big)$. The *delta sequence* of such a Gray code is the sequence of integers $\delta_0\delta_1 \ldots \delta_{n!-1}$ such that

$$\pi_{(k+1) \bmod n!} = (\delta_k\ \delta_k{+}1)\,\pi_k.$$

(See 7.2.1.1–(24), which describes the analogous situation for binary n-tuples.) For example, Fig. 23 illustrates the Gray code defined by plain changes when $n = 4$; its delta sequence is $(32131231)^3$.

a) Find all Gray codes for permutations of $\{1, 2, 3, 4\}$.

b) Two Gray codes are considered to be equivalent if their delta sequences can be obtained from each other by cyclic shifting $(\delta_k \ldots \delta_{n!-1}\delta_0 \ldots \delta_{k-1})$ and/or reversal $(\delta_{n!-1} \ldots \delta_1\delta_0)$ and/or complementation $((n{-}\delta_0)(n{-}\delta_1)\ldots(n{-}\delta_{n!-1}))$. Which of the Gray codes in (a) are equivalent?

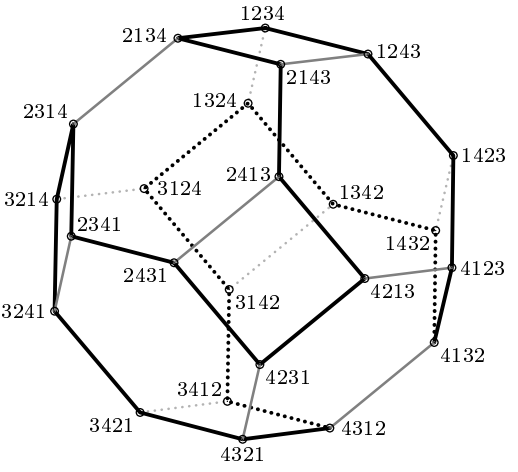

Fig. 23. Algorithm P traces out this Hamiltonian circuit on the truncated octahedron of Fig. 5–1.

61. [*21*] Continuing the previous exercise, a *Gray path for permutations* is like a Gray code except that the final permutation $\pi_{n!-1}$ is not required to be adjacent to the initial permutation π_0. Study the set of all Gray paths for $n = 4$ that start with 1234.

▸ **62.** [*M23*] What permutations can be reached as the final element of a Gray path that starts at $12\ldots n$?

63. [*M25*] Estimate the total number of Gray codes for permutations of $\{1, 2, 3, 4, 5\}$.

64. [*23*] A "doubly Gray" code for permutations is a Gray code with the additional property that $\delta_{k+1} = \delta_k \pm 1$ for all k. Compton and Williamson have proved that such codes exist for all $n \geq 3$. How many doubly Gray codes exist for $n = 5$?

65. [*M25*] For which integers N is there a Gray path through the N lexicographically smallest permutations of $\{1, \ldots, n\}$? (Exercise 7.2.1.1–26 solves the analogous problem for binary n-tuples.)

66. [*22*] Ehrlich's swap method suggests another type of Gray code for permutations, in which the $n-1$ generators are the star transpositions (1 2), (1 3), ..., (1 n). For example, Fig. 24 shows the relevant graph when $n = 4$. Analyze the Hamiltonian circuits of this graph.

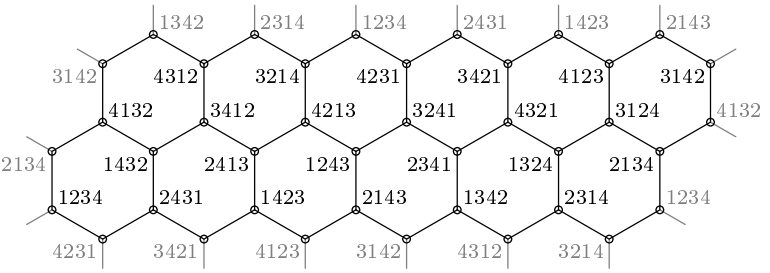

Fig. 24. The Cayley graph for permutations of $\{1, 2, 3, 4\}$, generated by the star transpositions (1 2), (1 3), and (1 4), drawn as a twisted torus.

67. [*26*] Continuing the previous exercise, find a first-element-swap Gray code for $n = 5$ in which each star transposition (1 j) occurs 30 times, for $2 \leq j \leq 5$.

68. [*M30*] (Kompel'makher and Liskovets, 1975.) Let G be the Cayley graph for all permutations of $\{1, \ldots, n\}$, with generators $(\alpha_1, \ldots, \alpha_k)$ where each α_j is a transposition $(u_j\ v_j)$; also let A be the graph with vertices $\{1, \ldots, n\}$ and edges u_j — v_j for $1 \leq j \leq k$. Prove that G has a Hamiltonian circuit if and only if A is connected. (Fig. 23 is the special case when A is a path; Fig. 24 is the special case when A is a "star.")

▸ **69.** [*28*] If $n \geq 4$, the following algorithm generates all permutations $A_1A_2A_3\ldots A_n$ of $\{1, 2, 3, \ldots, n\}$ using only three transformations,

$$\rho = (1\,2)(3\,4)(5\,6)\ldots, \qquad \sigma = (2\,3)(4\,5)(6\,7)\ldots, \qquad \tau = (3\,4)(5\,6)(7\,8)\ldots,$$

never applying ρ and τ next to each other. Explain why it works.

Z1. [Initialize.] Set $A_j \leftarrow j$ for $1 \leq j \leq n$. Also set $a_j \leftarrow 2j$ for $j \leq n/2$ and $a_{n-j} \leftarrow 2j + 1$ for $j < n/2$. Then invoke Algorithm P, but with parameter $n - 1$ instead of n. We will treat that algorithm as a coroutine, which should

return control to us whenever it "visits" $a_1 \dots a_{n-1}$ in step P2. We will also share its variables (except n).

Z2. [Set x and y.] Invoke Algorithm P again, obtaining a new permutation $a_1 \dots a_{n-1}$ and a new value of j. If $j = 2$, interchange $a_{1+s} \leftrightarrow a_{2+s}$ (thereby undoing the effect of step P5) and repeat this step; in such a case we are at the halfway point of Algorithm P. If $j = 1$ (so that Algorithm P has terminated), set $x \leftarrow y \leftarrow 0$ and go to Z3. Otherwise set

$$x \leftarrow a_{j-c_j+s+[d_j=-1]}, \qquad y \leftarrow a_{j-c_j+s-[d_j=+1]};$$

these are the two elements most recently interchanged in step P5.

Z3. [Visit.] Visit the permutation $A_1 \dots A_n$. Then go to Z5 if $A_1 = x$ and $A_2 = y$.

Z4. [Apply ρ, then σ.] Interchange $A_1 \leftrightarrow A_2$, $A_3 \leftrightarrow A_4$, $A_5 \leftrightarrow A_6$, ... Visit $A_1 \dots A_n$. Then interchange $A_2 \leftrightarrow A_3$, $A_4 \leftrightarrow A_5$, $A_6 \leftrightarrow A_7$, ... Terminate if $A_1 \dots A_n = 1 \dots n$, otherwise return to Z3.

Z5. [Apply τ, then σ.] Interchange $A_3 \leftrightarrow A_4$, $A_5 \leftrightarrow A_6$, $A_7 \leftrightarrow A_8$, ... Visit $A_1 \dots A_n$. Then interchange $A_2 \leftrightarrow A_3$, $A_4 \leftrightarrow A_5$, $A_6 \leftrightarrow A_7$, ..., and return to Z2. ∎

Hint: Show first that the algorithm works if modified so that $A_j \leftarrow n + 1 - j$ and $a_j \leftarrow j$ in step Z1, and if the "flip" permutations

$$\rho' = (1\ \ n)(2\ \ n{-}1)\dots, \qquad \sigma' = (2\ \ n)(3\ \ n{-}1)\dots, \qquad \tau' = (2\ \ n{-}1)(3\ \ n{-}2)\dots$$

are used instead of ρ, σ, τ in steps Z4 and Z5. In this modification, step Z3 should go to Z5 if $A_1 = x$ and $A_n = y$.

▸ **70.** [*M33*] The two 12-cycles (41) can be regarded as σ–τ cycles for the twelve permutations of $\{1, 1, 3, 4\}$:

$$1134 \to 1341 \to 3411 \to 4311 \to 3114 \to 1143 \to 1431 \\ \to 4131 \to 1314 \to 3141 \to 1413 \to 4113 \to 1134.$$

Replacing $\{1, 1\}$ by $\{1, 2\}$ yields disjoint cycles, and we obtained a Hamiltonian path by jumping from one to the other. Can a σ–τ path for all permutations of 6 elements be formed in a similar way, based on a 360-cycle for the permutations of $\{1, 1, 3, 4, 5, 6\}$?

71. [*M21*] Given a Cayley graph with generators $(\alpha_1, \dots, \alpha_k)$, assume that each α_j takes $x \mapsto y$. (For example, both σ and τ take $1 \mapsto 2$ when $\sigma = (1\,2\,\dots\,n)$ and $\tau = (1\,2)$.) Prove that any Hamiltonian path starting at $12 \dots n$ in G must end at a permutation that takes $y \mapsto x$.

▸ **72.** [*M30*] Let α, β, and σ be permutations of a set X, where $X = A \cup B$. Assume that $x\sigma = x\alpha$ when $x \in A$ and $x\sigma = x\beta$ when $x \in B$, and that the order of $\alpha\beta^-$ is odd.

a) Prove that all three permutations α, β, σ have the same sign; that is, they are all even or all odd. *Hint:* A permutation has odd order if and only if its cycles all have odd length.

b) Derive Theorem R from part (a).

73. [*M30*] (R. A. Rankin.) Assuming that $\alpha\beta = \beta\alpha$ in Theorem R, prove that a Hamiltonian circuit exists if and only if there is a number k such that $0 \le k \le g/c$ and $t + k \perp c$, where $\beta^{g/c} = \gamma^t$, $\gamma = \alpha\beta^-$. *Hint:* Represent elements of the group in the form $\beta^j\gamma^k$.

74. [*M25*] The directed torus $C_m \times C_n$ has mn vertices (x, y) for $0 \le x < m$, $0 \le y < n$, and arcs $(x, y) \to (x, y)\alpha = \big((x+1) \bmod m, y\big)$, $(x, y) \to (x, y)\beta = \big(x, (y+1) \bmod n\big)$. Prove that, if $m > 1$ and $n > 1$, the number of Hamiltonian circuits of this digraph is

$$\sum_{k=1}^{d-1} \binom{d}{k} [\gcd((d-k)m, kn) = d], \qquad d = \gcd(m, n).$$

75. [*M31*] The cells numbered $0, 1, \ldots, 63$ in Fig. 25 illustrate a *northeasterly knight's tour* on an 8×8 torus: If k appears in cell (x_k, y_k), then $(x_{k+1}, y_{k+1}) = (x_k + 2, y_k + 1)$ or (x_k+1, y_k+2), modulo 8, and $(x_{64}, y_{64}) = (x_0, y_0)$. How many such tours are possible on an $m \times n$ torus, when $m, n \ge 3$?

29	24	19	14	49	44	39	34
58	53	48	43	38	9	4	63
23	18	13	8	3	62	33	28
52	47	42	37	32	27	22	57
17	12	7	2	61	56	51	46
6	41	36	31	26	21	16	11
35	30	1	60	55	50	45	40
0	59	54	25	20	15	10	5

Fig. 25. A northeasterly knight's tour.

▸ **76.** [*22*] Complete the `MMIX` program whose inner loop appears in (42), using Heap's method (27).

77. [*M23*] Analyze the running time of the program in exercise 76, generalizing it so that the inner loop does $r!$ visits (with $a_0 \ldots a_{r-1}$ in global registers).

78. [*20*] What seven `MMIX` instructions will ⟨ Swap the nybbles ... ⟩ as (45) requires? For example, if register `t` contains the value 4 and register `a` contains the nybbles `#12345678`, register `a` should change to `#12345687`.

79. [*21*] Solve the previous exercise with only five `MMIX` instructions. *Hint:* Use `MXOR`.

▸ **80.** [*22*] Complete the `MMIX` program (46) by specifying how to ⟨ Continue with Langdon's method ⟩.

81. [*M21*] Analyze the running time of the program in exercise 80.

82. [*22*] Use the σ–τ path of exercise 70 to design an `MMIX` routine analogous to (42) that generates all permutations of `#123456` in register `a`.

83. [*20*] Suggest a good way to generate all $n!$ permutations of $\{1, \ldots, n\}$ on p processors that are running in parallel.

▸ **84.** [*25*] Assume that n is small enough that $n!$ fits in a computer word. What's a good way to convert a given permutation $\alpha = a_1 \ldots a_n$ of $\{1, \ldots, n\}$ into an integer $k = r(\alpha)$ in the range $0 \le k < n!$? Both functions $k = r(\alpha)$ and $\alpha = r^{[-1]}(k)$ should be computable in only $O(n)$ steps.

85. [*20*] A partial order relation is supposed to be transitive; that is, $x \prec y$ and $y \prec z$ should imply $x \prec z$. But Algorithm V does not require its input relation to satisfy this condition.

Show that if $x \prec y$ and $y \prec z$, Algorithm V will produce identical results whether or not $x \prec z$.

86. [*20*] (F. Ruskey.) Consider the inversion tables $c_1 \ldots c_n$ of the permutations visited by Algorithm V. What noteworthy property do they have? (Compare with the inversion tables (4) in Algorithm P.)

87. [*21*] Show that Algorithm V can be used to generate all ways to partition the digits $\{0, 1, \ldots, 9\}$ into two 3-element sets and two 2-element sets.

▸ **88.** [*M30*] Consider the numbers $t_0, t_1, \ldots, t_n$ in (51). Clearly $t_0 = t_1 = 1$.

a) Say that index j is "trivial" if $t_j = t_{j-1}$. For example, 9 is trivial with respect to the Young tableau relations (48). Explain how to modify Algorithm V so that the variable k takes on only nontrivial values.

b) Analyze the running time of the modified algorithm. What formulas replace (51)?

c) Say that the interval $[j\,..\,k]$ is not a chain if we do not have $l \prec l+1$ for $j \le l < k$. Prove that in such a case $t_k \ge 2t_{j-1}$.

d) Every inverse topological sort $a'_1 \ldots a'_n$ defines a labeling that corresponds to relations $a'_{j_1} \prec a'_{k_1}, \ldots, a'_{j_m} \prec a'_{k_m}$, which are equivalent to the original relations $j_1 \prec k_1, \ldots, j_m \prec k_m$. Explain how to find a labeling such that $[j\,..\,k]$ is not a chain when j and k are consecutive nontrivial indices.

e) Prove that with such a labeling, $M < 4N$ in the formulas of part (b).

89. [*M21*] Algorithm V can be used to produce all permutations that are h-ordered for all h in a given set, namely all $a'_1 \ldots a'_n$ such that $a'_j < a'_{j+h}$ for $1 \le j \le n - h$ (see Section 5.2.1). Analyze the running time of Algorithm V when it generates all permutations that are both 2-ordered and 3-ordered.

90. [*HM21*] Analyze the running time of Algorithm V when it is used with the relations (49) to find matchings.

91. [*M18*] How many permutations is Algorithm V likely to visit, in a "random" case? Let P_n be the number of partial orderings on $\{1, \ldots, n\}$, namely the number of relations that are reflexive, antisymmetric, and transitive. Let Q_n be the number of such relations with the additional property that $j < k$ whenever $j \prec k$. Express the expected number of ways to sort n elements topologically, averaged over all partial orderings, in terms of P_n and Q_n.

92. [*35*] Prove that all topological sorts can be generated in such a way that only one or two adjacent transpositions are made at each step. (The example $1 \prec 2$, $3 \prec 4$ shows that a single transposition per step cannot always be achieved, even if we allow nonadjacent swaps, because only two of the six relevant permutations are odd.)

▸ **93.** [*25*] Show that in the case of matchings, using the relations in (49), all topological sorts can be generated with just one transposition per step.

94. [*21*] Discuss how to generate all *up-down permutations* of $\{1, \ldots, n\}$, namely those $a_1 \ldots a_n$ such that $a_1 < a_2 > a_3 < a_4 > \cdots$.

95. [*21*] Discuss how to generate all *cyclic permutations* of $\{1, \ldots, n\}$, namely those $a_1 \ldots a_n$ whose cycle representation consists of a single n-cycle.

96. [*21*] Discuss how to generate all *derangements* of $\{1, \ldots, n\}$, namely those $a_1 \ldots a_n$ such that $a_1 \ne 1$, $a_2 \ne 2$, $a_3 \ne 3$, ...

97. [*HM23*] Analyze the asymptotic running time of the method in the previous exercise.

98. [*M30*] Given $n \ge 3$, show that all derangements of $\{1, \ldots, n\}$ can be generated by making at most two transpositions between visits.

99. [*21*] Discuss how to generate all *indecomposable* permutations of $\{1, \ldots, n\}$, namely those $a_1 \ldots a_n$ such that $\{a_1, \ldots, a_j\} \ne \{1, \ldots, j\}$ for $1 \le j < n$.

100. [*21*] Discuss how to generate all *involutions* of $\{1, \ldots, n\}$, namely those permutations $a_1 \ldots a_n$ with $a_{a_1} \ldots a_{a_n} = 1 \ldots n$.

101. [*M30*] Show that all involutions of $\{1,\ldots,n\}$ can be generated by making at most two transpositions between visits.

102. [*M32*] Show that all even permutations of $\{1,\ldots,n\}$ can be generated by successive *rotations of three consecutive elements*.

▸ **103.** [*M22*] A permutation $a_1\ldots a_n$ of $\{1,\ldots,n\}$ is *well-balanced* if

$$\sum_{k=1}^{n} k a_k = \sum_{k=1}^{n} (n+1-k)a_k.$$

For example, 3142 is well-balanced when $n=4$.

a) Prove that no permutation is well-balanced when $n \bmod 4 = 2$.

b) Prove that if $a_1\ldots a_n$ is well-balanced, so are its reversal $a_n\ldots a_1$, its complement $(n+1-a_1)\ldots(n+1-a_n)$, and its inverse $a'_1\ldots a'_n$.

c) Determine the number of well-balanced permutations for small values of n.

▸ **104.** [*26*] A *weak order* is a relation $\preceq$ that is transitive ($x\preceq y$ and $y\preceq z$ implies $x\preceq z$) and complete ($x\preceq y$ or $y\preceq x$ always holds). We can write $x\equiv y$ if $x\preceq y$ and $y\preceq x$; $x\prec y$ if $x\preceq y$ and $y\not\preceq x$. There are thirteen weak orders on three elements $\{1,2,3\}$, namely

$$1\equiv 2\equiv 3,\quad 1\equiv 2\prec 3,\quad 1\prec 2\equiv 3,\quad 1\prec 2\prec 3,\quad 1\equiv 3\prec 2,\quad 1\prec 3\prec 2,$$
$$2\prec 1\equiv 3,\quad 2\prec 1\prec 3,\quad 2\equiv 3\prec 1,\quad 2\prec 3\prec 1,\quad 3\prec 1\equiv 2,\quad 3\prec 1\prec 2,\quad 3\prec 2\prec 1.$$

a) Explain how to generate all weak orders of $\{1,\ldots,n\}$ systematically, as sequences of digits separated by the symbols $\equiv$ or $\prec$.

b) A weak order can also be represented as a sequence $a_1\ldots a_n$ where $a_j=k$ if j is preceded by k $\prec$ signs. For example, the thirteen weak orders on $\{1,2,3\}$ are respectively 000, 001, 011, 012, 010, 021, 101, 102, 100, 201, 110, 120, 210 in this form. Find a simple way to generate all such sequences of length n.

105. [*M40*] Can exercise 104(b) be solved with a Gray-like path?

▸ **106.** [*30*] (John H. Conway, 1973.) To play the solitaire game of "topswops," start by shuffling a pack of n cards labeled $\{1,\ldots,n\}$ and place them face up in a pile. Then if the top card is $k>1$, deal out the top k cards and put them back on top of the pile, thereby changing the permutation from $a_1\ldots a_n$ to $a_k\ldots a_1 a_{k+1}\ldots a_n$. Continue until the top card is 1. For example, the 7-step sequence

$$31452 \to 41352 \to 53142 \to 24135 \to 42135 \to 31245 \to 21345 \to 12345$$

might occur when $n=5$. What is the longest sequence possible when $n=13$?

107. [*M27*] If the longest n-card game of topswops has length $f(n)$, prove that $f(n)\le F_{n+1}-1$.

108. [*M47*] Find good upper and lower bounds on the topswops function $f(n)$.

▸ **109.** [*25*] Find all permutations $a_0\ldots a_9$ of $\{0,\ldots,9\}$ such that

$$\{a_0,a_2,a_3,a_7\}=\{2,5,7,8\},$$
$$\{a_1,a_4,a_5\}=\{0,3,6\},$$
$$\{a_1,a_3,a_7,a_8\}=\{3,4,5,7\},$$
$$\{a_0,a_3,a_4\}=\{0,7,8\}.$$

Also suggest an algorithm for solving large problems of this type.

▸ **110.** [*M25*] Several permutation-oriented analogs of de Bruijn cycles have been proposed. The simplest and nicest of these is the notion of a *universal cycle of permutations*, introduced by B. W. Jackson in *Discrete Math.* **117** (1993), 141–150, namely a cycle of $n!$ digits such that each permutation of $\{1,\ldots,n\}$ occurs exactly once as a block of $n-1$ consecutive digits (with its redundant final element suppressed). For example, (121323) is a universal cycle of permutations for $n=3$, and it is essentially the only such cycle.

Find a universal cycle of permutations for $n=4$, and prove that such cycles exist for all $n\geq 2$.

111. [*M46*] Exactly how many universal cycles exist, for permutations of order n?

SECTION 7.2.1.2

1. [J. P. N. Phillips, *Comp. J.* **10** (1967), 311.] Assuming that $n \ge 3$, we can replace steps L2–L4 by:

L2′. [Easiest case?] Set $y \leftarrow a_{n-1}$ and $z \leftarrow a_n$. If $y < z$, set $a_{n-1} \leftarrow z$, $a_n \leftarrow y$, and return to L1.

L2.1′. [Next easiest case?] Set $x \leftarrow a_{n-2}$. If $x \ge y$, go on to step L2.2′. Otherwise set $(a_{n-2}, a_{n-1}, a_n) \leftarrow (z, x, y)$ if $x < z$, (y, z, x) if $x \ge z$. Return to L1.

L2.2′. [Find j.] Set $j \leftarrow n-3$ and $y \leftarrow a_j$. If $y \ge x$, set $j \leftarrow j-1$, $x \leftarrow y$, $y \leftarrow a_j$, and repeat until $y < x$. Terminate if $j = 0$.

L3′. [Easy increase?] If $y < z$, set $a_j \leftarrow z$, $a_{j+1} \leftarrow y$, $a_n \leftarrow x$, and go to L4.1′.

L3.1′. [Increase a_j.] Set $l \leftarrow n-1$; if $y \ge a_l$, repeatedly decrease l by 1 until $y < a_l$. Then set $a_j \leftarrow a_l$ and $a_l \leftarrow y$.

L4′. [Begin to reverse.] Set $a_n \leftarrow a_{j+1}$ and $a_{j+1} \leftarrow z$.

L4.1′. [Reverse $a_{j+1} \ldots a_{n-1}$.] Set $k \leftarrow j+2$, $l \leftarrow n-1$. Then, if $k < l$, interchange $a_k \leftrightarrow a_l$, set $k \leftarrow k+1$, $l \leftarrow l-1$, and repeat until $k \ge l$. Return to L1. ∎

The program might run still faster if a_t is stored in memory location $\mathtt{A}[n-t]$ for $0 \le t \le n$, or if reverse colex order is used as in the following exercise.

2. Again we assume that $a_1 \le a_2 \le \cdots \le a_n$ initially; the permutations generated from $\{1, 2, 2, 3\}$ will, however, be 1223, 2123, 2213, ..., 2321, 3221. Let a_{n+1} be an auxiliary element, *larger* than a_n.

L1. [Visit.] Visit the permutation $a_1 a_2 \ldots a_n$.

L2. [Find j.] Set $j \leftarrow 2$. If $a_{j-1} \ge a_j$, increase j by 1 until $a_{j-1} < a_j$. Terminate if $j > n$.

L3. [Decrease a_j.] Set $l \leftarrow 1$. If $a_l \ge a_j$, increase l until $a_l < a_j$. Then swap $a_l \leftrightarrow a_j$.

L4. [Reverse $a_1 \ldots a_{j-1}$.] Set $k \leftarrow 1$ and $l \leftarrow j-1$. Then, if $k < l$, swap $a_k \leftrightarrow a_l$, set $k \leftarrow k+1$, $l \leftarrow l-1$, and repeat until $k \ge l$. Return to L1. ∎

3. Let $C_1 \ldots C_n = c_{a_1} \ldots c_{a_n}$ be the inversion table, as in exercise 5.1.1–7. Then $\operatorname{rank}(a_1 \ldots a_n)$ is the mixed-radix number $\left[\begin{smallmatrix} C_n, & \ldots, & C_2, & C_1 \\ n, & \ldots, & 2, & 1 \end{smallmatrix}\right]$. [See H. A. Rothe, *Sammlung combinatorisch-analytischer Abhandlungen* **2** (1800), 263–264.] For example, 314592687 has rank $\left[\begin{smallmatrix} 2, & 0, & 1, & 1, & 4, & 0, & 0, & 1, & 0 \\ 9, & 8, & 7, & 6, & 5, & 4, & 3, & 2, & 1 \end{smallmatrix}\right] = 2 \cdot 8! + 6! + 5! + 4 \cdot 4! + 1! = 81577$; this is the factorial number system featured in Eq. 4.1–(10).

4. Use the recurrence $\operatorname{rank}(a_1 \ldots a_n) = \frac{1}{n} \sum_{j=1}^{t} n_j [x_j < a_1] \binom{n}{n_1, \ldots, n_t} + \operatorname{rank}(a_2 \ldots a_n)$. For example, rank(314159265) is

$$\tfrac{3}{9}\tbinom{9}{2,1,1,1,2,1,1} + 0 + \tfrac{2}{7}\tbinom{7}{1,1,1,2,1,1} + 0 + \tfrac{1}{5}\tbinom{5}{1,2,1,1} + \tfrac{3}{4}\tbinom{4}{1,1,1,1} + 0 + \tfrac{1}{2}\tbinom{2}{1,1} = 30991.$$

5. (a) Step L2 is performed $n!$ times. The probability that exactly k comparisons are made is $q_k - q_{k+1}$, where q_t is the probability that $a_{n-t+1} > \cdots > a_n$, namely $[t \le n]/t!$. Therefore the mean is $\sum k(q_k - q_{k+1}) = q_1 + \cdots + q_n = \lfloor n!\, e \rfloor / n! - 1 \approx e - 1 \approx 1.718$, and the variance is

$$\sum k^2(q_k - q_{k+1}) - \text{mean}^2 = q_1 + 3q_2 + \cdots + (2n-1)q_n - (q_1 + \cdots + q_n)^2 \approx e(3-e) \approx 0.766.$$

[For higher moments, see R. Kemp, *Acta Informatica* **35** (1998), 17–89, Theorem 4.]

Incidentally, the average number of interchange operations in step L4 is therefore $\sum\lfloor k/2\rfloor(q_k - q_{k+1}) = q_2 + q_4 + \cdots \approx \cosh 1 - 1 = (e + e^{-1} - 2)/2 \approx 0.543$, a result due to R. J. Ord-Smith [*Comp. J.* **13** (1970), 152–155].

(b) Step L3 is performed only $n! - 1$ times, but we will assume for convenience that it occurs once more (with 0 comparisons). Then the probability that exactly k comparisons are made is $\sum_{j=k+1}^{n} 1/j!$ for $1 \le k < n$ and $1/n!$ for $k = 0$. Hence the mean is $\frac{1}{2}\sum_{j=0}^{n-2} 1/j! \approx e/2 \approx 1.359$; exercise 1 reduces this number by $\frac{2}{3}$. The variance is $\frac{1}{3}\sum_{j=0}^{n-3} 1/j! + \frac{1}{2}\sum_{j=0}^{n-2} 1/j! - \text{mean}^2 \approx \frac{5}{6}e - \frac{1}{4}e^2 \approx 0.418$.

6. (a) Let $e_n(z) = \sum_{k=0}^{n} z^k/k!$; then the number of different prefixes $a_1 \ldots a_j$ is $j!\,[z^j]\,e_{n_1}(z)\ldots e_{n_t}(z)$. This is $N = \binom{n}{n_1,\ldots,n_t}$ times the probability q_{n-j} that at least $n-j$ comparisons are made in step L2. Therefore the mean is $\frac{1}{N}w\big(e_{n_1}(z)\ldots e_{n_t}(z)\big) - 1$, where $w\big(\sum x_k z^k/k!\big) = \sum x_k$. In the binary case the mean is $M/\binom{n}{m} - 1$, where $M = \sum_{l=0}^{m}\sum_{k=l}^{n-m+l}\binom{k}{l} = \sum_{l=0}^{m}\binom{n-m+l+1}{l+1} = \binom{n+2}{m+1} - 1 = \binom{n}{m}\big(2 + \frac{m}{n-m+1} + \frac{n-m}{m+1}\big) - 1$.

(b) If $\{a_1, \ldots, a_j\} = \{n'_1 \cdot x_1, \ldots, n'_t \cdot x_t\}$, the prefix $a_1 \ldots a_j$ contributes altogether $\sum_{1\le k<l\le t}(n_k - n'_k)[n_l < n'_l]$ to the total number of comparisons made in step L3. Thus the mean is $\frac{1}{N}\sum_{1\le k<l\le t} w\big(f_{kl}(z)\big)$, where

$$f_{kl}(z) = \Bigg(\prod_{\substack{1\le m\le t\\ m\ne k,\ m\ne l}} e_{n_m}(z)\Bigg)\Bigg(\sum_{r=0}^{n_k}(n_k - r)\frac{z^r}{r!}\Bigg)e_{n_l-1}(z)$$

$$= n_k\Bigg(\prod_{\substack{1\le m\le t\\ m\ne l}} e_{n_m}(z)\Bigg)e_{n_l-1}(z) \;-\; z\Bigg(\prod_{\substack{1\le m\le t\\ m\ne k,\ m\ne l}} e_{n_m}(z)\Bigg)e_{n_l-1}(z)e_{n_k-1}(z).$$

In the two-valued case this formula reduces to $\frac{1}{N}w\big(me_m(z) - ze_{m-1}(z)\big)e_{n-m-1}(z)\big) = \frac{m}{N}\big(\binom{n+1}{m+1} - 1\big) - \frac{1}{N}\big(\binom{n+1}{m+1}\big(m - \frac{m+1}{n-m+1}\big) + 1\big) = \frac{1}{N}\big(-m - 1 + \binom{n+1}{m}\big) = \frac{n+1}{n-m+1} - \frac{m+1}{N}$.

7. In the notation of the previous answer, the quantity $\frac{1}{N}w\big(e_{n_1}(z)\ldots e_{n_t}(z)\big) - 1$ is

$$\frac{n_1 + \cdots + n_t}{n} + \frac{(n_1n_2 + n_1n_3 + \cdots + n_{t-1}n_t) + n_1(n_1-1) + \cdots + n_t(n_t-1)}{n(n-1)} + \cdots - 1.$$

One can show using Eq. 1.2.9–(38) that the limit is $-1 + \exp\sum_{k\ge1} r_k/k$, where $r_k = \lim_{t\to\infty}(n_1^k + \cdots + n_t^k)/(n_1 + \cdots + n_t)^k$. In cases (a) and (b) we have $r_k = [k=1]$, so the limit is $e - 1 \approx 1.71828$. In case (c) we have $r_k = 1/(2^k - 1)$, so the limit is $-1 + \exp\sum_{k\ge1} 1/(k(2^k - 1)) \approx 2.46275$.

8. Assume that j is initially zero, and change step L1 to

L1′. [Visit.] Visit the variation $a_1 \ldots a_j$. If $j < n$, set $j \leftarrow j + 1$ and repeat this step. ∎

This algorithm is due to L. J. Fischer and K. C. Krause, *Lehrbuch der Combinationslehre und der Arithmetik* (Dresden: 1812), 55–57.

Incidentally, the total number of variations is $w\big(e_{n_1}(z)\ldots e_{n_t}(z)\big)$ in the notation of answer 6. This counting problem was first treated by Jakob Bernoulli in *Ars Conjectandi* (1713), Part 2, Chapter 9.

9. **V1.** [Visit.] Visit the variation $a_1 \ldots a_r$. (At this point $a_{r+1} \le \cdots \le a_n$.)

V2. [Easy case?] If $a_r < a_n$, interchange $a_r \leftrightarrow a_j$ where j is the smallest subscript such that $j > r$ and $a_j > a_r$, and return to V1.

V3. [Reverse.] Set $(a_{r+1},\ldots,a_n) \leftarrow (a_n,\ldots,a_{r+1})$ as in step L4.

V4. [Find j.] Set $j \leftarrow r-1$. If $a_j \ge a_{j+1}$, decrease j by 1 repeatedly until $a_j < a_{j+1}$. Terminate if $j = 0$.

V5. [Increase a_j.] Set $l \leftarrow n$. If $a_j \ge a_l$, decrease l by 1 repeatedly until $a_j < a_l$. Then interchange $a_j \leftrightarrow a_l$.

V6. [Reverse again.] Set $(a_{j+1},\ldots,a_n) \leftarrow (a_n,\ldots,a_{j+1})$ as in step L4, and return to V1. ▮

The number of outputs is $r!\,[z^r]\,e_{n_1}(z)\ldots e_{n_t}(z)$; this is, of course, n^r when the elements are distinct.

10. $a_1a_2\ldots a_n = 213\ldots n$, $c_1c_2\ldots c_n = 010\ldots0$, $d_1d_2\ldots d_n = 1(-1)1\ldots1$, if $n \ge 2$.

11. Step (P1, ..., P7) is performed $(1, n!, n!, n!+x_n, n!, (x_n+3)/2, x_n)$ times, where $x_n = \sum_{k=1}^{n-1} k!$, because P7 is performed $(j-1)!$ times when $2 \le j \le n$.

12. We want the permutation of rank 999999. The answers are (a) 2783915460, by exercise 3; (b) 8750426319, because the reflected mixed-radix number corresponding to $\left[\begin{smallmatrix}0,&0,&1,&2,&3,&0,&2,&7,&0,&9\\1,&2,&3,&4,&5,&6,&7,&8,&9,&10\end{smallmatrix}\right]$ is $\left[\begin{smallmatrix}0,&0,&1,&3-2,&3,&5-0,&2,&7,&8-0,&9-9\\1,&2,&3,&4,&5,&6,&7,&8,&9,&10\end{smallmatrix}\right]$ by 7.2.1.1–(50); (c) the product $(0\,1\,\ldots\,9)^9(0\,1\,\ldots\,8)^0(0\,1\,\ldots\,7)^7(0\,1\,\ldots\,6)^2\ldots(0\,1\,2)^1$, namely 9703156248.

13. The first statement is true for all $n \ge 2$. But when 2 crosses 1, namely when c_2 changes from 0 to 1, we have $c_3 = 2$, $c_4 = 3$, $c_5 = \cdots = c_n = 0$, and the next permutation when $n \ge 5$ is $432156\ldots n$. [See *Time Travel* (1988), page 74.]

14. True at the beginning of steps P4, P5, and P6, because exactly $j-1-c_j+s$ elements lie to the left of x_j, namely $j-1-c_j$ from $\{x_1,\ldots,x_{j-1}\}$ and s from $\{x_{j+1},\ldots,x_n\}$. (In a sense, this formula is the main point of Algorithm P.)

15. If $\left[\begin{smallmatrix}b_{n-1},&\ldots,&b_0\\1,&\ldots,&n\end{smallmatrix}\right]$ corresponds to the reflected Gray code $\left[\begin{smallmatrix}c_1,&\ldots,&c_n\\1,&\ldots,&n\end{smallmatrix}\right]$, we get to step P6 if and only if $b_k = k-1$ for $j \le k \le n$ and B_{n-j+1} is even, by 7.2.1.1–(50). But $b_{n-k} = k-1$ for $j \le k \le n$ implies that B_{n-k} is odd for $j < k \le m$. Therefore $s = [c_{j+1} = j] + [c_{j+2} = j+1] = [d_{j+1} < 0] + [d_{j+2} < 0]$ in step P5. [See *Math. Comp.* **17** (1963), 282–285.]

16. **P1′.** [Initialize.] Set $c_j \leftarrow j$ and $d_j \leftarrow -1$ for $1 \le j < n$; also set $z \leftarrow a_n$.

P2′. [Visit.] Visit $a_1\ldots a_n$. Then go to P3.5′ if $a_1 = z$.

P3′. [Hunt down.] For $j \leftarrow n-1, n-2, \ldots, 1$ (in this order), set $a_{j+1} \leftarrow a_j$, $a_j \leftarrow z$, and visit $a_1\ldots a_n$. Then set $j \leftarrow n-1$, $s \leftarrow 1$, and go to P4′.

P3.5′. [Hunt up.] For $j \leftarrow 1, 2, \ldots, n-1$ (in this order), set $a_j \leftarrow a_{j+1}$, $a_{j+1} \leftarrow z$, and visit $a_1\ldots a_n$. Then set $j \leftarrow n-1$, $s \leftarrow 0$.

P4′. [Ready to change?] Set $q \leftarrow c_j + d_j$. If $q = 0$, go to P6′; if $q > j$, go to P7′.

P5′. [Change.] Interchange $a_{c_j+s} \leftrightarrow a_{q+s}$. Then set $c_j \leftarrow q$ and return to P2′.

P6′. [Increase s.] Terminate if $j = 1$; otherwise set $s \leftarrow s+1$.

P7′. [Switch direction.] Set $d_j \leftarrow -d_j$, $j \leftarrow j-1$, and go back to P4′. ▮

17. Initially $a_j \leftarrow a'_j \leftarrow j$ for $1 \le j \le n$. Step P5 should now set $t \leftarrow j - c_j + s$, $u \leftarrow j-q+s$, $v \leftarrow a_u$, $a_t \leftarrow v$, $a'_v \leftarrow t$, $a_u \leftarrow j$, $a'_j \leftarrow u$, $c_j \leftarrow q$. (See exercise 14.)

But with the inverse required and available we can actually simplify the algorithm significantly, avoiding the offset variable s and letting the control table $c_1\ldots c_n$ count only downwards, as noted by G. Ehrlich [*JACM* **20** (1973), 505–506]:

Q1. [Initialize.] Set $a_j \leftarrow a'_j \leftarrow j$, $c_j \leftarrow j-1$, and $d_j \leftarrow -1$ for $1 \le j \le n$. Also set $c_0 = -1$.

Q2. [Visit.] Visit the permutation $a_1 \dots a_n$ and its inverse $a'_1 \dots a'_n$.

Q3. [Find k.] Set $k \leftarrow n$. Then if $c_k = 0$, set $c_k \leftarrow k-1$, $d_k \leftarrow -d_k$, $k \leftarrow k-1$, and repeat until $c_k \neq 0$. Terminate if $k = 0$.

Q4. [Change.] Set $c_k \leftarrow c_k - 1$, $j \leftarrow a'_k$, and $i = j + d_k$. Then set $t \leftarrow a_i$, $a_i \leftarrow k$, $a_j \leftarrow t$, $a'_t \leftarrow j$, $a'_k \leftarrow i$, and return to Q2. ∎

18. Set $a_n \leftarrow n$, and use $(n-1)!/2$ iterations of Algorithm P to generate all permutations of $\{1, \dots, n-1\}$ such that 1 precedes 2. [M. K. Roy, *CACM* **16** (1973), 312–313; see also exercise 13.]

19. For example, we can use the idea of Algorithm P, with the n-tuples $c_1 \dots c_n$ changing as in Algorithm 7.2.1.1H with respect to the radices $(1, 2, \dots, n)$. That algorithm maintains the directions correctly, although it numbers subscripts differently. The offset s needed by Algorithm P can be computed as in the answer to exercise 15, or the inverse permutation can be maintained as in exercise 17. [See G. Ehrlich, *CACM* **16** (1973), 690–691.] Other algorithms, like that of Heap, can also be implemented looplessly.

(*Note:* In most applications of permutation generation we are interested in minimizing the *total* running time, not the maximum time between successive visits; from this standpoint looplessness is usually undesirable, except on a parallel computer. Yet there's something intellectually satisfying about the fact that a loopless algorithm exists, whether practical or not.)

20. For example, when $n = 3$ we can begin 123, 132, 312, $\overline{3}12$, $1\overline{3}2$, $12\overline{3}$, $21\overline{3}$, ..., 213, $\overline{2}13$, ... If the delta sequence for n is $(\delta_1\delta_2 \dots \delta_{2^n n!})$, the corresponding sequence for $n+1$ is $(\Delta_n\delta_1\Delta_n\delta_2 \dots \Delta_n\delta_{2^n n!})$, where Δ_n is the sequence of $2n-1$ operations $n\ n{-}1\ \dots\ 1\ -\ 1\ \dots\ n{-}1\ n$; here $\delta_k = j$ means $a_j \leftrightarrow a_{j+1}$ and $\delta_k = -$ means $a_1 \leftarrow -a_1$.

(Signed permutations appear in another guise in exercises 5.1.4–43 and 44. The set of all signed permutations is called the octahedral group.)

21. Clearly $\texttt{M} = 1$, hence $\texttt{O}$ must be 0 and $\texttt{S}$ must be $b-1$. Then $\texttt{N} = \texttt{E}+1$, $\texttt{R} = b-2$, and $\texttt{D}+\texttt{E} = b+\texttt{Y}$. This leaves exactly $\max(0, b-7-k)$ choices for $\texttt{E}$ when $\texttt{Y} = k \geq 2$, hence a total of $\sum_{k=2}^{b-7}(b-7-k) = \binom{b-8}{2}$ solutions when $b \geq 8$. [*Math. Mag.* **45** (1972), 48–49.]

22. $(\texttt{XY})_b + (\texttt{XX})_b = (\texttt{XYX})_b$ is solvable only when $b = 2$.

23. Almost true, because the number of solutions will be even, *unless* $[j \in F] \neq [k \in F]$. (Consider the ternary alphametic $\texttt{X} + (\texttt{XX})_3 + (\texttt{YY})_3 + (\texttt{XZ})_3 = (\texttt{XYX})_3$.)

24. (a) $9283 + 7 + 473 + 1062 = 10825$. (b) $698392 + 3192 = 701584$. (c) $63952 + 69275 = 133227$. (d) $653924 + 653924 = 1307848$. (e) $5718 + 3 + 98741 = 104462$. (f) $127503 + 502351 + 3947539 + 46578 = 4623971$. (g) $67432 + 704 + 8046 + 97364 = 173546$. (h) $59 + 577404251698 + 69342491650 + 49869442698 + 1504 + 40614 + 82591 + 344 + 41 + 741425 = 5216367650 + 691400684974$. [All solutions are unique. References for (b)–(g): *J. Recreational Math.* **10** (1977), 155; **5** (1972), 296; **10** (1977), 41; **10** (1978), 274; **12** (1979), 133–134; **9** (1977), 207.]

(i) In this case there are $\frac{8}{10}10! = 2903040$ solutions, because *every* permutation of $\{0, 1, \dots, 9\}$ works except those that assign $\texttt{H}$ or $\texttt{N}$ to 0. (A well-written general additive alphametic solver will be careful to reduce the amount of output in such cases.)

25. We may assume that $s_1 \leq \cdots \leq s_{10}$. Let i be the least index $\notin F$, and set $a_i \leftarrow 0$; then set the remaining elements a_j in order of increasing j. A proof like that

of Theorem 6.1S shows that this procedure maximizes $a \cdot s$. A similar procedure yields the minimum, because $\min(a \cdot s) = -\max(a \cdot (-s))$.

26. 400739 + 63930 − 2379 − 1252630 + 53430 − 1390 + 738300.

27. Readers can probably improve upon the following examples: BLOOD + SWEAT + TEARS = LATER; EARTH + WATER + WRATH = HELLO + WORLD; AWAIT + ROBOT + ERROR = SOBER + WORDS; CHILD + THEME + PEACE + ETHIC = IDEAL + ALPHA + METIC. (This exercise was inspired by WHERE + SEDGE + GRASS + GROWS = MARSH [A. W. Johnson, Jr., *J. Recr. Math.* **15** (1982), 51], which would be marvelously pure except that D and O have the same signature.)

28. (a) 11 = 3 + 3 + 2 + 2 + 1, 20 = 11 + 3 + 3 + 3, 20 = 11 + 3 + 3 + 2 + 1, 20 = 11+3+3+1+1+1, 20 = 8+8+2+1+1, 20 = 7+7+6, 20 = 7+7+2+2+2, 20 = 7+7+2+1+1+1+1, 20 = 7+5+5+2+1, 20 = 7+5+2+2+2+1+1, 20 = 7+5+2+2+1+1+1+1, 20 = 7+3+3+2+2+1+1+1, 20 = 7+3+3+1+1+1+1+1+1, 20 = 5+3+3+3+3+3. [These fourteen solutions were first computed by Roy Childs in 1999. The next doubly partitionable values of n are 30 (in 20 ways), then 40 (in 94 ways), 41 (in 67), 42 (in 57), 50 (in 190 ways, including $50 = 2 + 2 + \cdots + 2$), etc.]

(b) 51 = 20 + 15 + 14 + 2, 51 = 15 + 14 + 10 + 9 + 3, 61 = 19 + 16 + 11 + 9 + 6, 65 = 17 + 16 + 15 + 9 + 7 + 1, 66 = 20 + 19 + 16 + 6 + 5, 69 = 18 + 17 + 16 + 10 + 8, 70 = 30+20+10+7+3, 70 = 20+16+12+9+7+6, 70 = 20+15+12+11+7+5, 80 = 50+20+9+1, 90 = 50+12+11+9+5+2+1, 91 = 45+19+11+10+5+1. [The two 51s are due to Steven Kahan; see his book *Have Some Sums To Solve* (Farmingdale, New York: Baywood, 1978), 36–37, 84, 112. Amazing examples with seventeen distinct terms in Italian and fifty-eight distinct terms in Roman numerals have been found by Giulio Cesare, *J. Recr. Math.* **30** (1999), 63.]

Notes: The beautiful example THREE = TWO + ONE + ZERO [Richard L. Breisch, *Recreational Math. Magazine* **12** (December 1962), 24] is unfortunately ruled out by our conventions. The total number of doubly true partitions into distinct parts is probably finite, in English, although nomenclature for arbitrary large integers is not standard. Is there an example that exceeds NINETYNINENONILLIONNINETYNINETRILLIONNINETYONE = NINETYNINENONILLIONNINETYNINETRILLIONFORTYFIVE + NINETEEN + ELEVEN + TEN + FIVE + ONE?

29. 10 + 7 + 1 = 9 + 6 + 3, 11 + 10 = 8 + 7 + 6, 12 + 7 + 6 + 5 = 11 + 10 + 9, ..., 19 + 10 + 3 = 14 + 13 + 4 + 1 (31 examples in all).

30. (a) $567^2 = 321489$, $807^2 = 651249$, or $854^2 = 729316$. (b) $958^2 = 917764$. (c) $96 \times 7^2 = 4704$. (d) 51304/61904 = 7260/8760. [*Strand* **78** (1929), 91, 208; *J. Recr. Math* **3** (1970), 43; **13** (1981), 212; **27** (1995), 137. The solutions to (b), (c), and (d) are unique. With a right-to-left approach based on Algorithm X, the answers are found in (14, 13, 11, 3423) kilomems, respectively.]

31. 5/34 + 7/68 + 9/12(!). One can verify uniqueness with Algorithm X using the side condition A < D < G, in about 265 Kμ.

32. There are eleven ways, of which the most surprising is 3 + 69258/714. [See *The Weekly Dispatch* (9 and 23 June 1901); *Amusements in Mathematics* (1917), 158–159.]

33. (a) 1, 2, 3, 4, 15, 18, 118, 146. (b) 6, 9, 16, 20, 27, 126, 127, 129, 136, 145. [*The Weekly Dispatch* (11 and 30 November, 1902); *Amusements in Math.* (1917), 159.]

In this case one suitable strategy is to find all variations where $a_k \ldots a_{l-1}/a_l \ldots a_9$ is an integer, then to record solutions for all permutations of $a_1 \ldots a_{k-1}$. There are

exactly 164959 integers with a unique solution, the largest being 9876533. There are solutions for all years in the 21st century except 2091. The most solutions (125) occur when $n = 6443$; the longest stretch of representable n's is $5109 < n < 7060$. Dudeney was able to get the correct answers by hand for small n by "casting out nines."

34. (a) $x = 10^5$, 7378+155+92467 = 7178+355+92467 = 1016+733+98251 = 100000. (b) $x = 4^7$, 3036 + 455 + 12893 = 16384 is unique. The fastest way to resolve this problem is probably to start with a list of the 2529 primes that consist of five distinct digits (namely 10243, 10247, ..., 98731) and to permute the five remaining digits.

Incidentally, the unrestricted alphametic `EVEN + ODD = PRIME` has ten solutions; both `ODD` and `PRIME` are prime in just one of them. [See M. Arisawa, *J. Recr. Math.* **8** (1975), 153.]

35. In general, if $s_k = \|S_k\|$ for $1 \le k < n$, there are $s_1 \ldots s_{k-1}$ ways to choose each of the nonidentity elements of S_k. Hence the answer is $\prod_{k=1}^{n-1}(\prod_{j=1}^{k-1} s_j^{s_{k-1}})$, which in this case is $2^2 \cdot 6^3 \cdot 24^{15} = 4361966924740238361231 36$.

(But if the vertices are renumbered, the s_k values may change. For example, if vertices `(0,3,5)` of `(12)` are interchanged with `(e,d,c)`, we have $s_{14} = 1$, $s_{13} = 6$, $s_{12} = 4$, $s_{11} = 1$, and $4^5 \cdot 24^{15}$ Sims tables.)

36. Since each of {`0,3,5,6,9,a,c,f`} lies on three lines, but every other element lies on only two, it is clear that we may let $S_{\mathtt{f}} = \{(), \sigma, \sigma^2, \sigma^3, \alpha, \alpha\sigma, \alpha\sigma^2, \alpha\sigma^3\}$, where $\sigma =$ `(03fc)(17e4)(2bd4)(56a9)` is a 90° rotation and $\alpha =$ `(05)(14)(27)(36)(8d)(9c)(af)(be)` is an inside-out twist. Also $S_{\mathtt{e}} = \{(), \beta, \gamma, \beta\gamma\}$, where $\beta =$ `(14)(28)(3c)(69)(be)` is a transposition and $\gamma =$ `(12)(48)(5a)(69)(7b)(de)` is another twist; $S_{\mathtt{d}} = \cdots = S_{\mathtt{1}} = \{()\}$. (There are $4^7 - 1$ alternative answers.)

37. The set S_k can be chosen in $k!^{k-1}$ ways (see exercise 35), and its nonidentity elements can be assigned to $\sigma(k,1)$, ..., $\sigma(k,k)$ in $k!$ further ways. So the answer is $A_n = \prod_{k=1}^{n-1} k!^k = n!^{\binom{n}{2}} / \prod_{k=1}^{n} k^{\binom{k}{2}}$. For example, $A_{10} \approx 6.256 \times 10^{148}$. We have

$$\sum_{k=1}^{n-1} \binom{k}{2} \ln k = \frac{1}{2}\int_1^n x(x-1)\ln x\,dx + O(n^2 \log n) = \frac{1}{6}n^3 \ln n + O(n^3)$$

by Euler's summation formula; thus $\ln A_n = \frac{1}{3}n^3 \ln n + O(n^3)$.

38. The probability that $\phi(k)$ is needed in step G4 is $1/k! - 1/(k+1)!$, for $1 \le k < n$; the probability is $1/n!$ that we don't get to step G4 at all. Since $\phi(k)$ does $\lceil k/2 \rceil$ transpositions, the average is $\sum_{k=1}^{n-1}(1/k! - 1/(k+1)!)\lceil k/2 \rceil = \sum_{k=1}^{n-1}(\lceil k/2 \rceil - \lceil (k-1)/2 \rceil)/k! - \lceil (n-1)/2 \rceil/n! = \sum_{k\,\mathrm{odd}} 1/k! + O(1/(n-1)!)$.

39. (a) 0123, 1023, 2013, 0213, 1203, 2103, 3012, 0312, 1302, 3102, 0132, 1032, 2301, 3201, 0231, 2031, 3021, 0321, 1230, 2130, 3120, 1320, 2310, 3210; (b) 0123, 1023, 2013, 0213, 1203, 2103, 3102, 1302, 0312, 3012, 1032, 0132, 0231, 2031, 3021, 0321, 2301, 3201, 3210, 2310, 1320, 3120, 2130, 1230.

40. By induction we find $\sigma(1,1) = (0\ 1)$, $\sigma(2,2) = (0\ 1\ 2)$,

$$\sigma(k,k) = \begin{cases} (0\ k)(k{-}1\ k{-}2\ \ldots\ 1), & \text{if } k \ge 3 \text{ is odd,} \\ (0\ k{-}1\ k{-}2\ 1\ \ldots\ k{-}3\ k), & \text{if } k \ge 4 \text{ is even;} \end{cases}$$

also $\omega(k) = (0\ k)$ when k is even, $\omega(k) = (0\ k{-}2\ \ldots\ 1\ k{-}1\ k)$ when $k \ge 3$ is odd. Thus when $k \ge 3$ is odd, $\sigma(k,1) = (k\ k{-}1\ 0)$ and $\sigma(k,j)$ takes $k \mapsto j-1$ for $1 < j < k$; when $k \ge 4$ is even, $\sigma(k,j) = (0\ k\ k{-}3\ \ldots\ 1\ k{-}2\ k{-}1)^j$ for $1 \le j \le k$.

Notes: The first scheme that causes Algorithm G to generate all permutations by single transpositions was devised by Mark Wells [*Math. Comp.* **15** (1961), 192–195], but it was considerably more complicated. W. Lipski, Jr., studied such schemes in general and found a variety of additional methods [*Computing* **23** (1979), 357–365].

41. We may assume that $r < n$. Algorithm G will generate r-variations for any Sims table if we simply change '$k \leftarrow 1$' to '$k \leftarrow n - r$' in step G3, provided that we redefine $\omega(k)$ to be $\sigma(n-r, n-r)\ldots\sigma(k,k)$ instead of using (16).

If $n-r$ is odd, the method of (27) is still valid, although the formulas in answer 40 need to be revised when $k < n-r+2$. The new formulas are $\sigma(k,j) = (k\ j{-}1\ \ldots\ 1\ 0)$ and $\omega(k) = (k\ \ldots\ 1\ 0)$ when $k = n-r$; $\sigma(k,j) = (k\ \ldots\ 1\ 0)^j$ when $k = n-r+1$.

If $n-r$ is even, we can use (27) with even and odd reversed, if $r \le 3$. But when $r \ge 4$ a more complex scheme is needed, because a fixed transposition like $(k\ 0)$ can be used for odd k only if $\omega(k-1)$ is a k-cycle, which means that $\omega(k-1)$ must be an even permutation; but $\omega(k)$ is odd for $k \ge n-r+2$.

The following scheme works when $n-r$ is even: Let $\tau(k,j) = (k\ k{-}j)$ for $1 \le j \le k = n-r$, and use (27) when $k > n-r$. Then, when $k = n-r+1$, we have $\omega(k-1) = (0\ 1\ \ldots\ k{-}1)$, hence $\sigma(k,j)$ takes $k \mapsto (2j-1) \bmod k$ for $1 \le j \le k$, and $\sigma(k,k) = (k\ k{-}1\ k{-}3\ \ldots\ 0\ k{-}2\ \ldots\ 1)$, $\omega(k) = (k\ \ldots\ 1\ 0)$, $\sigma(k{+}1, j) = (k{+}1\ \ldots\ 0)^j$.

42. If $\sigma(k,j) = (k\ j{-}1)$ we have $\tau(k,1) = (k\ 0)$ and $\tau(k,j) = (k\ j{-}1)(k\ j{-}2) = (k\ j{-}1\ j{-}2)$ for $2 \le j \le k$.

43. Of course $\omega(1) = \sigma(1,1) = \tau(1,1) = (0\ 1)$. The following construction makes $\omega(k) = (k{-}2\ k{-}1\ k)$ for all $k \ge 2$: Let $\alpha(k,j) = \tau(k,j)\omega(k-1)^-$, where $\alpha(2,1) = (2\ 0)$, $\alpha(2,2) = (2\ 0\ 1)$, $\alpha(3,1) = \alpha(3,3) = (3\ 1)$, $\alpha(3,2) = (3\ 1\ 0)$; this makes $\sigma(2,2) = (0\ 2)$, $\sigma(3,3) = (0\ 3\ 1)$. Then for $k \ge 4$, let

	$k \bmod 3 = 0$		$k \bmod 3 = 1$		$k \bmod 3 = 2$
$\alpha(k,k{-}2)$	$(k\ k{-}2\ 0)$	or	$(k\ k{-}3\ 0)$	or	$(k\ k{-}1\ 0)$,
$\alpha(k,k{-}1)$	$(k\ k{-}2\ k{-}3)$	or	$(k\ k{-}3)$	or	$(k\ k{-}1\ k{-}3)$,
$\alpha(k,k)$	$(k\ k{-}2)$	or	$(k\ k{-}3\ k{-}2)$	or	$(k\ k{-}2)$;

this makes $\sigma(k,k) = (k{-}3\ k\ k{-}2)$ as required.

44. No, because $\tau(k,j)$ is a $(k+1)$-cycle, not a transposition. (See (19) and (24).)

45. (a) 202280070, since $u_k = \max\big(\{0, 1, \ldots, a_k - 1\} \setminus \{a_1, \ldots, a_{k-1}\}\big)$. (Actually u_n is never set by the algorithm, but we can assume that it is zero.) (b) 425368917.

46. True (assuming that $u_n = 0$). If either $u_k > u_{k+1}$ or $a_k > a_{k+1}$ we must have $a_k > u_k \ge a_{k+1} > u_{k+1}$.

47. Steps $(\text{X1}, \text{X2}, \ldots, \text{X6})$ are performed respectively $(1, A, B, A-1, B-N_n, A)$ times, where $A = N_0 + \cdots + N_{n-1}$ and $B = nN_0 + (n-1)N_1 + \cdots + 1N_{n-1}$.

48. Steps $(\text{X2}, \text{X3}, \text{X4}, \text{X5}, \text{X6})$ are performed respectively $A_n + (1, n!, 0, 0, 1)$ times, where $A_n = \sum_{k=1}^{n-1} n^{\underline{k}} = n! \sum_{k=1}^{n-1} 1/k! \approx n!\,(e-1)$. Assuming that they cost respectively $(1, 1, 3, 1, 3)$ mems, for operations involving a_j, l_j, or u_j, the total cost is about $9e - 8 \approx 16.46$ mems per permutation.

Algorithm L uses approximately $(e, 2 + e/2, 2e + 2e^{-1} - 4)$ mems per permutation in steps $(\text{L2}, \text{L3}, \text{L4})$, for a total of $3.5e + 2e^{-1} - 2 \approx 8.25$ (see exercise 5).

Algorithm X could be tuned up for this case by streamlining the code when k is near n. But so can Algorithm L, as shown in exercise 1.

49. Order the signatures so that $|s_0| \geq \cdots \geq |s_9|$; also prepare tables $w_0 \ldots w_9$, $x_0 \ldots x_9$, $y_0 \ldots y_9$, so that the signatures $\{s_k, \ldots, s_9\}$ are $w_{x_k} \leq \cdots \leq w_{y_k}$. For example, when SEND + MORE = MONEY we have $(s_0, \ldots, s_9) = (-9000, 1000, -900, 91, -90, 10, 1, -1, 0, 0)$ for the respective letters (M, S, O, E, N, R, D, Y, A, B); also $(w_0, \ldots, w_9) = (-9000, -900, -90, -1, 0, 0, 1, 10, 91, 1000)$ and $x_0 \ldots x_9 = 01122333344$, $y_0 \ldots y_9 = 9988776554$. Yet another table $f_0 \ldots f_9$ has $f_j = 1$ if the digit corresponding to w_j cannot be zero; in this case $f_0 \ldots f_9 = 1000000001$. These tables make it easy to compute the largest and smallest values of

$$s_k a_k + \cdots + s_9 a_9$$

over all choices $a_k \ldots a_9$ of the remaining digits, using the method of exercise 25, since the links l_j tell us those digits in increasing order.

This method requires a rather expensive computation at each node of the search tree, but it often succeeds in keeping that tree small. For example, it solves the first eight alphametics of exercise 24 with costs of only 7, 13, 7, 9, 5, 343, 44, and 89 kilomems; this is a substantial improvement in cases (a), (b), (e), and (h), although case (f) comes out significantly worse. Another bad case is the 'CHILD' example of answer 27, where left-to-right needs 2947 kilomems compared to 588 for the right-to-left approach. Left-to-right does, however, fare better on BLOOD + SWEAT + TEARS (73 versus 360) and HELLO + WORLD (340 versus 410).

50. If α is in a permutation group, so are all its powers α^2, α^3, ..., including $\alpha^{m-1} = \alpha^-$, where m is the order of α (the least common multiple of its cycle lengths). And (32) is equivalent to $\alpha^- = \sigma_1 \sigma_2 \ldots \sigma_{n-1}$.

51. False. For example, $\sigma(k,i)^-$ and $\sigma(k,j)^-$ might both take $k \mapsto 0$.

52. $\tau(k,j) = (k{-}j\ k{-}j{+}1)$ is an adjacent interchange, and

$$\omega(k) = (n{-}1\ \ldots\ 0)(n{-}2\ \ldots\ 0)\ldots(k\ \ldots\ 0) = \phi(n-1)\phi(k-1)$$

is a k-flip followed by an n-flip. The permutation corresponding to control table $c_0 \ldots c_{n-1}$ in Algorithm H has c_j elements to the right of j that are less than j, for $0 \leq j < n$; so it is the same as the permutation corresponding to $c_1 \ldots c_n$ in Algorithm P, except that subscripts are shifted by 1.

The only essential difference between Algorithm P and this version of Algorithm H is that Algorithm P uses a reflected Gray code to run through all possibilities of its control table, while Algorithm H runs through those mixed-radix numbers in ascending (lexicographic) order.

Indeed, Gray code can be used with any Sims table, by modifying either Algorithm G or Algorithm H. Then all transitions are by $\tau(k,j)$ or by $\tau(k,j)^-$, and the permutations $\omega(k)$ are irrelevant.

53. The text's proof that $n! - 1$ transpositions cannot be achieved for $n = 4$ also shows that we can reduce the problem from n to $n-2$ at the cost of a single transposition $(n{-}1\ n{-}2)$, which was called '$(3\,c)$' in the notation of that proof.

Thus we can generate all permutations by making the following transformation in step H4: If $k = n-1$ or $k = n-2$, transpose $a_{j \bmod n} \leftrightarrow a_{(j-1) \bmod n}$, where $j = c_{n-1} - 1$. If $k = n-3$ or $k = n-4$, transpose $a_{n-1} \leftrightarrow a_{n-2}$ and also $a_{j \bmod (n-2)} \leftrightarrow a_{(j-1) \bmod (n-2)}$, where $j = c_{n-3} - 1$. And in general if $k = n-2t-1$ or $k = n-2t-2$, transpose $a_{n-2i+1} \leftrightarrow a_{n-2i}$ for $1 \leq i \leq t$ and also $a_{j \bmod (n-2t)} \leftrightarrow a_{(j-1) \bmod (n-2t)}$, where $j = c_{n-2t-1} - 1$. [See *CACM* **19** (1976), 68–72.]

The corresponding Sims table permutations can be written down as follows, although they don't appear explicitly in the algorithm itself:

$$\sigma(k,j)^- = \begin{cases} (0\ 1\ \ldots\ j{-}1\ k), & \text{if } n-k \text{ is odd;} \\ (0\ 1\ \ldots\ k)^j, & \text{if } n-k \text{ is even.} \end{cases}$$

The value of $a_{j \bmod (n-2t)}$ will be $n-2t-1$ after the interchange. For efficiency we can also use the fact that k usually equals $n-1$. The total number of transpositions is $\sum_{t=0}^{\lfloor n/2 \rfloor}(n-2t)! - \lfloor n/2 \rfloor - 1$.

54. Yes; the transformation can be any k-cycle on positions $\{1,\ldots,k\}$.

55. (a) Since $\rho_!(m) = \rho_!(m \bmod n!)$ when $n > \rho_!(m)$, we have $\rho_!(n!+m) = \rho_!(m)$ for $0 < m < n\cdot n! = (n+1)! - n!$. Therefore $\beta_{n!+m} = \sigma_{\rho_!(n!+m)}\ldots\sigma_{\rho_!(n!+1)}\beta_{n!} = \sigma_{\rho_!(m)}\ldots\sigma_{\rho_!(1)}\beta_{n!} = \beta_m\beta_{n!}$ for $0 \le m < n\cdot n!$, and we have in particular

$$\beta_{(n+1)!} = \sigma_{n+1}\beta_{(n+1)!-1} = \sigma_{n+1}\beta_{n!-1}\beta_{n!}^n = \sigma_{n+1}\sigma_n^-\beta_{n!}^{n+1}.$$

Similarly $\alpha_{n!+m} = \beta_{n!}^-\alpha_m\beta_{n!}\alpha_{n!}$ for $0 \le m < n\cdot n!$.

Since $\beta_{n!}$ commutes with τ_n and τ_{n+1} we find $\alpha_{n!} = \tau_n\alpha_{n!-1}$, and

$$\begin{aligned} \alpha_{(n+1)!} = \tau_{n+1}\alpha_{(n+1)!-1} &= \tau_{n+1}\beta_{n!}^-\alpha_{(n+1)!-1-n}\beta_{n!}\alpha_{n!} \\ &= \cdots \\ &= \tau_{n+1}\beta_{n!}^{-n}\alpha_{n!-1}(\beta_{n!}\alpha_{n!})^n \\ &= \beta_{n!}^{-n-1}\tau_{n+1}\tau_n^-(\beta_{n!}\alpha_{n!})^{n+1} \\ &= \beta_{(n+1)!}^-\sigma_{n+1}\sigma_n^-\tau_{n+1}\tau_n^-(\beta_{n!}\alpha_{n!})^{n+1}. \end{aligned}$$

(b) In this case $\sigma_{n+1}\sigma_n^- = (n\ n{-}1\ \ldots\ 1)$ and $\tau_{n+1}\tau_n^- = (n{+}1\ n\ 0)$, and we have $\beta_{(n+1)!}\alpha_{(n+1)!} = (n{+}1\ n\ \ldots\ 0)$ by induction. Therefore $\alpha_{jn!+m} = \beta_{n!}^{-j}\alpha_m(n\ \ldots\ 0)^j$ for $0 \le j \le n$ and $0 \le m < n!$. All permutations of $\{0,\ldots,n\}$ are achieved because $\beta_{n!}^{-j}\alpha_m$ fixes n and $(n\ \ldots\ 0)^j$ takes $n \mapsto n-j$.

56. If we set $\sigma_k = (k{-}1\ k{-}2)(k{-}3\ k{-}4)\ldots$ in the previous exercise, we find by induction that $\beta_{n!}\alpha_{n!}$ is the $(n+1)$-cycle $(0\ n\ n{-}1\ n{-}3\ \ldots$ (2 or 1) (1 or 2) $\ldots\ n{-}4\ n{-}2)$.

57. Arguing as in answer 5, we obtain $\sum_{k=2}^{n-1}[k\ \text{odd}]/k! - (\lfloor n/2 \rfloor - 1)/n! = \sinh 1 - 1 - O(1/(n-1)!)$.

58. True. By the formulas of exercise 55 we have $\alpha_{n!-1} = (0\ n)\beta_{n!}^-(n\ \ldots\ 0)$, and this takes $0 \mapsto n-1$ because $\beta_{n!}$ fixes n. (Consequently Algorithm E will define a Hamiltonian *circuit* on the graph of exercise 66 if and only if $\beta_{n!} = (n{-}1\ \ldots\ 2\ 1)$, and this holds if and only if the length of every cycle of $\beta_{(n-1)!}$ is a divisor of n. The latter is true for $n = 2$, 3, 4, 6, 12, 20, and 40, but for no other $n \le 250{,}000$.)

59. The Cayley graph with generators $(\alpha_1,\ldots,\alpha_k)$ in the text's definition is isomorphic to the Cayley graph with generators $(\alpha_1^-,\ldots,\alpha_k^-)$ in the alternative definition, since $\pi \to \alpha_j\pi$ in the former if and only if $\pi^- \to \pi^-\alpha_j^-$ in the latter.

60. There are 88 delta sequences, which reduce to four classes: $P = (32131231)^3$ (plain changes, represented by 8 different delta sequences); $Q = (32121232)^3$ (a doubly Gray variant of plain changes, with 8 representatives); $R = (121232321232)^2$ (a doubly Gray code with 24 representatives); $S = 2\alpha3\alpha^R$, $\alpha = 12321312121$ (48 representatives). Classes P and Q are cyclic shifts of their complements; classes P, Q, and S are shifts of their reversals; class R is a shifted reversal of its complement. [See A. L. Leigh Silver, *Math. Gazette* **48** (1964), 1–16.]

61. There are respectively $(26, 36, 20, 26, 28, 40, 40, 20, 26, 28, 28, 26)$ such paths ending at $(1243, 1324, 1432, 2134, 2341, 2413, 3142, 3214, 3421, 4123, 4231, 4312)$.

62. There are only two paths when $n = 3$, ending respectively at 132 and 213. But when $n \geq 4$ there are Gray paths leading from $12\ldots n$ to any odd permutation $a_1a_2\ldots a_n$. Exercise 61 establishes this when $n = 4$, and we can prove it by induction for $n > 4$ as follows.

Let $A(j)$ be the set of all permutations that begin with j, and let $A(j,k)$ be those that begin with jk. If $(\alpha_0, \alpha_1, \ldots, \alpha_n)$ are any odd permutations such that $\alpha_j \in A(x_j, x_{j+1})$, then $(1\,2)\,\alpha_j$ is an even permutation in $A(x_{j+1}, x_j)$. Consequently, if $x_1x_2\ldots x_n$ is a permutation of $\{1, 2, \ldots, n\}$, there is at least one Hamiltonian path of the form

$$(1\,2)\,\alpha_0 \mathrel{—} \cdots \mathrel{—} \alpha_1 \mathrel{—} (1\,2)\,\alpha_1 \mathrel{—} \cdots \mathrel{—} \alpha_2 \mathrel{—} \cdots \mathrel{—} (1\,2)\,\alpha_{n-1} \mathrel{—} \cdots \mathrel{—} \alpha_n;$$

the subpath from $(1\,2)\,\alpha_{j-1}$ to α_j includes all elements of $A(x_j)$.

This construction solves the problem in at least $(n-2)!^n/2^{n-1}$ distinct ways when $a_1 \neq 1$, because we can take $\alpha_0 = 2\,1\ldots n$ and $\alpha_n = a_1a_2\ldots a_n$; there are $(n-2)!$ ways to choose $x_2\ldots x_{n-1}$, and $(n-2)!/2$ ways to choose each of $\alpha_1, \ldots, \alpha_{n-1}$.

Finally, if $a_1 = 1$, take any path $12\ldots n \mathrel{—} \cdots \mathrel{—} a_1a_2\ldots a_n$ that runs through all of $A(1)$, and choose any step $\alpha \mathrel{—} \alpha'$ with $\alpha \in A(1,j)$ and $\alpha' \in A(1,j')$ for some $j \neq j'$. Replace that step by

$$\alpha \mathrel{—} (1\,2)\,\alpha_1 \mathrel{—} \cdots \mathrel{—} \alpha_2 \mathrel{—} \cdots \mathrel{—} (1\,2)\,\alpha_{n-1} \mathrel{—} \cdots \mathrel{—} \alpha_n \mathrel{—} \alpha',$$

using a construction like the Hamiltonian path above but now with $\alpha_1 = \alpha$, $\alpha_n = (1\,2)\,\alpha'$, $x_1 = 1$, $x_2 = j$, $x_n = j'$, and $x_{n+1} = 1$. (In this case the permutations α_1, $\ldots$, α_n might all be even.)

63. Monte Carlo estimates using the techniques of Section 7.2.3 suggest that the total number of equivalence classes will be roughly 1.2×10^{21}; most of those classes will contain 480 Gray codes.

64. Exactly 2,005,200 delta sequences have the doubly Gray property; they belong to 4206 equivalence classes under cyclic shift, reversal, and/or complementation. Nine classes, such as the code $2\alpha2\alpha^R$ where

$$\alpha = 123432343212321212323212321212343432121234321234321212323 21,$$

are shifts of their reversal; 48 classes are composed of repeated 60-cycles. One of the most interesting of the latter type is $\alpha\alpha$ where

$$\alpha = \beta2\beta4\beta4\beta4\beta4, \qquad \beta = 32121232123.$$

65. Such a path exists for any given $N \leq n!$: Let the Nth permutation be $\alpha = a_1\ldots a_n$, and let $j = a_1$. Also let Π_k be the set of all permutations $\beta = b_1\ldots b_n$ for which $b_1 = k$ and $\beta \leq \alpha$. By induction on N there is a Gray path P_1 for Π_j. We can then construct Gray paths P_k for $\Pi_j \cup \Pi_1 \cup \cdots \cup \Pi_{k-1}$ for $2 \leq k \leq j$, successively combining P_{k-1} with a Gray code for Π_{k-1}. (See the "absorption" construction of answer 62. In fact, P_j will be a Gray *code* when N is a multiple of 6.)

66. Defining the delta sequence by the rule $\pi_{(k+1) \bmod n!} = (1\,\delta_k)\,\pi_k$, we find exactly 36 such sequences, all of which are cyclic shifts of a pattern like $(xyzyzyxzyzyz)^2$. (The next case, $n = 5$, probably has about 10^{18} solutions that are inequivalent with respect to cyclic shifting, reversal, and permutation of coordinates, thus about 6×10^{21} different

delta sequences.) Incidentally, Igor Pak has shown that the Cayley graph generated by star transpositions is an $(n-2)$-dimensional torus in general.

67. If we let π be equivalent to $\pi(12345)$, we get a reduced graph on 24 vertices that has 40768 Hamiltonian circuits, 240 of which lead to delta sequences of the form α^5 in which α uses each transposition 6 times (for example, $\alpha = 354232534234532454352452$). The total number of solutions to this problem is probably about 10^{16}.

68. If A isn't connected, neither is G. If A is connected, we can assume that it is a free tree. Moreover, in this case we can prove a generalization of the result in exercise 62: For $n \geq 4$ there is a Hamiltonian path in G from the identity permutation to any odd permutation. For we can assume without loss of generality that A contains the edge $1 \mathrel{—} 2$ where 1 is a leaf of the tree, and a proof like that of exercise 62 applies.

[This elegant construction is due to M. Tchuente, *Ars Combinatoria* **14** (1982), 115–122. Extensive generalizations have been discussed by Ruskey and Savage in *SIAM J. Discrete Math.* **6** (1993), 152–166. See also the original Russian publication in *Kibernetika* **11**, 3 (1975), 17–25; English translation, *Cybernetics* **11** (1975), 362–366.]

69. Following the hint, the modified algorithm behaves like this when $n = 5$:

$\underset{\downarrow}{12\underset{}{34}}$	$\underset{\uparrow}{12\underset{}{43}}$	$\underset{\downarrow}{1\underset{}{423}}$	$\underset{\uparrow}{41\underset{}{23}}$	$\underset{\downarrow}{4\underset{}{132}}$	$\underset{\uparrow}{14\underset{}{32}}$	$\underset{\downarrow}{13\underset{}{42}}$	$\underset{\uparrow}{1\underset{}{324}}$	$\underset{\downarrow}{31\underset{}{24}}$	$\underset{\uparrow}{3\underset{}{142}}$	$\underset{\downarrow}{34\underset{}{12}}$	$\underset{\uparrow}{4312}$

$\downarrow$	$\uparrow$	$\downarrow$	$\uparrow$	$\downarrow$	$\uparrow$	$\downarrow$	$\uparrow$	$\downarrow$	$\uparrow$	$\downarrow$	$\uparrow$

Here the columns represent sets of permutations that are cyclically rotated and/or reflected in all $2n$ ways; therefore each column contains exactly one "rosary permutation" (exercise 18). We can use Algorithm P to run through the rosary permutations systematically, knowing that the pair xy will occur before yx in its column, at which time τ' instead of ρ' will move us to the right or to the left. Step Z2 omits the interchange $a_1 \leftrightarrow a_2$, thereby causing the permutations $a_1 \ldots a_{n-1}$ to repeat themselves going backwards. (We implicitly use the fact that $t[k] = t[n! - k]$ in the output of Algorithm T.)

Now if we replace $1 \ldots n$ by $24 \ldots 31$ and change $A_1 \ldots A_n$ to $A_1 A_n A_2 A_{n-1} \ldots$, we get the unmodified algorithm whose results are shown in Fig. 22(b).

This method was inspired by a (nonconstructive) theorem of E. S. Rapoport, *Scripta Math.* **24** (1959), 51–58. It illustrates a more general fact observed by Carla Savage in 1989, namely that the Cayley graph for *any* group generated by three involutions ρ, σ, τ has a Hamiltonian circuit when $\rho\tau = \tau\rho$ [see I. Pak and R. Radoičić, "Hamiltonian expanders," to appear.]

70. No; the longest cycle in that digraph has length 358. But there do exist pairs of disjoint 180-cycles from which a Hamiltonian path of length 720 can be derived. For

example, consider the cycles $\alpha\sigma\beta\sigma$ and $\gamma\sigma\sigma$ where

$$\alpha = \tau\sigma^5\tau\sigma^5\tau\sigma^3\tau\sigma^2\tau\sigma^5\tau\sigma^3\tau\sigma^2\tau\sigma^5\tau\sigma^5\tau\sigma^2\tau\sigma^3\tau\sigma^1\tau\sigma^5\tau\sigma^5\tau\sigma^5\tau\sigma^3\tau\sigma^1\tau\sigma^1\tau\sigma^3\tau\sigma^2\tau\sigma^1\tau\sigma^1;$$
$$\beta = \sigma^3\tau\sigma^5\tau\sigma^2\tau\sigma^2\tau\sigma^5\tau\sigma^2\tau\sigma^3\tau\sigma^1\tau\sigma^1\tau\sigma^5\tau\sigma^1\tau\sigma^3\tau\sigma^5\tau\sigma^5\tau\sigma^3\tau\sigma^2\tau\sigma^1\tau\sigma^2\tau\sigma^3\tau\sigma^1\tau\sigma^1\tau\sigma^3\tau\sigma^2\tau\sigma^4;$$
$$\gamma = \sigma\tau\sigma^5\tau\sigma^5\tau\sigma^3\tau\sigma^1\tau\sigma^1\tau\sigma^3\tau\sigma^2\tau\sigma^5\tau\sigma^2\tau\sigma^3\tau\sigma^5\tau\sigma^1\tau\sigma^5\tau\sigma^3\tau\sigma^2\tau\sigma^1\tau\sigma^2\tau\sigma^3\tau\sigma^1\tau\sigma^1\tau\sigma^3\tau\sigma^2$$
$$\tau\sigma^5\tau\sigma^5\tau\sigma^5\tau\sigma^3\tau\sigma^5\tau\sigma^2\tau\sigma^5\tau\sigma^2\tau\sigma^3\tau\sigma^1\tau\sigma^1\tau\sigma^5\tau\sigma^1\tau\sigma^3\tau\sigma^3\tau\sigma^5\tau\sigma^5\tau\sigma^1\tau\sigma^5\tau\sigma^2\tau\sigma^3\tau\sigma^1\tau\sigma^2.$$

If we start with 134526 and follow $\alpha\sigma\beta\tau$ we reach 163452; then follow $\gamma\sigma\tau$ and reach 126345; then follow $\sigma\gamma\tau$ and reach 152634; then follow $\beta\sigma\alpha$, ending at 415263.

71. Any Hamiltonian path includes $(n-1)!$ vertices that take $y \mapsto x$, each of which (if not the last) is followed by a vertex that takes $x \mapsto x$. So one must be last; otherwise $(n-1)!+1$ vertices would take $x \mapsto x$.

72. (a) Assume first that β is the identity permutation $()$. Then every cycle of α that contains an element of A lies entirely within A. Hence the cycles of σ are obtained by omitting all cycles of α that contain no element of A. All remaining cycles have odd length, so σ is an even permutation.

If β is not the identity, we apply this argument to $\alpha' = \alpha\beta^-$, $\beta' = ()$, and $\sigma' = \sigma\beta^-$, concluding that σ' is an even permutation; thus σ and β have the same sign.

Similarly, σ and α have the same sign, because $\beta\alpha^- = (\alpha\beta^-)^-$ has the same order as $\alpha\beta^-$.

(b) Let X be the vertices of the Cayley graph in Theorem R, and let α be the permutation of X that takes a vertex π into $\alpha\pi$; this permutation has g/a cycles of length a. Define the permutation β similarly. Then $\alpha\beta^-$ has g/c cycles of length c. If c is odd, any Hamiltonian circuit in the graph defines a cycle σ that contains all the vertices and satisfies the hypotheses of (a). Therefore α and β have an odd number of cycles, because the sign of a permutation on n elements with r cycles is $(-1)^{n-r}$ (see exercise 5.2.2–2).

[This proof, which shows that X cannot be the union of any odd number of cycles, was presented by Rankin in *Proc. Cambridge Phil. Soc.* **62** (1966), 15–16.]

73. The representation $\beta^j\gamma^k$ is unique if we require $0 \le j < g/c$ and $0 \le k < c$. For if we had $\beta^j = \gamma^k$ for some j with $0 < j < g/c$, the group would have at most jc elements. It follows that $\beta^{g/c} = \gamma^t$ for some t.

Let σ be a Hamiltonian circuit, as in the previous answer. If $x\sigma = x\alpha$ then $x\gamma\sigma$ must be $x\gamma\alpha$, because $x\gamma\beta = \alpha$. And if $x\sigma = x\beta$ then $x\gamma\sigma$ cannot be $x\gamma\alpha$, because that would imply $x\gamma^c\sigma = x\gamma^c\alpha$. Thus the elements $x\gamma^k$ all have equivalent behavior with respect to their successors in σ.

Notice that if $j \ge 0$ there is a $k \le j$ such that $x\sigma^j = x\alpha^k\beta^{j-k} = x\beta^j\gamma^k$. Therefore $x\sigma^{g/c} = x\gamma^{t+k}$ is equivalent to x, and the same behavior will repeat. We return to x for the first time in g steps if and only if $t+k$ is relatively prime to c.

74. Apply the previous exercise with $g = mn$, $a = m$, $b = n$, $c = mn/d$. The number t satisfies $t \equiv 0$ (modulo m), $t + d \equiv 0$ (modulo n); and it follows that $k + t \perp c$ if and only if $(d-k)m/d \perp kn/d$.

Notes: The modular Gray path of exercise 7.2.1.1–78 is a Hamiltonian path from $(0,0)$ to $\big(m-1, (-m) \bmod n\big)$, so it is a Hamiltonian circuit if and only if m is a multiple of n. It is natural to conjecture (falsely) that at least one Hamiltonian circuit exists whenever $d > 1$. But P. Erdős and W. T. Trotter have observed [*J. Graph Theory* **2** (1978), 137–142] that if p and $2p+1$ are odd prime numbers, no suitable k exists when $m = p(2p+1)(3p+1)$ and $n = (3p+1)\prod_{q=1}^{3p} q^{[q \text{ is prime}][q \ne p][q \ne 2p+1]}$.

See J. A. Gallian, *Mathematical Intelligencer* **13**, 3 (Summer 1991), 40–43, for interesting facts about other kinds of cycles in $C_m \times C_n$.

75. We may assume that the tour begins in the lower left corner. There are no solutions when m and n are both divisible by 3, because 2/3 of the cells are unreachable in that case. Otherwise, letting $d = \gcd(m, n)$ and arguing as in the previous exercise but with $(x, y)\alpha = ((x+2) \bmod m, (y+1) \bmod n)$ and $(x, y)\beta = ((x+1) \bmod m, (y+2) \bmod n)$, we find the answer

$$\sum_{k=1}^{d-1} \binom{d}{k} \big[\gcd\big((2d-k)\,m, (k+d)\,n\big) = d \text{ or } \big(mn \perp 3 \text{ and } \gcd\big((2d-k)\,m, (k+d)\,n\big) = 3d\big)\big].$$

76.

77. Lines 31–38 become $2r-1$ instructions, lines 61–63 become r, and lines 56–58 become $3+(r-2)[r \text{ even}]$ instructions (see $\omega(r-1)$ in answer 40). The total running time is therefore $\big((2r!+2)A+2B+r-5\big)\mu+\big((2r!+2r+7+(r-2)[r \text{ even}])A+7B-r-4\big)\upsilon$, where $A=n!/r!$ and $B=n!(1/r!+\cdots+1/n!)$.

78. `SLU u,[#f],t; SLU t,a,4; XOR t,t,a; AND t,t,u; SRU u,t,4; OR t,t,u; XOR a,a,t`; here, as in the answer to exercise 1.3.1′–34, the notation '`[#f]`' denotes a register that contains the constant value `#f`.

79. `SLU u,a,t; MXOR u,[#8844221188442211],u; AND u,u,[#ff000000]; SRU u,u,t; XOR a,a,u`. This cheats, since it transforms `#12345678` to `#13245678` when $t=4$, but (45) still works.

Even faster and trickier would be a routine analogous to (42): Consider

```
PUSHJ 0,Visit; MXOR a,a,c1; PUSHJ 0,Visit; ... MXOR a,a,c5; PUSHJ 0,Visit
```

where `c1`, ..., `c5` are constants that would cause `#12345678` to become successively `#12783456`, `#12567834`, `#12563478`, `#12785634`, `#12347856`. Other instructions, executed only 1/6 or 1/24 as often, can take care of shuffling nybbles within and between bytes. Very clever, but it doesn't beat (46) in view of the `PUSHJ/POP` overhead.

80.
```
t  IS   $255 ;k IS $0 ;kk IS $1 ;c IS $2 ;d IS $3
   SET  k,1      k ← 1.
3H SRU  d,a,60   d ← leftmost nybble.
   SLU  a,a,4    a ← 16a mod 16^16.
   CMP  c,d,k
   SLU  kk,k,2
   SLU  d,d,kk
   OR   t,t,d    t ← t + 16^k d.
   PBNZ c,1B     Return to main loop if d ≠ k.
   INCL k,1      k ← k + 1.
   PBNZ a,3B     Return to second loop if k < n.   ∎
```

81. $\mu+\big(5n!+11A-(n-1)!+6\big)\upsilon=\big((5+10/n)\upsilon+O(n^{-2})\big)n!$, plus the visiting time, where $A=\sum_{k=1}^{n-1}k!$ is the number of times the loop at `3H` is used.

82. With suitable initialization and a 13-octabyte table, only about a dozen `MMIX` instructions are needed:

```
magic  GREG #8844221188442211
0H     ⟨Visit register a⟩
       PBN  c,Sigma
Tau    MXOR t,magic,a; ANDNL t,#ffff; JMP 1F
Sigma  SRU  t,a,20; SLU a,a,4; ANDNML a,#f00
1H     XOR  a,a,t; SLU c,c,1
2H     PBNZ c,0B; INCL p,8
3H     LDOU c,p,0; PBNZ c,0B                    ∎
```

83. Assuming that the processors all have essentially the same speed, we can let the kth processor generate all permutations of rank r for $(k-1)n!/p \le r < kn!/p$, using any method based on control tables $c_1 \ldots c_n$. The starting and ending control tables are easily computed by converting their ranks to mixed-radix notation.

84. We can use a technique like that of Algorithm 3.4.2P: To compute $k = r(\alpha)$, first set $a'_{a_j} \leftarrow j$ for $1 \le j \le n$ (the inverse permutation). Then set $k \leftarrow 0$, and for $j = n$, $n-1$, ..., 2 (in this order) set $t \leftarrow a'_j$, $k \leftarrow kj + t - 1$, $a_t \leftarrow a_j$, $a'_{a_j} \leftarrow t$. To compute $r^{[-1]}(k)$, start with $a_1 \leftarrow 1$. Then for $j = 2$, ..., $n-1$, n (in this order) set $t \leftarrow (k \bmod j) + 1$, $a_j \leftarrow a_t$, $a_t \leftarrow j$, $k \leftarrow \lfloor k/j \rfloor$. [See S. Pleszczyński, *Inf. Proc. Letters* **3** (1975), 180–183; W. Myrvold and F. Ruskey, *Inf. Proc. Letters* **79** (2001), 281–284.]

85. If $x \prec y$ and $y \prec z$, the algorithm will never move y to the left of x, nor z to the left of y, so it will never test x versus z.

86. They appear in lexicographic order; Algorithm P used a reflected Gray order.

87. Generate inverse permutations with $a'_0 < a'_1 < a'_2$, $a'_3 < a'_4 < a'_5$, $a'_6 < a'_7$, $a'_8 < a'_9$, $a'_0 < a'_3$, $a'_6 < a'_8$.

88. (a) Let $d_k = \max\{j \mid 0 \le j \le k \text{ and } j \text{ is nontrivial}\}$, where 0 is considered nontrivial. This table is easily precomputed, because j is trivial if and only if it must follow $\{1, \ldots, j-1\}$. Set $k \leftarrow d_n$ in step V2 and $k \leftarrow d_{k-1}$ in step V5.

(b) Now $M = \sum_{j=1}^{n} t_j\,[j \text{ is nontrivial}]$.

(c) There are at least two topological sorts $a_j \ldots a_k$ of the set $\{j, \ldots, k\}$, and either of them can be placed after any topological sort $a_1 \ldots a_{j-1}$ of $\{1, \ldots, j-1\}$.

(d) Algorithm 2.2.3T repeatedly outputs minimal elements (elements with no predecessors), removing them from the relation graph. We use it in reverse, repeatedly removing and giving the highest labels to *maximal* elements (elements with no successors). If only one maximal element exists, it is trivial. If j and k are both maximal, they both are output before any element x with $x \prec j$ or $x \prec k$, because steps T5 and T7 keep maximal elements in a queue (not a stack). Thus if k is nontrivial and output first, the next nontrivial element will not be output before j; and k is unrelated to j.

(e) Let the nontrivial t's be $s_1 < s_2 < \cdots < s_r = N$. Then we have $s_j \ge 2s_{j-2}$, by (c). Consequently $M = s_1 + \cdots + s_r \le s_r(1 + \frac{1}{2} + \frac{1}{4} + \cdots) + s_{r-1}(1 + \frac{1}{2} + \frac{1}{4} + \cdots) < 4s_r$. (A sharper estimate is probably possible, but exercise 89 shows that M can be larger than $2.6N$.)

89. The number N of such permutations is F_{n+1} by exercise 5.2.1–25. Therefore $M = F_{n+1} + \cdots + F_1 = F_{n+3} - 1 \approx \phi^2 N$. Notice incidentally that all such permutations satisfy $a_1 \ldots a_n = a'_1 \ldots a'_n$. They can be arranged in a Gray path (exercise 7.2.1.1–89).

90. Since $t_j = (j-1)(j-3)\ldots(2 \text{ or } 1)$, we find $M = \big(1 + 2/\sqrt{\pi n} + O(1/n)\big)N$.

Note: The inversion tables $c_1 \ldots c_n$ for permutations satisfying (49) are characterized by the conditions $c_1 = 0$, $0 \le c_{2k} \le c_{2k-1}$, $0 \le c_{2k+1} \le c_{2k-1} + 1$.

91. The total number of pairs (R, S), where R is a partial ordering and S is a linear ordering that includes R, is equal to P_n times the expected number of topological sorts; it is also Q_n times $n!$. So the answer is $n!\,Q_n/P_n$.

We will discuss the computation of P_n and Q_n in Section 7.2.3. For $1 \le n \le 12$ the expectation turns out to be approximately

$$(1,\ 1.33,\ 2.21,\ 4.38,\ 10.1,\ 26.7,\ 79.3,\ 262,\ 950,\ 3760,\ 16200,\ 74800).$$

Asymptotic values as $n \to \infty$ have been deduced by Brightwell, Prömel, and Steger [*J. Combinatorial Theory* **A73** (1996), 193–206], but the limiting behavior is quite different from what happens when n is in a practical range. The values of Q_n were first determined for $n \le 5$ by S. P. Avann [*Aequationes Math.* **8** (1972), 95–102].

92. The basic idea is to introduce dummy elements $n+1$ and $n+2$ with $j \prec n+1$ and $j \prec n+2$ for $1 \le j \le n$, and to find all topological sorts of such an extended relation via adjacent interchanges; then take every *second* permutation, suppressing the dummy elements. An algorithm similar to Algorithm V can be used, but with a recursion that reduces n to $n-2$ by inserting $n-1$ and n among $a_1 \ldots a_{n-2}$ in all possible ways, assuming that $n-1 \not\prec n$, occasionally swapping $n+1$ with $n+2$. [See G. Pruesse and F. Ruskey, *SICOMP* **23** (1994), 373–386. A loopless implementation has been described by Canfield and Williamson, *Order* **12** (1995), 57–75.]

93. The case $n = 3$ illustrates the general idea of a pattern that begins with $1 \ldots (2n)$ and ends with $1(2n)2(2n{-}1)\ldots n(n{+}1)$: 123456, 123546, 123645, 132645, 132546, 132456, 142356, 142536, 142635, 152634, 152436, 152346, 162345, 162435, 162534.

Matchings can also be regarded as involutions of $\{1, \ldots, 2n\}$ that have n cycles. With that representation this pattern involves two transpositions per step.

Notice that the C inversion tables of the permutations just listed are respectively 000000, 000100, 000200, 010200, 010100, 010000, 020000, 020100, 020200, 030200, 030100, 030000, 040000, 040100, 040200. In general, $C_1 = C_3 = \cdots = C_{2n-1} = 0$ and the n-tuples $(C_2, C_4, \ldots, C_{2n})$ run through a reflected Gray code on the radices $(2n-1, 2n-3, \ldots, 1)$. Thus the generation process can easily be made loopless if desired. [See Timothy Walsh, *J. Combinatorial Math. and Combinatorial Computing* **36** (2001), 95–118, Section 1.]

94. Generate inverse permutations with $a'_1 < a'_n > a'_2 < a'_{n-1} > \cdots$, using Algorithm V. (See exercise 5.1.4–23 for the number of solutions.)

95. For example, we can start with $a_1 \ldots a_{n-1}a_n = 2 \ldots n1$ and $b_1 b_2 \ldots b_n b_{n+1} = 12 \ldots n1$, and use Algorithm P to generate the $(n-1)!$ permutations $b_2 \ldots b_n$ of $\{2, \ldots, n\}$. Just after that algorithm swaps $b_i \leftrightarrow b_{i+1}$, we set $a_{b_{i-1}} \leftarrow b_i$, $a_{b_i} \leftarrow b_{i+1}$, $a_{b_{i+1}} \leftarrow b_{i+2}$, and visit $a_1 \ldots a_n$.

96. Use Algorithm X, with $t_k(a_1, \ldots, a_k) =$ '$a_k \ne k$'.

97. Using the notation of exercise 47, we have $N_k = \sum \binom{k}{j}(-1)^j (n-j)^{\underline{k-j}}$ by the method of inclusion and exclusion (exercise 1.3.3–26). If $k = O(\log n)$ then $N_{n-k} = (n!\,e^{-1}/k!)(1 + O(\log n)^2/n)$; hence $A/n! \approx (e-1)/e$ and $B/n! \approx 1$. The number of memory references, under the assumptions of answer 48, is therefore $\approx A + B + 3A + B - N_n + 3A \approx n!(9 - \frac{8}{e}) \approx 6.06\,n!$, about 16.5 per derangement. [See S. G. Akl, *BIT* **20** (1980), 2–7, for a similar method.]

98. Suppose L_n generates $D_n \cup D_{n-1}$, beginning with $(1\ 2\ \ldots\ n)$, then $(2\ 1\ \ldots\ n)$, and ending with $(1\ \ldots\ n{-}1)$; for example, $L_3 = (1\ 2\ 3), (2\ 1\ 3), (1\ 2)$. Then we can generate

D_{n+1} as K_{nn}, ..., K_{n2}, K_{n1}, where $K_{nk} = (1\ 2\ \ldots\ n)^{-k}(n\ n{+}1)L_n(1\ 2\ \ldots\ n)^k$; for example, D_4 is

$$(1\,2\,3\,4),\ (2\,1\,3\,4),\ (1\,2)(3\,4),\ (3\,1\,2\,4),\ (1\,3\,2\,4),\ (3\,1)(2\,4),\ (2\,3\,1\,4),\ (3\,2\,1\,4),\ (2\,3)(1\,4).$$

Notice that K_{nk} begins with the cycle $(k{+}1\ \ldots\ n\ 1\ \ldots\ k\ n{+}1)$ and ends with $(k{+}1\ \ldots\ n\ 1\ \ldots\ k{-}1)(k\ n{+}1)$; so premultiplication by $(k{-}1\ k)$ takes us from K_{nk} to $K_{n(k-1)}$. Also, premultiplication by $(1\ n)$ will return from the last element of D_{n+1} to the first. Premultiplication by $(1\ 2\ n{+}1)$ takes us from the last element of D_{n+1} to $(2\ 1\ 3\ \ldots\ n)$, from which we can return to $(1\ 2\ \ldots\ n)$ by following the cycle for D_n backwards, thereby completing the list L_{n+1} as desired.

99. Use Algorithm X, with $t_k(a_1, \ldots, a_k) =$ '$p > 0$ or $l[q] \neq k+1$'.

Notes: The number of indecomposable permutations is $[z^n]\left(1{-}1/\sum_{k=0}^{\infty} k!\,z^k\right)$; see L. Comtet, *Comptes Rendus Acad. Sci. Paris* **A275** (1972), 569–572. It appears likely that the indecomposable permutations can be generated by adjacent transpositions; for example, when $n = 4$ they are 3142, 3412, 3421, 3241, 2341, 2431, 4231, 4321, 4312, 4132, 4123, 4213, 2413.

100. Here is a lexicographic involution generator analogous to Algorithm X.

Y1. [Initialize.] Set $a_k \leftarrow k$ and $l_{k-1} \leftarrow k$ for $1 \le k \le n$. Then set $l_n \leftarrow 0$, $k \leftarrow 1$.

Y2. [Enter level k.] If $k > n$, visit $a_1 \ldots a_n$ and go to Y3. Otherwise set $p \leftarrow l_0$, $u_k \leftarrow p$, $l_0 \leftarrow l_p$, $k \leftarrow k+1$, and repeat this step. (We have decided to let $a_p = p$.)

Y3. [Decrease k.] Set $k \leftarrow k-1$, and terminate if $k = 0$. Otherwise set $q \leftarrow u_k$ and $p \leftarrow a_q$. If $p = q$, set $l_0 \leftarrow q$, $q \leftarrow 0$, $r \leftarrow l_p$, and $k \leftarrow k+1$ (preparing to make $a_p > p$). Otherwise set $l_{u_{k-1}} \leftarrow q$, $r \leftarrow l_q$ (preparing to make $a_p > q$).

Y4. [Increase a_p.] If $r = 0$ go to Y5. Otherwise set $l_q \leftarrow l_r$, $u_{k-1} \leftarrow q$, $u_k \leftarrow r$, $a_p \leftarrow r$, $a_q \leftarrow q$, $a_r \leftarrow p$, $k \leftarrow k+1$, and go to Y2.

Y5. [Restore a_p.] Set $l_0 \leftarrow p$, $a_p \leftarrow p$, $a_q \leftarrow q$, $k \leftarrow k-1$, and return to Y3. ▮

Let $t_{n+1} = t_n + nt_{n-1}$, $a_{n+1} = 1 + a_n + na_{n-1}$, $t_0 = t_1 = 1$, $a_0 = 0$, $a_1 = 1$. (See Eq. 5.1.4–(40).) Step Y2 is performed t_n times with $k > n$ and a_n times with $k \le n$. Step Y3 is performed a_n times with $p = q$ and $a_n + t_n$ times altogether. Step Y4 is performed $t_n - 1$ times; step Y5, a_n times. The total number of mems for all t_n outputs is therefore approximately $11a_n + 12t_n$, where $a_n < 1.25331414t_n$. (Optimizations are clearly possible if speed is essential.)

101. We construct a list L_n that begins with () and ends with $(n{-}1\ n)$, starting with $L_3 = (),\ (1\ 2),\ (1\ 3),\ (2\ 3)$. If n is odd, L_{n+1} is L_n, K^R_{n1}, K_{n2}, ..., K^R_{nn}, where $K_{nk} = (k\ \ldots\ n)^- L_{n-1}(k\ \ldots n)(k\ n{+}1)$. For example,

$$L_4 = (),\ (1\,2),\ (1\,3),\ (2\,3),\ (2\,3)(1\,4),\ (1\,4),\ (2\,4),\ (1\,3)(2\,4),\ (1\,2)(3\,4),\ (3\,4).$$

If n is even, L_{n+1} is L_n, $K_{n(n-1)}$, $K^R_{n(n-2)}$, ..., K_{n1}, $(1\ n{-}2)L^R_{n-1}(1\ n{-}2)(n\ n{+}1)$.

For further developments, see the article by Walsh cited in answer 93.

102. The following elegant solution by Carla Savage needs only $n-2$ different operations ρ_j, for $1 < j < n$, where ρ_j replaces $a_{j-1}a_ja_{j+1}$ by $a_{j+1}a_{j-1}a_j$ when j is even, $a_ja_{j+1}a_{j-1}$ when j is odd. We may assume that $n \ge 4$; let $A_4 = (\rho_3\rho_2\rho_2\rho_3)^3$. In general A_n will begin and end with ρ_{n-1}, and it will contain $2n-2$ occurrences of ρ_{n-1} altogether. To get A_{n+1}, replace the kth ρ_{n-1} of A_n by $\rho_nA'_n\rho_n$, where $k = 1, 2, 4, \ldots, 2n-2$ if n is even and $k = 1, 3, \ldots, 2n-3, 2n-2$ if n is

odd, and where A'_n is A_n with its first or last element deleted. Then, if we begin with $a_1 \ldots a_n = 1 \ldots n$, the operations ρ_{n-1} of A_n will cause position a_n to run through the successive values $n \to p_1 \to n \to p_2 \to \cdots \to p_{n-1} \to n$, where $p_1 \ldots p_{n-1} = (n{-}1 - [n \text{ even}]) \ldots 4213 \ldots (n{-}1 - [n \text{ odd}])$; the final permutation will again be $1 \ldots n$.

103. (a) A well-balanced permutation has $\sum_{k=1}^n k a_k = n(n+1)^2/4$, an integer.

(b) Replace k by a_k when summing over k.

(c) A fairly fast way to count, when n is not too large, can be based on the streamlined plain-change algorithm of exercise 16, because the quantity $\sum k a_k$ changes in a simple way with each adjacent interchange, and because $n-1$ of every n steps are "hunts" that can be done rapidly. We can save half the work by considering only permutations in which 1 precedes 2. The values for $1 \le n \le 15$ are 0, 0, 0, 2, 6, 0, 184, 936, 6688, 0, 420480, 4298664, 44405142, 0, 6732621476.

104. (a) For each permutation $a_1 \ldots a_n$, insert $\prec$ between a_j and a_{j+1} if $a_j > a_{j+1}$; insert either $\equiv$ or $\prec$ between them if $a_j < a_{j+1}$. (A permutation with k "ascents" therefore yields 2^k weak orders. Weak orders are sometimes called "preferential arrangements; exercise 5.3.1–4 shows that there are approximately $n!/(2(\ln 2)^{n+1})$ of them.)

(b) Start with $a_0 a_1 \ldots a_n a_{n+1} = 01 \ldots 11$. Perform Algorithm L until it stops with $j = 0$. Find k such that $a_1 > \cdots > a_k = a_{k+1}$, and terminate if $k = n$. Otherwise set $a_l \leftarrow a_{k+1} + 1$ for $1 \le l \le k$ and go to step L4. [See M. Mor and A. S. Fraenkel, *Discrete Math.* **48** (1984), 101–112.]

105. All weak ordering sequences can be obtained by a sequence of elementary operations $a_i \leftrightarrow a_j$ or $a_i \leftarrow a_j$. (Perhaps one could actually restrict the transformations further, allowing only $a_j \leftrightarrow a_{j+1}$ or $a_j \leftarrow a_{j+1}$ for $1 \le j < n$.)

106. Every step increases the quantity $\sum_{k=1}^n 2^k [a_k = k]$, as noted by H. S. Wilf, so the game must terminate. At least three approaches to the solution are plausible: one bad, one good, and one better.

The bad one is to play the game on all 13! shuffles and to record the longest. This method does produce the correct answer; but 13! is 6,227,020,800, and the average game lasts ≈ 8.728 steps.

The good one [A. Pepperdine, *Math. Gazette* **73** (1989), 131–133] is to play backwards, starting with the final position $1{*}\ldots{*}$ where $*$ denotes a card that is face down; we will turn a card up only when its value becomes relevant. To move backward from a given position $a_1 \ldots a_n$, consider all $k > 1$ such that either $a_k = k$ or $a_k = *$ and k has not yet turned up. Thus the next-to-last positions are $21{*}\ldots{*}$, $3{*}1{*}\ldots{*}$, $\ldots$, $n{*}\ldots{*}1$. Some positions (like $6{*}{*}213$ for $n = 6$) have no predecessors, even though we haven't turned all the cards up. It is easy to explore the tree of potential backwards games systematically, and one can in fact show that the number of nodes with t $*$'s is exactly $(n-1)!/t!$. Hence the total number of nodes considered is exactly $\lfloor (n-1)!\, e \rfloor$. When $n = 13$ this is 1,302,061,345.

The better one is to play forwards, starting with initial position $*\ldots*$ and turning over the top card when it is face down, running through all $(n-1)!$ permutations of $\{2, \ldots, n\}$ as cards are turned. If the bottom $n-m$ cards are known to be equal to $(m{+}1)(m{+}2)\ldots n$, in that order, at most $f(m)$ further moves are possible; thus we need not pursue a line of play any further if it cannot last long enough to be interesting. A permutation generator like Algorithm X allows us to share the computation for all

permutations with the same prefix and to reject unimportant prefixes. The card in position j need not take the value j when it is turned. When $n = 13$ this method needs to consider only respectively $(1, 11, 940, 6960, 44745, 245083, 1118216, 4112676, 11798207, 26541611, 44380227, 37417359)$ branches at levels $(1, 2, \ldots, 12)$ and to make a total of only 482,663,902 forward moves. Although it repeats some lines of play, the early cutoffs of unprofitable branches make it run more than 11 times faster than the backward method when $n = 13$.

The unique way to attain length 80 is to start with 2 9 4 5 11 12 10 1 8 13 3 6 7.

107. This result holds for any game in which

$$a_1 \ldots a_n \to a_k a_{p(k,2)} \ldots a_{p(k,k-1)} a_1 a_{k+1} \ldots a_n$$

when $a_1 = k$, where $p(k, 2) \ldots p(k, k-1)$ is an arbitrary permutation of $\{2, \ldots, k-1\}$. Suppose a_1 takes on exactly m distinct values $d(1) < \cdots < d(m)$ during a play of the game; we will prove that at most F_{m+1} permutations occur, including the initial shuffle. This assertion is obvious when $m = 1$.

Let $d(j)$ be the initial value of $a_{d(m)}$, where $j < m$, and suppose $a_{d(m)}$ changes on step r. If $d(j) = 1$, the number of permutations is $r + 1 \le F_m + 1 \le F_{m+1}$. Otherwise $r \le F_{m-1}$, and at most F_m further permutations follow step r. [*SIAM Review* **19** (1977), 239–241.]

The values of $f(n)$ for $1 \le n \le 16$ are (0, 1, 2, 4, 7, 10, 16, 22, 30, 38, 51, 65, 80, 101, 113, 139), and they are attainable in respectively (1, 1, 2, 2, 1, 5, 2, 1, 1, 1, 1, 1, 1, 4, 6, 1) ways. The unique longest-winded permutation for $n = 16$ is

$$9\ 12\ 6\ 7\ 2\ 14\ 8\ 1\ 11\ 13\ 5\ 4\ 15\ 16\ 10\ 3.$$

108. The forward method of answer 106 suggests that $f(n)$ probably grows at least as fast as $n \log n$ (by comparison with coupon collecting).

109. For $0 \le j \le 9$ construct the bit vectors $A_j = [a_j \in S_1] \ldots [a_j \in S_m]$ and $B_j = [j \in S_1] \ldots [j \in S_m]$. Then the number of j such that $A_j = v$ must equal the number of k such that $B_k = v$, for all bit vectors v. And if so, the values $\{a_j \mid A_j = v\}$ should be assigned to permutations of $\{k \mid B_k = v\}$ in all possible ways.

For example, the bit vectors in the given problem are

$$(A_0, \ldots, A_9) = (\mathtt{9}, \mathtt{6}, \mathtt{8}, \mathtt{b}, \mathtt{5}, \mathtt{4}, \mathtt{0}, \mathtt{a}, \mathtt{2}, \mathtt{0}), \qquad (B_0, \ldots, B_9) = (\mathtt{5}, \mathtt{0}, \mathtt{8}, \mathtt{6}, \mathtt{2}, \mathtt{a}, \mathtt{4}, \mathtt{b}, \mathtt{9}, \mathtt{0}),$$

in hexadecimal notation; hence $a_0 \ldots a_9 = 8327061549$ or 8327069541.

In a larger problem we would keep the bit vectors in a hash table. It would be better to give the answer in terms of equivalence classes, not permutations; indeed, this problem has comparatively little to do with permutations.

110. In the directed graph with $n!/2$ vertices $a_1 \ldots a_{n-2}$ and $n!$ arcs $a_1 \ldots a_{n-2} \to a_2 \ldots a_{n-1}$ (one for each permutation $a_1 \ldots a_n$), each vertex has in-degree 2 and out-degree 2. Furthermore, from paths like $a_1 \ldots a_{n-2} \to a_2 \ldots a_{n-1} \to a_3 \ldots a_n \to a_4 \ldots a_n a_2 \to a_5 \ldots a_n a_2 a_1 \to \cdots \to a_2 a_1 a_3 \ldots a_{n-2}$, we can see that any vertex is reachable from any other. Therefore an Eulerian circuit exists by Theorem 2.3.4.2D, and such a circuit clearly is equivalent to a universal cycle of permutations. The lexicographically smallest example when $n = 4$ is (123124132134214324314234).

Mark Cooke has pointed out that a universal cycle of permutations is also equivalent to a *Hamiltonian* circuit on the Cayley graph with generators $\sigma = (1\ 2\ \ldots\ n)$ and $\rho = (1\ 2\ \ldots\ n{-}1)$. For example, the cycle just given for $n = 4$ corresponds to $\sigma^3\rho^2\sigma\rho\sigma^2\rho^2\sigma^3\rho\sigma^2\rho^2\sigma\rho\sigma^2\rho$.

111. By exercise 2.3.4.2–22 it suffices to count the oriented trees rooted at $12\ldots(n-2)$, in the digraph of the preceding answer. For $n = 2$, 3, 4, 5, 6, the numbers can be calculated by exercise 2.3.4.2–19, and they turn out to be tantalizingly simple: 1, 3, $2^7 \cdot 3$, $2^{33} \cdot 3^8 \cdot 5^3$, $2^{190} \cdot 3^{49} \cdot 5^{33}$. (Here we consider (121323) to be the same cycle as (213231), but different from (131232).) The graph has symmetries related to Young tableaux in beautiful ways, so the answer to this problem should be quite instructive.

At least one of these cycles must almost surely be easy to describe and to compute, as we did for de Bruijn cycles in Section 7.2.1.1. But no simple construction has yet been found.

INDEX AND GLOSSARY

When an index entry refers to a page containing a relevant exercise, see also the *answer* to that exercise for further information. An answer page is not indexed here unless it refers to a topic not included in the statement of the exercise.

PREFACE

[The Art of Combinations] has a relation
to almost every species of useful knowledge
that the mind of man can be employed upon.
— JACQUES BERNOULLI, *Ars Conjectandi* (1713)

THIS BOOKLET contains draft material that I'm circulating to experts in the field, in hopes that they can help remove its most egregious errors before too many other people see it. I am also, however, posting it on the Internet for courageous and/or random readers who don't mind the risk of reading a few pages that have not yet reached a very mature state. *Beware:* This material has not yet been proofread as thoroughly as the manuscripts of Volumes 1, 2, and 3 were at the time of their first printings. Those volumes, alas, were subsequently found to contain thousands of mistakes.

Given this caveat, I hope that my errors this time will not be so numerous and/or obtrusive that you will be discouraged from reading the material carefully. I did try to make it both interesting and authoritative, as far as it goes. But the field is so vast, I cannot hope to have surrounded it enough to corral it completely. Therefore I beg you to let me know about any deficiencies you discover.

To put the material in context, this is Section 7.2.1.3 of a long, long chapter on combinatorial algorithms. Chapter 7 will eventually fill three volumes (namely Volumes 4A, 4B, and 4C), assuming that I'm able to remain healthy. It will begin with a short review of graph theory, with emphasis on some highlights of significant graphs in The Stanford GraphBase, from which I will be drawing many examples. Then comes Section 7.1, which deals with the topic of bitwise manipulations. (I drafted about 60 pages about that subject in 1977, but those pages need extensive revision; meanwhile I've decided to work for awhile on the material that follows it, so that I can get a better feel for how much to cut.) Section 7.2 is about generating all possibilities, and it begins with Section 7.2.1: Generating Basic Combinatorial Patterns—which, in turn, begins with Section 7.2.1.1, "Generating all n-tuples," and Section 7.2.1.2, "Generating all permutations." (Readers of the present booklet should have already looked at those sections, drafts of which are available as Prefascicles 2A and 2B.) The stage is now set for the main contents of this booklet, Section 7.2.1.3: "Generating all combinations." Then will come Section 7.2.1.4 (about partitions), etc. Section 7.2.2 will deal with backtracking in general. And so it will go on, if all goes well; an outline of the entire Chapter 7 as currently envisaged appears on the `taocp` webpage that is cited on page ii.

Even the apparently lowly topic of combination generation turns out to be surprisingly rich, with ties to Sections 1.2.1, 1.2.4, 1.2.6, 2.3.2, 2.3.4.2, 4.3.2, 4.6.1, 4.6.2, 5.1.2, 5.4.1, 5.4.2, 6.1, and 6.3 of the first three volumes. I strongly believe in building up a firm foundation, so I have discussed this topic much more thoroughly than I will be able to do with material that is newer or less basic. To my surprise, I came up with 109 exercises, even though — believe it or not — I had to eliminate quite a bit of the interesting material that appears in my files.

Some of the things presented are new, to the best of my knowledge, although I will not be at all surprised to learn that my own little "discoveries" have been discovered before. Please look, for example, at the exercises that I've classed as research problems (rated with difficulty level 46 or higher), namely exercises 53, 55, 66, and 82; I've also implicitly posed additional unsolved questions in the answers to exercises 62, 100, 104, and 108. Are those problems still open? Please let me know if you know of a solution to any of these intriguing questions. And of course if no solution is known today but you do make progress on any of them in the future, I hope you'll let me know.

I urgently need your help also with respect to some exercises that I made up as I was preparing this material. I certainly don't like to get credit for things that have already been published by others, and most of these results are quite natural "fruits" that were just waiting to be "plucked." Therefore please tell me if you know who I should have credited, with respect to the ideas found in exercises 9, 18, 19, 20, 26, 27, 28, 30, 31, 32, 33, 34, 35, 36, 37, 41, 42, 43, 44, 45, 48, 49, 51, 58, 61, 62, 63, 64, 65, 68, 78, 81(b–f), 84, 85, 86, 92, and/or 109.

I shall happily pay a finder's fee of \$2.56 for each error in this draft when it is first reported to me, whether that error be typographical, technical, or historical. The same reward holds for items that I forgot to put in the index. And valuable suggestions for improvements to the text are worth 32¢ each. (Furthermore, if you find a better solution to an exercise, I'll actually reward you with immortal glory instead of mere money, by publishing your name in the eventual book:–)

Happy reading!

Stanford, California D. E. K.
13 June 2002

7.2.1.3. Generating all combinations. Combinatorial mathematics is often described as "the study of permutations, combinations, etc.," so we turn our attention now to combinations. A *combination of n things, taken t at a time*, often called simply a t-combination of n things, is a way to select a subset of size t from a given set of size n. We know from Eq. 1.2.6–(2) that there are exactly $\binom{n}{t}$ ways to do this; and we learned in Section 3.4.2 how to choose t-combinations at random.

Selecting t of n objects is equivalent to choosing the $n-t$ elements not selected. We will emphasize this symmetry by letting

$$n \;=\; s \,+\, t \tag{1}$$

throughout our discussion, and we will often refer to a t-combination of n things as an "(s,t)-combination." Thus, an (s,t)-combination is a way to subdivide $s+t$ objects into two collections of sizes s and t.

> *If I ask how many combinations of 21 can be taken out of 25,*
> *I do in effect ask how many combinations of 4 may be taken.*
> *For there are just as many ways of taking 21 as there are of leaving 4.*
> — AUGUSTUS DE MORGAN, *An Essay on Probabilities* (1838)

There are two main ways to represent (s,t)-combinations: We can list the elements $c_t \ldots c_2 c_1$ that have been selected, or we can work with binary strings $a_{n-1} \ldots a_1 a_0$ for which

$$a_{n-1} + \cdots + a_1 + a_0 \;=\; t. \tag{2}$$

The latter representation has s 0s and t 1s, corresponding to elements that are unselected or selected. The list representation $c_t \ldots c_2 c_1$ tends to work out best if we represent the objects as subsets of the set $\{0, 1, \ldots, n-1\}$ and if we list them in *decreasing* order:

$$n > c_t > \cdots > c_2 > c_1 \geq 0. \tag{3}$$

Binary notation connects these two representations nicely, because the item list $c_t \ldots c_2 c_1$ corresponds to the sum

$$2^{c_t} + \cdots + 2^{c_2} + 2^{c_1} \;=\; \sum_{k=0}^{n-1} a_k 2^k \;=\; (a_{n-1} \ldots a_1 a_0)_2. \tag{4}$$

Of course we could also list the positions $b_s \dots b_2 b_1$ of the 0s in $a_{n-1} \dots a_1 a_0$, where

$$n > b_s > \cdots > b_2 > b_1 \geq 0. \tag{5}$$

Combinations are important not only because subsets are omnipresent in mathematics but also because they are equivalent to many other configurations. For example, every (s,t)-combination corresponds to a combination of $s+1$ things taken t at a time *with repetitions permitted*, also called a *multicombination*, namely a sequence of integers $d_t \dots d_2 d_1$ with

$$s \geq d_t \geq \cdots \geq d_2 \geq d_1 \geq 0. \tag{6}$$

One reason is that $d_t \dots d_2 d_1$ solves (6) if and only if $c_t \dots c_2 c_1$ solves (3), where

$$c_t = d_t + t - 1, \quad \dots, \quad c_2 = d_2 + 1, \quad c_1 = d_1 \tag{7}$$

(see exercise 1.2.6–60). And there is another useful way to relate combinations with repetition to ordinary combinations, suggested by Solomon Golomb [*AMM* **75** (1968), 530–531], namely to define

$$e_j = \begin{cases} c_j, & \text{if } c_j \leq s; \\ e_{c_j - s}, & \text{if } c_j > s. \end{cases} \tag{8}$$

In this form the numbers $e_t \dots e_1$ don't necessarily appear in descending order, but the multiset $\{e_1, e_2, \dots, e_t\}$ is equal to $\{c_1, c_2, \dots, c_t\}$ if and only if $\{e_1, e_2, \dots, e_t\}$ is a set. (See Table 1 and exercise 1.)

An (s,t)-combination is also equivalent to a *composition* of $n+1$ into $t+1$ parts, namely an ordered sum

$$n+1 = p_t + \cdots + p_1 + p_0, \qquad \text{where } p_t, \dots, p_1, p_0 \geq 1. \tag{9}$$

The connection with (3) is now

$$p_t = n - c_t, \quad p_{t-1} = c_t - c_{t-1}, \quad \dots, \quad p_1 = c_2 - c_1, \quad p_0 = c_1 + 1. \tag{10}$$

Equivalently, if $q_j = p_j - 1$, we have

$$s = q_t + \cdots + q_1 + q_0, \qquad \text{where } q_t, \dots, q_1, q_0 \geq 0, \tag{11}$$

a composition of s into $t+1$ *nonnegative* parts, related to (6) by setting

$$q_t = s - d_t, \quad q_{t-1} = d_t - d_{t-1}, \quad \dots, \quad q_1 = d_2 - d_1, \quad q_0 = d_1. \tag{12}$$

Furthermore it is easy to see that an (s,t)-combination is equivalent to a path of length $s+t$ from corner to corner of an $s \times t$ grid, because such a path contains s vertical steps and t horizontal steps. Thus, combinations can be studied in at least eight different guises. Table 1 illustrates all $\binom{6}{3} = 20$ possibilities in the case $s = t = 3$.

These cousins of combinations might seem rather bewildering at first glance, but most of them can be understood directly from the binary representation $a_{n-1} \dots a_1 a_0$. Consider, for example, the "random" bit string

$$a_{23} \dots a_1 a_0 = 01100100100000111111101101, \tag{13}$$

Table 1

111000	210	543	333	333	1114	0003	

which has $s = 11$ zeros and $t = 13$ ones, hence $n = 24$. The dual combination $b_s \ldots b_1$ lists the positions of the zeros, namely

$$23\ 20\ 19\ 17\ 16\ 14\ 13\ 12\ 11\ 4\ 1,$$

because the leftmost position is $n-1$ and the rightmost is 0. The primal combination $c_t \ldots c_1$ lists the positions of the ones, namely

$$22\ 21\ 18\ 15\ 10\ 9\ 8\ 7\ 6\ 5\ 3\ 2\ 0.$$

The corresponding multicombination $d_t \ldots d_1$ lists the number of 0s to the right of each 1:

$$10\ 10\ 8\ 6\ 2\ 2\ 2\ 2\ 2\ 2\ 1\ 1\ 0.$$

The composition $p_t \ldots p_0$ lists the distances between consecutive 1s, if we imagine additional 1s at the left and the right:

$$2\ 1\ 3\ 3\ 5\ 1\ 1\ 1\ 1\ 1\ 2\ 1\ 2\ 1.$$

And the nonnegative composition $q_t \ldots q_0$ counts how many 0s appear between "fenceposts" represented by 1s:

$$1\ 0\ 2\ 2\ 4\ 0\ 0\ 0\ 0\ 0\ 1\ 0\ 1\ 0;$$

thus we have

$$a_{n-1} \ldots a_1 a_0 = 0^{q_t} 1 0^{q_{t-1}} 1 \ldots 1 0^{q_1} 1 0^{q_0}. \tag{14}$$

The paths in Table 1 also have a simple interpretation (see exercise 2).

Lexicographic generation. Table 1 shows combinations $a_{n-1}\dots a_1a_0$ and $c_t\dots c_1$ in lexicographic order, which is also the lexicographic order of $d_t\dots d_1$. Notice that the dual combinations $b_s\dots b_1$ and the corresponding compositions $p_t\dots p_0$, $q_t\dots q_0$ then appear in *reverse* lexicographic order.

Lexicographic order usually suggests the most convenient way to generate combinatorial configurations. Indeed, Algorithm 7.2.1.2L already solves the problem for combinations in the form $a_{n-1}\dots a_1a_0$, since (s,t)-combinations in bitstring form are the same as permutations of the multiset $\{s\cdot 0, t\cdot 1\}$. That general-purpose algorithm can be streamlined in obvious ways when it is applied to this special case. (See also exercise 7.1–00, which presents a remarkable sequence of seven bitwise operations that will convert any given binary number $(a_{n-1}\dots a_1a_0)_2$ to the lexicographically next t-combination, assuming that n does not exceed the computer's word length.)

Let's focus, however, on generating combinations in the other principal form $c_t\dots c_2c_1$, which is more directly relevant to the ways in which combinations are often needed, and which is more compact than the bit strings when t is small compared to n. In the first place we should keep in mind that a simple sequence of nested loops will do the job nicely when t is very small. For example, when $t=3$ the following instructions suffice:

$$\begin{aligned}&\text{For } c_3 = 2,\ 3,\ \dots,\ n-1 \text{ (in this order) do the following:}\\ &\quad\text{For } c_2 = 1,\ 2,\ \dots,\ c_3-1 \text{ (in this order) do the following:}\\ &\qquad\text{For } c_1 = 0,\ 1,\ \dots,\ c_2-1 \text{ (in this order) do the following:}\\ &\qquad\quad\text{Visit the combination } c_3c_2c_1.\end{aligned}\tag{15}$$

(See the analogous situation in 7.2.1.1–(3).)

On the other hand when t is variable or not so small, we can generate combinations lexicographically by following the general recipe discussed after Algorithm 7.2.1.2L, namely to find the rightmost element c_j that can be increased and then to set the subsequent elements $c_{j-1}\dots c_1$ to their smallest possible values:

Algorithm L (*Lexicographic combinations*). This algorithm generates all t-combinations $c_t\dots c_2c_1$ of the n numbers $\{0,1,\dots,n-1\}$, given $n\ge t\ge 0$. Additional variables c_{t+1} and c_{t+2} are used as sentinels.

L1. [Initialize.] Set $c_j\leftarrow j-1$ for $1\le j\le t$; also set $c_{t+1}\leftarrow n$ and $c_{t+2}\leftarrow 0$.

L2. [Visit.] Visit the combination $c_t\dots c_2c_1$.

L3. [Find j.] Set $j\leftarrow 1$. Then, while $c_j+1=c_{j+1}$, set $c_j\leftarrow j-1$ and $j\leftarrow j+1$; repeat until $c_j+1\ne c_{j+1}$.

L4. [Done?] Terminate the algorithm if $j>t$.

L5. [Increase c_j.] Set $c_j\leftarrow c_j+1$ and return to L2. ∎

The running time of this algorithm is not difficult to analyze. Step L3 sets $c_j\leftarrow j-1$ just after visiting a combination for which $c_{j+1}=c_1+j$, and the number of such combinations is the number of solutions to the inequalities

$$n>c_t>\cdots>c_{j+1}\ge j;\tag{16}$$

but this formula is equivalent to a $(t-j)$-combination of the $n-j$ objects $\{n-1,\ldots,j\}$, so the assignment $c_j \leftarrow j-1$ occurs exactly $\binom{n-j}{t-j}$ times. Summing for $1 \le j \le t$ tells us that the loop in step L3 is performed

$$\binom{n-1}{t-1}+\binom{n-2}{t-2}+\cdots+\binom{n-t}{0} = \binom{n-1}{s}+\binom{n-2}{s}+\cdots+\binom{s}{s} = \binom{n}{s+1} \quad (17)$$

times altogether, or an average of

$$\binom{n}{s+1}\Big/\binom{n}{t} = \frac{n!}{(s+1)!\,(t-1)!}\Big/\frac{n!}{s!\,t!} = \frac{t}{s+1} \quad (18)$$

times per visit. This ratio is less than 1 when $t \le s$, so Algorithm L is quite efficient in such cases.

But the quantity $t/(s+1)$ can be embarrassingly large when t is near n and s is small. Indeed, Algorithm L occasionally sets $c_j \leftarrow j-1$ needlessly, at times when c_j already equals $j-1$. Further scrutiny reveals that we need not always search for the index j that is needed in steps L4 and L5, since the correct value of j can often be predicted from the actions just taken. For example, after we have increased c_4 and reset $c_3c_2c_1$ to their starting values 210, the next combination will inevitably increase c_3. These observations lead to a tuned-up version of the algorithm:

Algorithm T (*Lexicographic combinations*). This algorithm is like Algorithm L, but faster. It also assumes, for convenience, that $t < n$.

T1. [Initialize.] Set $c_j \leftarrow j-1$ for $1 \le j \le t$; then set $c_{t+1} \leftarrow n$, $c_{t+2} \leftarrow 0$, and $j \leftarrow t$.

T2. [Visit.] (At this point j is the smallest index such that $c_{j+1} > j$.) Visit the combination $c_t \ldots c_2c_1$. Then, if $j > 0$, set $x \leftarrow j$ and go to step T6.

T3. [Easy case?] If $c_1 + 1 < c_2$, set $c_1 \leftarrow c_1 + 1$ and return to T2. Otherwise set $j \leftarrow 2$.

T4. [Find j.] Set $c_{j-1} \leftarrow j-1$ and $x \leftarrow c_j + 1$. If $x = c_{j+1}$, set $j \leftarrow j+1$ and repeat this step until $x < c_{j+1}$.

T5. [Done?] Terminate the algorithm if $j > t$.

T6. [Increase c_j.] Set $c_j \leftarrow x$, $j \leftarrow j-1$, and return to T2. ∎

Now $j = 0$ in step T2 if and only if $c_1 > 0$, so the assignments in step T4 are never redundant. Exercise 6 carries out a complete analysis of Algorithm T.

Notice that the parameter n appears only in the initialization steps L1 and T1, not in the principal parts of Algorithms L and T. Thus we can think of the process as generating the first $\binom{n}{t}$ combinations of an *infinite* list, which depends only on t. This simplification arises because the list of t-combinations for $n+1$ things begins with the list for n things, under our conventions; we have been using lexicographic order on the decreasing sequences $c_t \ldots c_1$ for this very reason, instead of working with the increasing sequences $c_1 \ldots c_t$.

Derrick Lehmer noticed another pleasant property of Algorithms L and T [*Applied Combinatorial Mathematics*, edited by E. F. Beckenbach (1964), 27–30]:

Theorem L. *The combination $c_t \ldots c_2 c_1$ is visited after exactly*

$$\binom{c_t}{t} + \cdots + \binom{c_2}{2} + \binom{c_1}{1} \tag{19}$$

other combinations have been visited.

Proof. There are $\binom{c_k}{k}$ combinations $c'_t \ldots c'_2 c'_1$ with $c'_j = c_j$ for $t \ge j > k$ and $c'_k < c_k$, namely $c_t \ldots c_{k+1}$ followed by the k-combinations of $\{0, \ldots, c_k - 1\}$. ∎

When $t = 3$, for example, the numbers

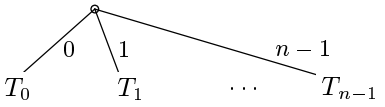
$$\tbinom{2}{3} + \tbinom{1}{2} + \tbinom{0}{1},\ \tbinom{3}{3} + \tbinom{1}{2} + \tbinom{0}{1},\ \tbinom{3}{3} + \tbinom{2}{2} + \tbinom{0}{1},\ \ldots,\ \tbinom{5}{3} + \tbinom{4}{2} + \tbinom{3}{1}$$

that correspond to the combinations $c_3 c_2 c_1$ in Table 1 simply run through the sequence 0, 1, 2, ..., 19. Theorem L gives us a nice way to understand the *combinatorial number system* of degree t, which represents every nonnegative integer N uniquely in the form

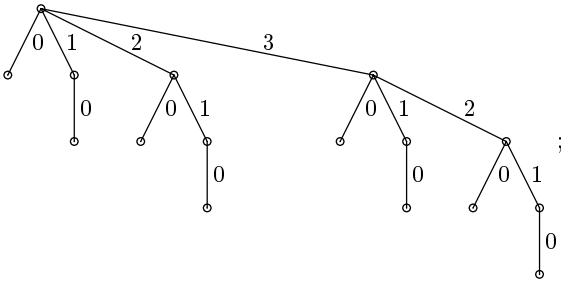
$$N = \binom{n_t}{t} + \cdots + \binom{n_2}{2} + \binom{n_1}{1}, \qquad n_t > \cdots > n_2 > n_1 \ge 0. \tag{20}$$

Binomial trees. The family of trees T_n defined by

$$T_0 = \circ\ , \qquad T_n = \quad \text{for } n > 0, \tag{21}$$



arises in several important contexts and sheds further light on combination generation. For example, T_4 is



; (22)

and T_5, rendered more artistically, appears as the frontispiece to Volume 1 of this series of books.

Notice that T_n is like T_{n-1}, except for an additional copy of T_{n-1}; therefore T_n has 2^n nodes altogether. Furthermore, the number of nodes on level t is the binomial coefficient $\binom{n}{t}$; this fact accounts for the name "binomial tree." Indeed, the sequence of labels encountered on the path from the root to each node on level t defines a combination $c_t \ldots c_1$, and all combinations occur in lexicographic order from left to right. Thus, Algorithms L and T can be regarded as procedures to traverse the nodes on level t of the binomial tree T_n.

The infinite binomial tree T_∞ is obtained by letting $n \to \infty$ in (21). The root of this tree has infinitely many branches, but every other node is the root

of a finite binomial subtree. All possible t-combinations appear in lexicographic order on level t of T_∞.

Let's get more familiar with binomial trees by considering all possible ways to pack a rucksack. More precisely, suppose we have n items that take up respectively $w_{n-1}, \ldots, w_1, w_0$ units of capacity, where

$$w_{n-1} \geq \cdots \geq w_1 \geq w_0; \tag{23}$$

we want to generate all binary vectors $a_{n-1} \ldots a_1 a_0$ such that

$$a \cdot w = a_{n-1}w_{n-1} + \cdots + a_1 w_1 + a_0 w_0 \leq N, \tag{24}$$

where N is the total capacity of a rucksack. Equivalently, we want to find all subsets C of $\{0, 1, \ldots, n-1\}$ such that $w(C) = \sum_{c\in C} w_c \leq N$; such subsets will be called *feasible*. We will write a feasible subset as $c_1 \ldots c_t$, where $c_1 > \cdots > c_t \geq 0$, numbering the subscripts differently from the convention of (3) above because t is variable in this problem.

Every feasible subset corresponds to a node of T_n, and our goal is to visit each feasible node. Clearly the parent of every feasible node is feasible, and so is the left sibling, if any; therefore a simple tree exploration procedure solves the problem.

Algorithm F (*Filling a rucksack*). This algorithm generates all feasible ways $c_1 \ldots c_t$ to fill a rucksack, given $w_{n-1}, \ldots, w_1, w_0$, and N. We let $\delta_j = w_j - w_{j-1}$ for $1 \leq j < n$.

F1. [Initialize.] Set $t \leftarrow 0$, $c_0 \leftarrow n$, and $r \leftarrow N$.

F2. [Visit.] Visit the combination $c_1 \ldots c_t$, which uses $N - r$ units of capacity.

F3. [Try to add w_0.] If $c_t > 0$ and $r \geq w_0$, set $t \leftarrow t + 1$, $c_t \leftarrow 0$, $r \leftarrow r - w_0$, and return to F2.

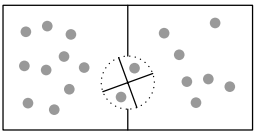
F4. [Try to increase c_t.] Terminate if $t = 0$. Otherwise, if $c_{t-1} > c_t + 1$ and $r \geq \delta_{c_t+1}$, set $c_t \leftarrow c_t + 1$, $r \leftarrow r - \delta_{c_t}$, and return to F2.

F5. [Remove c_t.] Set $r \leftarrow r + w_{c_t}$, $t \leftarrow t - 1$, and return to F4. ∎

Notice that the algorithm implicitly visits nodes of T_n in preorder, skipping over unfeasible subtrees. An element $c > 0$ is never placed in the rucksack until after the procedure has explored all possibilities using element $c-1$. The running time is proportional to the number of feasible combinations visited (see exercise 20).

Incidentally, the classical "knapsack problem" of operations research is different: It asks for a feasible subset C such that $v(C) = \sum_{c\in C} v(c)$ is maximum, where each item c has been assigned a value $v(c)$. Algorithm F is not a particularly good way to solve that problem, because it often considers cases that could be ruled out. For example, if C and C' are subsets of $\{1, \ldots, n-1\}$ with $w(C) \leq w(C') \leq N - w_0$ and $v(C) \geq v(C')$, Algorithm F will examine both $C \cup \{0\}$ and $C' \cup \{0\}$, but the latter subset will never improve the maximum. We will consider methods for the classical knapsack problem later; Algorithm F is intended only for situations when *all* of the feasible possibilities are potentially relevant.

Gray codes for combinations. Instead of merely generating all combinations, we often prefer to visit them in such a way that each one is obtained by making only a small change to its predecessor.



For example, we can ask for what Nijenhuis and Wilf have called a "revolving door algorithm": Imagine two rooms that contain respectively s and t people, with a revolving door between them. Whenever a person goes into the opposite room, somebody else comes out. Can we devise a sequence of moves so that each (s,t)-combination occurs exactly once?

The answer is yes, and in fact a huge number of such patterns exist. For example, it turns out that if we examine all n-bit strings $a_{n-1}\ldots a_1a_0$ in the well-known order of Gray binary code (Section 7.2.1.1), but select only those that have exactly s 0s and t 1s, the resulting strings form a revolving door code.

Here's the proof: Gray binary code is defined by the recurrence $\Gamma_n = 0\Gamma_{n-1}$, $1\Gamma_{n-1}^R$ of 7.2.1.1–(5), so its (s,t) subset satisfies the recurrence

$$\Gamma_{st} \;=\; 0\Gamma_{(s-1)t},\; 1\Gamma_{s(t-1)}^R \tag{25}$$

when $st > 0$. We also have $\Gamma_{s0} = 0^s$ and $\Gamma_{0t} = 1^t$. Therefore it is clear by induction that Γ_{st} begins with 0^s1^t and ends with 10^s1^{t-1} when $st > 0$. The transition at the comma in (25) is from the last element of $0\Gamma_{(s-1)t}$ to the last element of $1\Gamma_{s(t-1)}$, namely from $010^{s-1}1^{t-1} = 010^{s-1}11^{t-2}$ to $110^s1^{t-2} = 110^{s-1}01^{t-2}$ when $t \ge 2$, and this satisfies the revolving-door constraint. The case $t = 1$ also checks out. For example, Γ_{33} is given by the columns of

000111	011010	110001	101010
001101	011100	110010	101100
001110	010101	110100	100101
001011	010110	111000	100110
011001	010011	101001	100011

(26)

and Γ_{23} can be found in the first two columns of this array. One more turn of the door takes the last element into the first. [These properties of Γ_{st} were discovered by D. T. Tang and C. N. Liu, *IEEE Trans.* **C-22** (1973), 176–180; a loopless implementation was presented by J. R. Bitner, G. Ehrlich, and E. M. Reingold, *CACM* **19** (1976), 517–521.]

When we convert the bitstrings $a_5a_4a_3a_2a_1a_0$ in (26) to the corresponding index-list forms $c_3c_2c_1$, a striking pattern becomes evident:

210	431	540	531
320	432	541	532
321	420	542	520
310	421	543	521
430	410	530	510

(27)

The first components c_3 occur in increasing order; but for each fixed value of c_3, the values of c_2 occur in *decreasing* order. And for fixed c_3c_2, the values of c_1 are again increasing. The same is true in general: *All combinations* $c_t\ldots c_2c_1$

appear in lexicographic order of

$$(c_t,\ -c_{t-1},\ c_{t-2},\ \ldots,\ (-1)^t c_1) \tag{28}$$

in the revolving-door Gray code Γ_{st}. This property follows by induction, because (25) becomes

$$\Gamma_{st} \ = \ \Gamma_{(s-1)t},\ (s+t-1)\Gamma^R_{s(t-1)} \tag{29}$$

for $st > 0$ when we use index-list notation instead of bitstring notation. Consequently the sequence can be generated efficiently by the following algorithm due to W. H. Payne [see *ACM Trans. Math. Software* **5** (1979), 163–172]:

Algorithm R (*Revolving-door combinations*). This algorithm generates all t-combinations $c_t \ldots c_2 c_1$ of $\{0, 1, \ldots, n-1\}$ in lexicographic order of the alternating sequence (28), assuming that $n > t > 1$. Step R3 has two variants, depending on whether t is even or odd.

R1. [Initialize.] Set $c_j \leftarrow j-1$ for $t \geq j \geq 1$, and $c_{t+1} \leftarrow n$.

R2. [Visit.] Visit the combination $c_t \ldots c_2 c_1$.

R3. [Easy case?] If t is odd: If $c_1 + 1 < c_2$, increase c_1 by 1 and return to R2, otherwise set $j \leftarrow 2$ and go to R4. If t is even: If $c_1 > 0$, decrease c_1 by 1 and return to R2, otherwise set $j \leftarrow 2$ and go to R5.

R4. [Try to decrease c_j.] (At this point $c_j = c_{j-1} + 1$.) If $c_j \geq j$, set $c_j \leftarrow c_{j-1}$, $c_{j-1} \leftarrow j-2$, and return to R2. Otherwise increase j by 1.

R5. [Try to increase c_j.] (At this point $c_{j-1} = j-2$.) If $c_j + 1 < c_{j+1}$, set $c_{j-1} \leftarrow c_j$, $c_j \leftarrow c_j + 1$, and return to R2. Otherwise increase j by 1, and go to R4 if $j \leq t$. ∎

Exercises 21–25 explore further properties of this interesting sequence. One of them is a nice companion to Theorem L: *The combination* $c_t c_{t-1} \ldots c_2 c_1$ *is visited by Algorithm R after exactly*

$$N = \binom{c_t+1}{t} - \binom{c_{t-1}+1}{t-1} + \cdots + (-1)^t \binom{c_2+1}{2} - (-1)^t \binom{c_1+1}{1} - [t \text{ odd}] \tag{30}$$

other combinations have been visited. We may call this the representation of N in the "alternating combinatorial number system" of degree t; one consequence, for example, is that every positive integer has a unique representation of the form $N = \binom{a}{3} - \binom{b}{2} + \binom{c}{1}$ with $a > b > c > 0$. Algorithm R tells us how to add 1 to N in this system.

Although the strings of (26) and (27) are not in lexicographic order, they are examples of a more general concept called *genlex order*, a name coined by Timothy Walsh. A sequence of strings $\alpha_1, \ldots, \alpha_N$ is said to be in genlex order when all strings with a common prefix occur consecutively. For example, all 3-combinations that begin with 53 appear together in (27).

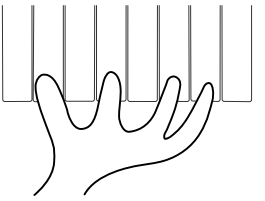
Genlex order means that the strings can be arranged in a trie structure, as in Fig. 31 of Section 6.3, but with the children of each node ordered arbitrarily. When a trie is traversed in any order such that each node is visited just before or just after its descendants, all nodes with a common prefix—that is, all nodes of

a subtrie — appear consecutively. This principle makes genlex order convenient, because it corresponds to recursive generation schemes. Many of the algorithms we have seen for generating n-tuples have therefore produced their results in some version of genlex order; similarly, the method of "plain changes" (Algorithm 7.2.1.2P) visits permutations in a genlex order of the corresponding inversion tables.

The revolving-door method of Algorithm R is a genlex routine that changes only one element of the combination at each step. But it isn't totally satisfactory, because it frequently must change two of the indices c_j simultaneously, in order to preserve the condition $c_t > \cdots > c_2 > c_1$. For example, Algorithm R changes 210 into 320, and (27) includes nine such "crossing" moves.

The source of this defect can be traced to our proof that (25) satisfies the revolving-door property: We observed that the string $010^{s-1}11^{t-2}$ is followed by $110^{s-1}01^{t-2}$ when $t \geq 2$. Hence the recursive construction Γ_{st} involves transitions of the form $110^a0 \leftrightarrow 010^a1$, when a substring like 11000 is changed to 01001 or vice versa; the two 1s cross each other.

A Gray path for combinations is said to be *homogeneous* if it changes only one of the indices c_j at each step. A homogeneous scheme is characterized in bitstring form by having only transitions of the forms $10^a \leftrightarrow 0^a1$ within strings, for $a \geq 1$, when we pass from one string to the next. With a homogeneous scheme we can, for example, play all t-note chords on an n-note keyboard by moving only one finger at a time.



A slight modification of (25) yields a genlex scheme for (s,t)-combinations that is pleasantly homogeneous. The basic idea is to construct a sequence that begins with 0^s1^t and ends with 1^t0^s, and the following recursion suggests itself almost immediately: Let $K_{s0} = 0^s$, $K_{0t} = 1^t$, $K_{s(-1)} = \emptyset$, and

$$K_{st} \;=\; 0K_{(s-1)t},\; 10K^R_{(s-1)(t-1)},\; 11K_{s(t-2)} \quad \text{for } st > 0. \tag{31}$$

At the commas of this sequence we have 01^t0^{s-1} followed by $101^{t-1}0^{s-1}$, and 10^s1^{t-1} followed by 110^s1^{t-2}; both of these transitions are homogeneous, although the second one requires the 1 to jump across s 0s. The combinations K_{33} for $s = t = 3$ are

000111	010101	101100	100011
001011	010011	101001	110001
001101	011001	101010	110010
001110	011010	100110	110100
010110	011100	100101	111000

(32)

in bitstring form, and the corresponding "finger patterns" are

210	420	532	510
310	410	530	540
320	430	531	541
321	431	521	542
421	432	520	543

(33)

When a homogeneous scheme for ordinary combinations $c_t \dots c_1$ is converted to the corresponding scheme (6) for combinations with repetitions $d_t \dots d_1$, it retains the property that only one of the indices d_j changes at each step. And when it is converted to the corresponding schemes (9) or (11) for compositions $p_t \dots p_0$ or $q_t \dots q_0$, only two (adjacent) parts change when c_j changes.

Near-perfect schemes. But we can do even better! All (s,t)-combinations can be generated by a sequence of strongly homogeneous transitions that are either $01 \leftrightarrow 10$ or $001 \leftrightarrow 100$. In other words, we can insist that each step causes a single index c_j to change by at most 2. Let's call such generation schemes *near-perfect*.

Imposing such strong conditions actually makes it easier to discover near-perfect schemes, because comparatively few choices are available. Indeed, if we restrict ourselves to genlex methods that are near-perfect on n-bit strings, T. A. Jenkyns and D. McCarthy observed that all such methods can be easily characterized [*Ars Combinatoria* **40** (1995), 153–159]:

Theorem N. *If $st > 0$, there are exactly $2s$ near-perfect ways to list all (s,t)-combinations in a genlex order. In fact, when $1 \le a \le s$, there is exactly one such listing, N_{sta}, that begins with 1^t0^s and ends with $0^a1^t0^{s-a}$; the other s possibilities are the reverse lists, N^R_{sta}.*

Proof. The result certainly holds when $s = t = 1$; otherwise we use induction on $s + t$. The listing N_{sta}, if it exists, must have the form $1X_{s(t-1)}$, $0Y_{(s-1)t}$ for some near-perfect genlex listings $X_{s(t-1)}$ and $Y_{(s-1)t}$. If $t = 1$, $X_{s(t-1)}$ is the single string 0^s; hence $Y_{(s-1)t}$ must be $N_{(s-1)1(a-1)}$ if $a > 1$, $N_{(s-1)11}$ if $a = 1$. On the other hand if $t > 1$, the near-perfect condition implies that the last string of $X_{s(t-1)}$ cannot begin with 1; hence $X_{s(t-1)} = N_{s(t-1)b}$ for some b. If $a > 1$, $Y_{(s-1)t}$ must be $N_{(s-1)t(a-1)}$, hence b must be 1; similarly, b must be 1 if $s = 1$. Otherwise we have $a = 1 < s$, and this forces $Y_{(s-1)t} = N^R_{(s-1)tc}$ for some c. The transition from $10^b1^{t-1}0^{s-b}$ to $0^{c+1}1^t0^{s-1-c}$ is near-perfect only if $c = 1$ and $b = 2$. ∎

The proof of Theorem N yields the following recursive formulas when $st > 0$:

$$N_{sta} = \begin{cases} 1N_{s(t-1)1},\ 0N_{(s-1)t(a-1)}, & \text{if } 1 < a \le s; \\ 1N_{s(t-1)2},\ 0N^R_{(s-1)t1}, & \text{if } 1 = a < s; \\ 1N_{1(t-1)1},\ 01^t, & \text{if } 1 = a = s. \end{cases} \tag{34}$$

Also, of course, $N_{s0a} = 0^s$.

Let us set $A_{st} = N_{st1}$ and $B_{st} = N_{st2}$. These near-perfect listings, discovered by Phillip J. Chase in 1976, have the net effect of shifting a leftmost block of 1s to the right by one or two positions, respectively, and they satisfy the following mutual recursions:

$$A_{st} = 1B_{s(t-1)},\ 0A^R_{(s-1)t}; \qquad B_{st} = 1A_{s(t-1)},\ 0A_{(s-1)t}. \tag{35}$$

"To take one step forward, take two steps forward, then one step backward; to take two steps forward, take one step forward, then another." These equations

Table 2

CHASE'S SEQUENCES FOR (3, 3)-COMBINATIONS

$A_{33} = \widehat{C}_{33}^R$				$B_{33} = C_{33}$			
543	531	321	420	543	520	432	410
541	530	320	421	542	510	430	210
540	510	310	431	540	530	431	310
542	520	210	430	541	531	421	320
532	521	410	432	521	532	420	321

hold for all integer values of s and t, if we define A_{st} and B_{st} to be $\emptyset$ when s or t is negative, except that $A_{00} = B_{00} = \epsilon$ (the empty string). Thus A_{st} actually takes $\min(s, 1)$ forward steps, and B_{st} actually takes $\min(s, 2)$. For example, Table 2 shows the relevant listings for $s = t = 3$, using an equivalent index-list form $c_3c_2c_1$ instead of the bit strings $a_5a_4a_3a_2a_1a_0$.

Chase noticed that a computer implementation of these sequences becomes simpler if we define

$$C_{st} = \begin{cases} A_{st}, & \text{if } s+t \text{ is odd;} \\ B_{st}, & \text{if } s+t \text{ is even;} \end{cases} \qquad \widehat{C}_{st} = \begin{cases} A_{st}^R, & \text{if } s+t \text{ is even;} \\ B_{st}^R, & \text{if } s+t \text{ is odd.} \end{cases} \tag{36}$$

[See *Congressus Numerantium* **69** (1989), 215–242.] Then we have

$$C_{st} = \begin{cases} 1C_{s(t-1)},\ 0\widehat{C}_{(s-1)t}, & \text{if } s+t \text{ is odd;} \\ 1C_{s(t-1)},\ 0C_{(s-1)t}, & \text{if } s+t \text{ is even;} \end{cases} \tag{37}$$

$$\widehat{C}_{st} = \begin{cases} 0C_{(s-1)t},\ 1\widehat{C}_{s(t-1)}, & \text{if } s+t \text{ is even;} \\ 0\widehat{C}_{(s-1)t},\ 1\widehat{C}_{s(t-1)}, & \text{if } s+t \text{ is odd.} \end{cases} \tag{38}$$

When bit a_j is ready to change, we can tell where we are in the recursion by testing whether j is even or odd.

Indeed, the sequence C_{st} can be generated by a surprisingly simple algorithm, based on general ideas that apply to *any* genlex scheme. Let us say that bit a_j is *active* in a genlex algorithm if it is supposed to change before anything to its left is altered. (The node for an active bit in the corresponding trie is not the rightmost child of its parent.) Suppose we have an auxiliary table $w_n \ldots w_1 w_0$, where $w_j = 1$ if and only if either a_j is active or $j < r$, where r is the least subscript such that $a_r \neq a_0$; we also let $w_n = 1$. Then the following method will find the successor of $a_{n-1} \ldots a_1 a_0$:

> Set $j \leftarrow r$. If $w_j = 0$, set $w_j \leftarrow 1$, $j \leftarrow j+1$, and repeat until $w_j = 1$. Terminate if $j = n$; otherwise set $w_j \leftarrow 0$. Change a_j to $1 - a_j$, and make any other changes to $a_{j-1} \ldots a_0$ and r that apply to the particular genlex scheme being used. (39)

The beauty of this approach comes from the fact that the loop is guaranteed to be efficient: We can prove that the operation $j \leftarrow j+1$ will be performed less than once per generation step, on the average (see exercise 36).

By analyzing the transitions that occur when bits change in (37) and (38), we can readily flesh out the remaining details:

Algorithm C (*Chase's sequence*). This algorithm visits all (s,t)-combinations $a_{n-1}\ldots a_1a_0$, where $n=s+t$, in the near-perfect order of Chase's sequence C_{st}.

C1. [Initialize.] Set $a_j\leftarrow 0$ for $0\le j<s$, $a_j\leftarrow 1$ for $s\le j<n$, and $w_j\leftarrow 1$ for $0\le j\le n$. If $s>0$, set $r\leftarrow s$; otherwise set $r\leftarrow t$.

C2. [Visit.] Visit the combination $a_{n-1}\ldots a_1a_0$.

C3. [Find j and branch.] Set $j\leftarrow r$. If $w_j=0$, set $w_j\leftarrow 1$, $j\leftarrow j+1$, and repeat until $w_j=1$. Terminate if $j=n$; otherwise set $w_j\leftarrow 0$ and make a four-way branch: Go to C4 if j is odd and $a_j\neq 0$, to C5 if j is even and $a_j\neq 0$, to C6 if j is even and $a_j=0$, to C7 if j is odd and $a_j=0$.

C4. [Move right one.] Set $a_{j-1}\leftarrow 1$, $a_j\leftarrow 0$. If $r=j>1$, set $r\leftarrow j-1$; otherwise if $r=j-1$ set $r\leftarrow j$. Return to C2.

C5. [Move right two.] If $a_{j-2}\neq 0$, go to C4. Otherwise set $a_{j-2}\leftarrow 1$, $a_j\leftarrow 0$. If $r=j$, set $r\leftarrow\max(j-2,1)$; otherwise if $r=j-2$, set $r\leftarrow j-1$. Return to C2.

C6. [Move left one.] Set $a_j\leftarrow 1$, $a_{j-1}\leftarrow 0$. If $r=j>1$, set $r\leftarrow j-1$; otherwise if $r=j-2$ set $r\leftarrow j-1$. Return to C2.

C7. [Move left two.] If $a_{j-1}\neq 0$, go to C6. Otherwise set $a_j\leftarrow 1$, $a_{j-2}\leftarrow 0$. If $r=j-2$, set $r\leftarrow j$; otherwise if $r=j-1$, set $r\leftarrow j-2$. Return to C2. ∎

***Analysis of Chase's sequence.** The magical properties of Algorithm C cry out for further exploration, and a closer look turns out to be quite instructive. Given a bit string $a_{n-1}\ldots a_1a_0$, let us define $a_n=1$, $u_n=n \bmod 2$, and

$$u_j=a_{j+1}(1-u_{j+1}),\quad v_j=(u_j+j)\bmod 2,\quad w_j=(v_j+a_j)\bmod 2, \tag{40}$$

for $n>j\ge 0$. For example, we might have $n=26$ and

$$\begin{aligned} a_{25}\ldots a_1a_0&=11001001000011111101101010,\\ u_{25}\ldots u_1u_0&=10100100100001010100100101,\\ v_{25}\ldots v_1v_0&=00001110001011111110001111,\\ w_{25}\ldots w_1w_0&=11000111001000000011100101. \end{aligned} \tag{41}$$

With these definitions we can prove by induction that $v_j=0$ if and only if bit a_j is being "controlled" by C rather than by $\widehat{C}$ in the recursions (37)–(38) that generate $a_{n-1}\ldots a_1a_0$, except when a_j is part of the final run of 0s or 1s at the right end. Therefore w_j agrees with the value computed by Algorithm C at the moment when $a_{n-1}\ldots a_1a_0$ is visited, for $r\le j<n$. These formulas can be used to determine exactly where a given combination appears in Chase's sequence (see exercise 39).

If we want to work with the index-list form $c_t\ldots c_2c_1$ instead of the bit strings $a_{n-1}\ldots a_1a_0$, it is convenient to change the notation slightly, writing

$C_t(n)$ for C_{st} and $\widehat{C}_t(n)$ for $\widehat{C}_{st}$ when $s+t=n$. Then $C_0(n)=\widehat{C}_0(n)=\epsilon$, and the recursions for $t\ge 0$ take the form

$$C_{t+1}(n+1)=\begin{cases} nC_t(n),\ \widehat{C}_{t+1}(n), & \text{if } n \text{ is even;}\\ nC_t(n),\ C_{t+1}(n), & \text{if } n \text{ is odd;}\end{cases} \tag{42}$$

$$\widehat{C}_{t+1}(n+1)=\begin{cases} C_{t+1}(n),\ n\widehat{C}_t(n), & \text{if } n \text{ is odd;}\\ \widehat{C}_{t+1}(n),\ n\widehat{C}_t(n), & \text{if } n \text{ is even.}\end{cases} \tag{43}$$

These new equations can be expanded to tell us, for example, that

$$\begin{aligned} C_{t+1}(9) &= 8C_t(8),\ 6C_t(6),\ 4C_t(4),\ \ldots,\ 3\widehat{C}_t(3),\ 5\widehat{C}_t(5),\ 7\widehat{C}_t(7);\\ C_{t+1}(8) &= 7C_t(7),\ 6C_t(6),\ 4C_t(4),\ \ldots,\ 3\widehat{C}_t(3),\ 5\widehat{C}_t(5);\\ \widehat{C}_{t+1}(9) &= \quad 6C_t(6),\ 4C_t(4),\ \ldots,\ 3\widehat{C}_t(3),\ 5\widehat{C}_t(5),\ 7\widehat{C}_t(7),\ 8\widehat{C}_t(8);\\ \widehat{C}_{t+1}(8) &= \quad 6C_t(6),\ 4C_t(4),\ \ldots,\ 3\widehat{C}_t(3),\ 5\widehat{C}_t(5),\ 7\widehat{C}_t(7); \end{aligned} \tag{44}$$

notice that the same pattern predominates in all four sequences. The meaning of "..." in the middle depends on the value of t: We simply omit all terms $nC_t(n)$ and $n\widehat{C}_t(n)$ where $n<t$.

Except for edge effects at the very beginning or end, all of the expansions in (44) are based on the infinite progression

$$\ldots,\ 10,\ 8,\ 6,\ 4,\ 2,\ 0,\ 1,\ 3,\ 5,\ 7,\ 9,\ \ldots, \tag{45}$$

which is a natural way to arrange the nonnegative integers into a doubly infinite sequence. If we omit all terms of (45) that are $<t$, given any integer $t\ge 0$, the remaining terms retain the property that adjacent elements differ by either 1 or 2. Richard Stanley has suggested the name *endo-order* for this sequence, because we can remember it by thinking "even numbers decreasing, odd ...". (Notice that if we retain only the terms less than N and complement with respect to N, endo-order becomes organ-pipe order; see exercise 6.1–18.)

We could program the recursions of (42) and (43) directly, but it is interesting to unwind them using (44), thus obtaining an iterative algorithm analogous to Algorithm C. The result needs only $O(t)$ memory locations, and it is especially efficient when t is relatively small compared to n. Exercise 45 contains the details.

***Near-perfect multiset permutations.** Chase's sequences lead in a natural way to an algorithm that will generate permutations of any multiset $\{s_0\cdot 0, s_1\cdot 1, \ldots, s_d\cdot d\}$ in a near-perfect manner, meaning that

i) every transition is either $a_{j+1}a_j \leftrightarrow a_ja_{j+1}$ or $a_{j+2}a_{j+1}a_j \leftrightarrow a_ja_{j+1}a_{j+2}$;

ii) transitions of the second kind have $a_{j+1}=\min(a_j,a_{j+2})$.

Algorithm C tells us how to do this when $d=1$, and we can extend it to larger values of d by the following recursive construction [*CACM* **13** (1970), 368–369, 376]: Suppose

$$\alpha_0,\ \alpha_1,\ \ldots,\ \alpha_{N-1}$$

is any near-perfect listing of the permutations of $\{s_1 \cdot 1, \ldots, s_d \cdot d\}$. Then Algorithm C, with $s = s_0$ and $t = s_1 + \cdots + s_d$, tells us how to generate a listing

$$\Lambda_j \;=\; \alpha_j 0^s,\; \ldots,\; 0^a \alpha_j 0^{s-a} \tag{46}$$

in which all transitions are $0x \leftrightarrow x0$ or $00x \leftrightarrow x00$; the final entry has $a = 1$ or 2 leading zeros, depending on s and t. Therefore all transitions of the sequence

$$\Lambda_0,\; \Lambda_1^R,\; \Lambda_2,\; \ldots,\; (\Lambda_{N-1} \text{ or } \Lambda_{N-1}^R) \tag{47}$$

are near-perfect; and this list clearly contains all the permutations.

For example, the permutations of $\{0, 0, 0, 1, 1, 2\}$ generated in this way are

211000, 210100, 210001, 210010, 200110, 200101, 200011, 201001, 201010, 201100,
021100, 021001, 021010, 020110, 020101, 020011, 000211, 002011, 002101, 002110,
001210, 001201, 001021, 000121, 010021, 010201, 010210, 012010, 012001, 012100,
102100, 102010, 102001, 100021, 100201, 100210, 120010, 120001, 120100, 121000,
112000, 110200, 110002, 110020, 100120, 100102, 100012, 101002, 101020, 101200,
011200, 011002, 011020, 010120, 010102, 010012, 000112, 001012, 001102, 001120.

***Perfect schemes.** Why should we settle for a near-perfect generator like C_{st}, instead of insisting that all transitions have the simplest possible form $01 \leftrightarrow 10$?

One reason is that perfect schemes don't always exist. For example, we observed in 7.2.1.2–(2) that there is no way to generate all six permutations of $\{1, 1, 2, 2\}$ with adjacent interchanges; thus there is no perfect scheme for $(2, 2)$-combinations. In fact, our chances of achieving perfection are only about 1 in 4:

Theorem P. *The generation of all (s, t)-combinations $a_{s+t-1} \ldots a_1 a_0$ by adjacent interchanges $01 \leftrightarrow 10$ is possible if and only if $s \le 1$ or $t \le 1$ or st is odd.*

Proof. Consider all permutations of the multiset $\{s \cdot 0, t \cdot 1\}$. We learned in exercise 5.1.2–16 that the number m_k of such permutations having k inversions is the coefficient of z^k in the z-nomial coefficient

$$\binom{s+t}{t}_z \;=\; \prod_{k=s+1}^{s+t} (1 + z + \cdots + z^{k-1}) \Big/ \prod_{k=1}^{t} (1 + z + \cdots + z^{k-1}). \tag{48}$$

Every adjacent interchange changes the number of inversions by ± 1, so a perfect generation scheme is possible only if approximately half of all the permutations have an odd number of inversions. More precisely, the value of $\binom{s+t}{t}_{-1} = m_0 - m_1 + m_2 - \cdots$ must be 0 or ± 1. But exercise 49 shows that

$$\binom{s+t}{t}_{-1} \;=\; \binom{\lfloor (s+t)/2 \rfloor}{\lfloor t/2 \rfloor} [st \text{ is even}], \tag{49}$$

and this quantity exceeds 1 unless $s \le 1$ or $t \le 1$ or st is odd.

Conversely, perfect schemes are easy with $s \le 1$ or $t \le 1$, and they turn out to be possible also whenever st is odd. The first nontrivial case occurs for $s = t = 3$, when there are four essentially different solutions; the most symmetrical of these is

$$\begin{aligned} &210 — 310 — 410 — 510 — 520 — 521 — 531 — 532 — 432 — 431 — \\ &\quad 421 — 321 — 320 — 420 — 430 — 530 — 540 — 541 — 542 — 543 \end{aligned} \tag{50}$$

(see exercise 51). Several authors have constructed Hamiltonian paths in the relevant graph for arbitrary odd numbers s and t, most notably Eades, Hickey, and Read [*JACM* **31** (1984), 19–29], whose method makes an interesting exercise in programming with recursive coroutines. Unfortunately, however, none of the known constructions are sufficiently simple to describe in a short space, or to implement with reasonable efficiency. Perfect combination generators have therefore not yet proved to be of practical importance. ▮

In summary, then, we have seen that the study of (s,t)-combinations leads to many fascinating patterns, some of which are of great practical importance and some of which are merely elegant and/or beautiful. Fig. 26 illustrates the principal options that are available in the case $s = t = 5$, when $\binom{10}{5} = 252$ combinations arise. Lexicographic order (Algorithm L), the revolving-door Gray code (Algorithm R), the homogeneous scheme K_{55} of (31), and Chase's near-perfect scheme (Algorithm C) are shown in parts (a), (b), (c), and (d) of the illustration. Part (e) shows the near-perfect scheme that is as close to perfection as possible while still being in genlex order (see exercise 34), while part (f) is the perfect scheme of Eades, Hickey, and Read. Finally, Fig. 26(g) is a listing that proceeds by swapping $a_j \leftrightarrow a_0$, akin to Algorithm 7.2.1.2E (see exercise 55).

***Combinations of a multiset.** If multisets can have permutations, they can have combinations too. For example, consider the multiset $\{b,b,b,b,g,g,g,r,r,r,w,w\}$, representing a sack that contains four blue balls and three that are green, three red, two white. There are 37 ways to choose five balls from this sack; in lexicographic order (but descending in each combination) they are

gbbbb, *ggbbb*, *gggbb*, *rbbbb*, *rgbbb*, *rggbb*, *rgggb*, *rrbbb*, *rrgbb*, *rrggb*,
rrggg, *rrrbb*, *rrrgb*, *rrrgg*, *wbbbb*, *wgbbb*, *wggbb*, *wgggb*, *wrbbb*, *wrgbb*,
wrggb, *wrggg*, *wrrbb*, *wrrgb*, *wrrgg*, *wrrrb*, *wrrrg*, *wwbbb*, *wwgbb*, *wwggb*,
wwggg, *wwrbb*, *wwrgb*, *wwrgg*, *wwrrb*, *wwrrg*, *wwrrr*. (51)

This fact might seem frivolous and/or esoteric, yet we will see in Theorem W below that the lexicographic generation of multiset combinations yields optimal solutions to significant combinatorial problems.

James Bernoulli observed in his *Ars Conjectandi* (1713), 119–123, that we can count the number of such combinations by looking at the coefficient of z^5 in $(1+z+z^2)(1+z+z^2+z^3)^2(1+z+z^2+z^3+z^4)$. Indeed, his observation is easy to understand, because we get all possible selections from the sack if we multiply out the polynomials

$$(1+w+ww)(1+r+rr+rrr)(1+g+gg+ggg)(1+b+bb+bbb+bbbb).$$

Multiset combinations are also equivalent to *bounded compositions*, namely to compositions in which the individual parts are bounded. For example, the 37 multicombinations listed in (51) correspond to 37 solutions of

$$5 = r_3 + r_2 + r_1 + r_0, \quad 0 \le r_3 \le 2, \quad 0 \le r_2, r_1 \le 3, \quad 0 \le r_0 \le 4,$$

namely $5 = 0{+}0{+}1{+}4 = 0{+}0{+}2{+}3 = 0{+}0{+}3{+}2 = 0{+}1{+}0{+}4 = \cdots = 2{+}3{+}0{+}0$.

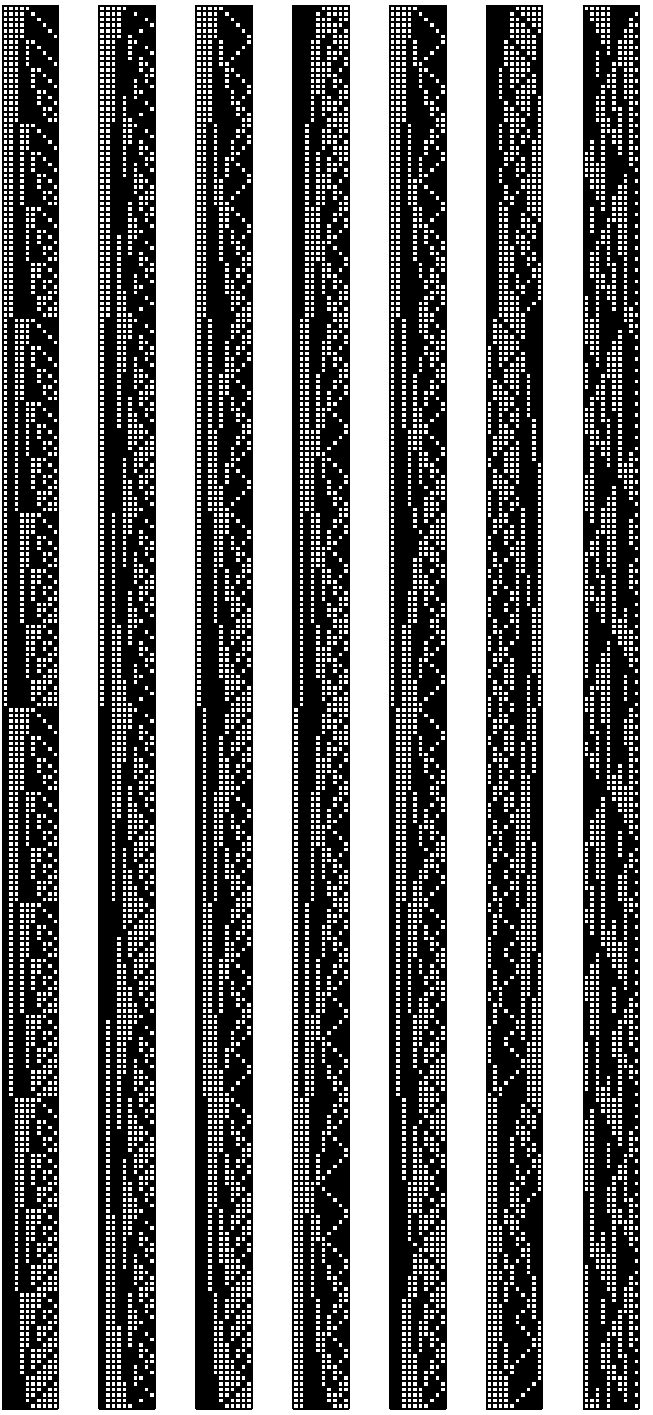


Fig. 26. Examples of $(5,5)$-combinations:
a) lexicographic;
b) revolving-door;
c) homogeneous;
d) near-perfect;
e) nearer-perfect;
f) perfect;
g) right-swapped.

Bounded compositions, in turn, are special cases of *contingency tables*, which are of great importance in statistics. And all of these combinatorial configurations can be generated with Graylike codes as well as in lexicographic order. Exercises 59–62 explore some of the basic ideas involved.

***Shadows.** Sets of combinations appear frequently in mathematics. For example, a set of 2-combinations (namely a set of pairs) is essentially a graph, and a set of t-combinations for general t is called a uniform hypergraph. If the vertices of a convex polyhedron are perturbed slightly, so that no three are collinear, no four lie in a plane, and in general no $t+1$ lie in a $(t-1)$-dimensional hyperplane, the resulting $(t-1)$-dimensional faces are "simplexes" whose vertices have great significance in computer applications. Researchers have learned that such sets of combinations have important properties related to lexicographic generation.

If α is any t-combination $c_t \dots c_2 c_1$, its *shadow* $\partial\alpha$ is the set of all its $(t-1)$-element subsets $c_{t-1} \dots c_2 c_1$, $\dots$, $c_t \dots c_3 c_1$, $c_t \dots c_3 c_2$. For example, $\partial 5310 = \{310, 510, 530, 531\}$. We can also represent a t-combination as a bit string $a_{n-1} \dots a_1 a_0$, in which case $\partial\alpha$ is the set of all strings obtained by changing a 1 to a 0: $\partial 101011 = \{001011, 100011, 101001, 101010\}$. If A is any set of t-combinations, we define its shadow

$$\partial A \;=\; \{\, \partial\alpha \mid \alpha \in A \,\} \tag{52}$$

to be the set of all $(t-1)$-combinations in the shadows of its members. For example, $\partial\partial 5310 = \{10, 30, 31, 50, 51, 53\}$.

These definitions apply also to combinations with repetitions, namely to multicombinations: $\partial 5330 = \{330, 530, 533\}$ and $\partial\partial 5330 = \{30, 33, 50, 53\}$. In general, when A is a set of t-element multisets, ∂A is a set of $(t-1)$-element multisets. Notice, however, that ∂A never has repeated elements itself.

The *upper shadow* $\partial\alpha$ with respect to a universe U is defined similarly, but it goes from t-combinations to $(t+1)$-combinations:

$$\partial\alpha \;=\; \{\, \beta \in U \mid \alpha \in \partial\beta \,\}, \qquad \text{for } \alpha \in U; \tag{53}$$

$$\partial A \;=\; \{\, \partial\alpha \mid \alpha \in A \,\}, \qquad \text{for } A \subseteq U. \tag{54}$$

If, for example, $U = \{0, 1, 2, 3, 4, 5, 6\}$, we have $\partial 5310 = \{53210, 54310, 65310\}$; on the other hand, if $U = \{\infty\cdot 0, \infty\cdot 1, \dots, \infty\cdot 6\}$, we have $\partial 5310 = \{53100, 53110, 53210, 53310, 54310, 55310, 65310\}$.

The following fundamental theorems, which have many applications in various branches of mathematics and computer science, tell us how small a set's shadows can be:

Theorem K. *If A is a set of N t-combinations contained in $U = \{0, 1, \dots, n-1\}$, then*

$$\|\partial A\| \ge \|\partial P_{Nt}\| \qquad \textit{and} \qquad \|\partial A\| \ge \|\partial Q_{Nnt}\|, \tag{55}$$

where P_{Nt} denotes the first N combinations generated by Algorithm L, namely the N lexicographically smallest combinations $c_t \dots c_2 c_1$ that satisfy (3), and Q_{Nnt} denotes the N lexicographically largest. ∎

Theorem M. *If A is a set of N t-multicombinations contained in the multiset $U = \{\infty \cdot 0, \infty \cdot 1, \ldots, \infty \cdot s\}$, then*

$$\|\partial A\| \ge \|\partial \widehat{P}_{Nt}\| \qquad \text{and} \qquad \|\varrho A\| \ge \|\varrho \widehat{Q}_{Nst}\|, \tag{56}$$

where $\widehat{P}_{Nt}$ denotes the N lexicographically smallest multicombinations $d_t \ldots d_2 d_1$ that satisfy (6)*, and $\widehat{Q}_{Nst}$ denotes the N lexicographically largest.* ∎

Both of these theorems are consequences of a stronger result that we shall prove later. Theorem K is generally called the Kruskal–Katona theorem, because it was discovered by J. B. Kruskal [*Math. Optimization Techniques*, edited by R. Bellman (1963), 251–278] and rediscovered by G. Katona [*Theory of Graphs*, Tihany 1966, edited by Erdős and Katona, (Academic Press, 1968), 187–207]; M. P. Schützenberger had previously stated it in a less-well-known publication, with incomplete proof [*RLE Quarterly Progress Report* **55** (1959), 117–118]. Theorem M goes back to F. S. Macaulay, many years earlier [*Proc. London Math. Soc.* (2) **26** (1927), 531–555].

Before proving (55) and (56), let's take a closer look at what those formulas mean. We know from Theorem L that the first N combinations visited by Algorithm L are those that precede $n_t \ldots n_2 n_1$, where

$$N = \binom{n_t}{t} + \cdots + \binom{n_2}{2} + \binom{n_1}{1}, \qquad n_t > \cdots > n_2 > n_1 \ge 0$$

is the degree-t combinatorial representation of N. Sometimes this representation has fewer than t nonzero terms, because n_j can be equal to $j-1$; let's suppress the zeros, and write

$$N = \binom{n_t}{t} + \binom{n_{t-1}}{t-1} + \cdots + \binom{n_v}{v}, \qquad n_t > n_{t-1} > \cdots > n_v \ge v \ge 1. \tag{57}$$

Now the first $\binom{n_t}{t}$ combinations $c_t \ldots c_1$ are the t-combinations of $\{0, \ldots, n_t-1\}$; the next $\binom{n_{t-1}}{t-1}$ are those in which $c_t = n_t$ and $c_{t-1} \ldots c_1$ is a $(t-1)$-combination of $\{0, \ldots, n_{t-1}-1\}$; and so on. For example, if $t = 5$ and $N = \binom{9}{5} + \binom{7}{4} + \binom{4}{3}$, the first N combinations are

$$P_{N5} = \{43210, \ldots, 87654\} \cup \{93210, \ldots, 96543\} \cup \{97210, \ldots, 97321\}. \tag{58}$$

The shadow of this set P_{N5} is, fortunately, easy to understand: It is

$$\partial P_{N5} = \{3210, \ldots, 8765\} \cup \{9210, \ldots, 9654\} \cup \{9710, \ldots, 9732\}, \tag{59}$$

namely the first $\binom{9}{4} + \binom{7}{3} + \binom{4}{2}$ combinations in lexicographic order when $t = 4$.

In other words, if we define Kruskal's function κ_t by the formula

$$\kappa_t N = \binom{n_t}{t-1} + \binom{n_{t-1}}{t-2} + \cdots + \binom{n_v}{v-1} \tag{60}$$

when N has the unique representation (57), we have

$$\partial P_{Nt} \;=\; P_{(\kappa_t N)(t-1)}. \tag{61}$$

Theorem K tells us, for example, that a graph with a million edges can contain at most

$$\binom{1414}{3}+\binom{1009}{2} = 470{,}700{,}300$$

triangles, that is, at most 470,700,300 sets of vertices $\{u,v,w\}$ with u — v — w — u. The reason is that $1000000=\binom{1414}{2}+\binom{1009}{1}$ by exercise 17, and the edges $P_{(1000000)_2}$ do support $\binom{1414}{3}+\binom{1009}{2}$ triangles; but if there were more, the graph would necessarily have at least $\kappa_3 470700301 = \binom{1414}{2}+\binom{1009}{1}+\binom{1}{0} = 1000001$ edges in their shadow.

Kruskal defined the companion function

$$\lambda_t N = \binom{n_t}{t+1}+\binom{n_{t-1}}{t}+\cdots+\binom{n_v}{v+1} \tag{62}$$

to deal with questions such as this. The κ and λ functions are related by an interesting law proved in exercise 71:

$$M+N=\binom{s+t}{t} \quad\text{implies}\quad \kappa_s M+\lambda_t N = \binom{s+t}{t+1}, \quad \text{if } st>0. \tag{63}$$

Turning to Theorem M, the sizes of $\partial\widehat{P}_{Nt}$ and $\varrho\widehat{Q}_{Nst}$ turn out to be

$$\|\partial\widehat{P}_{Nt}\| = \mu_t N \qquad\text{and}\qquad \|\varrho\widehat{Q}_{Nst}\| = N+\kappa_s N \tag{64}$$

(see exercise 80), where the function μ_t satisfies

$$\mu_t N = \binom{n_t-1}{t-1}+\binom{n_{t-1}-1}{t-2}+\cdots+\binom{n_v-1}{v-1} \tag{65}$$

when N has the combinatorial representation (57).

Table 3 shows how these functions $\kappa_t N$, $\lambda_t N$, and $\mu_t N$ behave for small values of t and N. When t and N are large, they can be well approximated in terms of a remarkable function $\tau(x)$ introduced by Teiji Takagi in 1903; see Fig. 27 and exercises 81–84.

Theorems K and M are corollaries of a much more general theorem of discrete geometry, discovered by Da-Lun Wang and Ping Wang [*SIAM J. Applied Math.* **33** (1977), 55–59], which we shall now proceed to investigate. Consider the *discrete n-dimensional torus* $T(m_1,\ldots,m_n)$ whose elements are integer vectors $x=(x_1,\ldots,x_n)$ with $0\le x_1<m_1$, …, $0\le x_n<m_n$. We define the sum and difference of two such vectors x and y as in Eqs. 4.3.2–(2) and 4.3.2–(3):

$$x+y = \big((x_1+y_1) \bmod m_1,\ldots,(x_n+y_n) \bmod m_n\big), \tag{66}$$
$$x-y = \big((x_1-y_1) \bmod m_1,\ldots,(x_n-y_n) \bmod m_n\big). \tag{67}$$

We also define the so-called *cross order* on such vectors by saying that $x\preceq y$ if and only if

$$\nu x<\nu y \quad\text{or}\quad (\nu x=\nu y \text{ and } x\ge y \text{ lexicographically}); \tag{68}$$

here, as usual, $\nu(x_1,\ldots,x_n)=x_1+\cdots+x_n$. For example, when $m_1=m_2=2$ and $m_3=3$, the 12 vectors $x_1x_2x_3$ in cross order are

$$000,\ 100,\ 010,\ 001,\ 110,\ 101,\ 011,\ 002,\ 111,\ 102,\ 012,\ 112, \tag{69}$$

Table 3

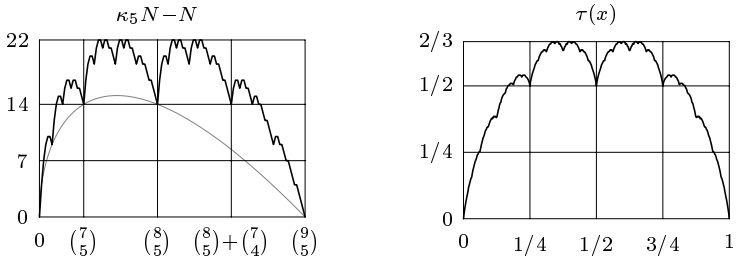

Fig. 27. Approximating a Kruskal function with the Takagi function. (The smooth curve in the left-hand graph is the lower bound $\underline{\kappa}_5 N - N$ of exercise 79.)

omitting parentheses and commas for convenience. The *complement* of a vector in $T(m_1, \ldots, m_n)$ is

$$\overline{x} \;=\; (m_1 - 1 - x_1, \ldots, m_n - 1 - x_n). \tag{70}$$

Notice that $x \preceq y$ holds if and only if $\overline{x} \succeq \overline{y}$. Therefore we have

$$\operatorname{rank}(x) + \operatorname{rank}(\overline{x}) \;=\; T - 1, \qquad \text{where } T = m_1 \ldots m_n, \tag{71}$$

if $\operatorname{rank}(x)$ denotes the number of vectors that precede x in cross order.

We will find it convenient to call the vectors "points" and to name the points e_0, e_1, $\ldots$, e_{T-1} in increasing cross order. Thus we have $e_7 = 002$ in (69), and $\overline{e}_r = e_{T-1-r}$ in general. Notice that

$$e_1 = 100\ldots00, \quad e_2 = 010\ldots00, \quad \ldots, \quad e_n = 000\ldots01; \tag{72}$$

these are the so-called *unit vectors*. The set

$$S_N = \{e_0, e_1, \ldots, e_{N-1}\} \tag{73}$$

consisting of the smallest N points is called a *standard set*, and in the special case $N = n + 1$ we write

$$E = \{e_0, e_1, \ldots, e_n\} = \{000\ldots00, 100\ldots00, 010\ldots00, \ldots, 000\ldots01\}. \tag{74}$$

Any set of points X has a *spread* X^+, a *core* X°, and a *dual* $X^\sim$, defined by the rules

$$X^+ = \{\, x \in S_T \mid x \in X \text{ or } x - e_1 \in X \text{ or } \cdots \text{ or } x - e_n \in X \,\}; \tag{75}$$

$$X^\circ = \{\, x \in S_T \mid x \in X \text{ and } x + e_1 \in X \text{ and } \cdots \text{ and } x + e_n \in X \,\}; \tag{76}$$

$$X^\sim = \{\, x \in S_T \mid \overline{x} \notin X \,\}. \tag{77}$$

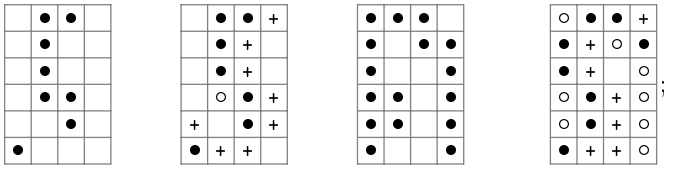
We can also define the spread of X algebraically, writing

$$X^+ = X + E, \tag{78}$$

where $X + Y$ denotes $\{\, x + y \mid x \in X \text{ and } y \in Y \,\}$. Clearly

$$X^+ \subseteq Y \qquad \text{if and only if} \qquad X \subseteq Y^\circ. \tag{79}$$

These notions can be illustrated in the two-dimensional case $m_1 = 4$, $m_2 = 6$, by the more-or-less random toroidal arrangements



X $\quad$ X° and X^+ $\quad$ $X^\sim$ $\quad$ $X^{\sim\circ}$ and $X^{\sim+}$; (80)

here X consists of points marked $\bullet$ or $\circ$, X° comprises just the $\circ$s, and X^+ consists of $+$s plus $\bullet$s plus $\circ$s. Notice that if we rotate the diagram for $X^{\sim\circ}$ and $X^{\sim+}$ by 180°, we obtain the diagram for X° and X^+, but with $(\bullet, \circ, +, \ )$ respectively changed to $(+, \ , \bullet, \circ)$; and in fact the identities

$$X^\circ = X^{\sim+\sim}, \qquad X^+ = X^{\sim\circ\sim} \tag{81}$$

hold in general (see exercise 85).

Now we are ready to state the theorem of Wang and Wang:

Theorem W. *Let X be any set of N points in the discrete torus $T(m_1, \ldots, m_n)$, where $m_1 \le \cdots \le m_n$. Then $\|X^+\| \ge \|S_N^+\|$ and $\|X^\circ\| \le \|S_N^\circ\|$.*

In other words, the standard sets S_N have the smallest spread and largest core, among all N-point sets. We will prove this result by following a general approach first used by F. W. J. Whipple to prove Theorem M [*Proc. London Math. Soc.* (2) **28** (1928), 431–437]. The first step is to prove that the spread and the core of standard sets are standard:

Lemma S. *There are functions α and β such that $S_N^+ = S_{\alpha N}$ and $S_N^\circ = S_{\beta N}$.*

Proof. We may assume that $N > 0$. Let r be maximum with $e_r \in S_N^+$, and let $\alpha N = r + 1$; we must prove that $e_q \in S_N^+$ for $0 \le q < r$. Suppose $e_q = x = (x_1, \ldots, x_n)$ and $e_r = y = (y_1, \ldots, y_n)$, and let k be the largest subscript with $x_k > 0$. Since $y \in S_N^+$, there is a subscript j such that $y - e_j \in S_N$. It suffices to prove that $x - e_k \preceq y - e_j$, and exercise 87 does this.

The second part follows from (81), with $\beta N = T - \alpha(T - N)$, because $S_N^\sim = S_{T-N}$. ∎

Theorem W is obviously true when $n = 1$, so we assume by induction that it has been proved in $n - 1$ dimensions. The next step is to *compress* the given set X in the kth coordinate position, by partitioning it into disjoint sets

$$X_k(a) \;=\; \{\, x \in X \mid x_k = a \,\} \tag{82}$$

for $0 \le a < m_k$ and replacing each $X_k(a)$ by

$$X'_k(a) \;=\; \{\, (s_1, \ldots, s_{k-1}, a, s_k, \ldots, s_{n-1}) \mid (s_1, \ldots, s_{n-1}) \in S_{\|X_k(a)\|} \,\}, \tag{83}$$

a set with the same number of elements. The sets S used in (83) are standard in the $(n-1)$-dimensional torus $T(m_1, \ldots, m_{k-1}, m_{k+1}, \ldots, m_n)$. Notice that we have $(x_1, \ldots, x_{k-1}, a, x_{k+1}, \ldots, x_n) \preceq (y_1, \ldots, y_{k-1}, a, y_{k+1}, \ldots, y_n)$ if and only if $(x_1, \ldots, x_{k-1}, x_{k+1}, \ldots, x_n) \preceq (y_1, \ldots, y_{k-1}, y_{k+1}, \ldots, y_n)$; therefore $X'_k(a) = X_k(a)$ if and only if the $(n-1)$-dimensional points $(x_1, \ldots, x_{k-1}, x_{k+1}, \ldots, x_n)$ with $(x_1, \ldots, x_{k-1}, a, x_{k+1}, \ldots, x_n) \in X$ are as small as possible when projected onto the $(n-1)$-dimensional torus. We let

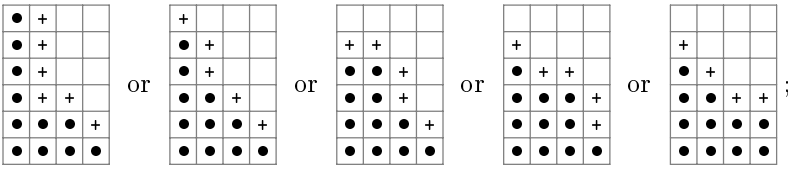
$$C_k X \;=\; X'_k(0) \cup X'_k(1) \cup \cdots \cup X'_k(m_k - 1) \tag{84}$$

be the compression of X in position k. Exercise 89 proves the basic fact that compression does not increase the size of the spread:

$$\|X^+\| \;\ge\; \|(C_k\, X)^+\|, \qquad \text{for } 1 \le k \le n. \tag{85}$$

Furthermore, if compression changes X, it replaces some of the elements by other elements of lower rank. Therefore we need only prove Theorem W for sets X that are totally compressed, having $X = C_k\, X$ for all k.

Consider, for example, the case $n = 2$. A totally compressed set in two dimensions has all points moved to the left of their rows and the bottom of their columns, as in



the rightmost of these is standard, and has the smallest spread. Exercise 90 completes the proof of Theorem W in two dimensions.

When $n > 2$, suppose $x = (x_1, \ldots, x_n) \in X$ and $x_j > 0$. The condition $C_k X = X$ implies that, if $0 \le i < j$ and $i \ne k \ne j$, we have $x + e_i - e_j \in X$. Applying this fact for three values of k tells us that $x + e_i - e_j \in X$ whenever $0 \le i < j$. Consequently

$$X_n(a) + E_n(0) \;\subseteq\; X_n(a-1) + e_n \quad \text{for } 0 < a < m, \tag{86}$$

where $m = m_n$ and $E_n(0)$ is a clever abbreviation for the set $\{e_0, \ldots, e_{n-1}\}$.

Let $X_n(a)$ have N_a elements, so that $N = \|X\| = N_0 + N_1 + \cdots + N_{m-1}$, and let $Y = X^+$. Then

$$Y_n(a) \;=\; \big(X_n\big((a-1) \bmod m\big) + e_n\big) \cup \big(X_n(a) + E_n(0)\big)$$

is standard in $n-1$ dimensions, and (86) tells us that

$$N_{m-1} \le \beta N_{m-2} \le N_{m-2} \le \cdots \le N_1 \le \beta N_0 \le N_0 \le \alpha N_0,$$

where α and β refer to coordinates 1 through $n-1$. Therefore

$$\begin{aligned} \|Y\| &= \|Y_n(0)\| + \|Y_n(1)\| + \|Y_n(2)\| + \cdots + \|Y_n(m-1)\| \\ &= \alpha N_0 + N_0 + N_1 + \cdots + N_{m-2} = \alpha N_0 + N - N_{m-1}. \end{aligned}$$

The proof of Theorem W now has a beautiful conclusion. Let $Z = S_N$, and suppose $\|Z_n(a)\| = M_a$. We want to prove that $\|Y\| \ge \|Z^+\|$, namely that

$$\alpha N_0 + N - N_{m-1} \;\ge\; \alpha M_0 + N - M_{m-1}, \tag{87}$$

because the arguments of the previous paragraph apply to Z as well as to X. We will prove (87) by showing that $N_{m-1} \le M_{m-1}$ and $N_0 \ge M_0$.

Using the $(n-1)$-dimensional α and β functions, let us define

$$N'_{m-1} = N_{m-1},\; N'_{m-2} = \alpha N'_{m-1},\; \ldots,\; N'_1 = \alpha N'_2,\; N'_0 = \alpha N'_1; \tag{88}$$

$$N''_0 = N_0,\; N''_1 = \beta N''_0,\; N''_2 = \beta N''_1,\; \ldots,\; N''_{m-1} = \beta N''_{m-2}. \tag{89}$$

Then we have $N'_a \le N_a \le N''_a$ for $0 \le a < m$, and it follows that

$$N' = N'_0 + N'_1 + \cdots + N'_{m-1} \;\le\; N \;\le\; N'' = N''_0 + N''_1 + \cdots + N''_{m-1}. \tag{89}$$

Exercise 91 proves that the standard set $Z'' = S_{N''}$ has exactly N''_a elements with nth coordinate equal to a, for each a; and by the duality between α and β, the standard set $Z' = S_{N'}$ likewise has exactly N'_a elements with nth coordinate a. Finally, therefore,

$$\begin{aligned} M_{m-1} = \|Z_n(m-1)\| &\ge \|Z'_n(m-1)\| = N_{m-1}, \\ M_0 = \|Z_n(0)\| &\le \|Z''_n(0)\| = N_0, \end{aligned}$$

because $Z' \subseteq Z \subseteq Z''$ by (89). ∎

Now we are ready to prove the claimed results about shadows, which are in fact special cases of a more general theorem of Clements and Lindström that applies to arbitrary multisets [*J. Combinatorial Theory* **7** (1969), 230–238]:

Corollary C. *If A is a set of N t-multicombinations contained in the multiset $U = \{s_0 \cdot 0, s_1 \cdot 1, \ldots, s_d \cdot d\}$, where $s_0 \geq s_1 \geq \cdots \geq s_d$, then*

$$\|\partial A\| \geq \|\partial P_{Nt}\| \qquad \text{and} \qquad \|\varrho A\| \geq \|\varrho Q_{Nt}\|, \tag{90}$$

where P_{Nt} denotes the N lexicographically smallest multicombinations $c_t \ldots c_2 c_1$ of U, and Q_{Nt} denotes the N lexicographically largest.

Proof. Multicombinations of U can be represented as points $x_1 \ldots x_n$ of the torus $T(m_1, \ldots, m_n)$, where $n = d + 1$ and $m_j = s_{n-j} + 1$; we let x_j be the number of occurrences of $n - j$. This correspondence preserves lexicographic order. For example, if $U = \{0, 0, 0, 1, 1, 2, 3\}$, its 3-multicombinations are

$$000,\ 100,\ 110,\ 200,\ 210,\ 211,\ 300,\ 310,\ 311,\ 321, \tag{91}$$

in lexicographic order, and the corresponding points $x_1 x_2 x_3 x_4$ are

$$0003, 0012, 0021, 0102, 0111, 0120, 1002, 1011, 1020, 1110. \tag{92}$$

Let T_w be the points of the torus that have weight $x_1 + \cdots + x_n = w$. Then every allowable set A of t-multicombinations is a subset of T_t. Furthermore—and this is the main point—the spread of $T_0 \cup T_1 \cup \cdots \cup T_{t-1} \cup A$ is

$$\begin{aligned} (T_0 \cup T_1 \cup \cdots \cup T_{t-1} \cup A)^+ &= T_0^+ \cup T_1^+ \cup \cdots \cup T_{t-1}^+ \cup A^+ \\ &= T_0 \cup T_1 \cup \cdots \cup T_t \cup \varrho A. \end{aligned} \tag{93}$$

Thus the upper shadow ϱA is simply $(T_0 \cup T_1 \cup \cdots \cup T_{t-1} \cup A)^+ \cap T_{t+1}$, and Theorem W tells us that $\|A\| = N$ implies $\|\varrho A\| \geq \|\varrho(S_{M+N} \cap T_t)\|$, where $M = \|T_0 \cup \cdots \cup T_{t-1}\|$. Hence, by the definition of cross order, $S_{M+N} \cup T_t$ consists of the lexicographically largest N t-multicombinations, namely Q_{Nt}.

The proof that $\|\partial A\| \geq \|\partial P_{Nt}\|$ follows by complementation (see exercise 93). ∎

EXERCISES

1. [*M23*] Explain why Golomb's rule (8) makes all sets $\{c_1, \ldots, c_t\} \subseteq \{0, \ldots, n-1\}$ correspond uniquely to multisets $\{e_1, \ldots, e_t\} \subseteq \{\infty \cdot 0, \ldots, \infty \cdot n - t\}$.

2. [*16*] What path in an 11×13 grid corresponds to the bit string (113)?

▸ **3.** [*21*] (R. R. Fenichel, 1968.) Show that the compositions $q_t + \cdots + q_1 + q_0$ of s into $t + 1$ nonnegative parts can be generated in lexicographic order by a simple loopless algorithm.

4. [*16*] Show that every composition $q_t \ldots q_0$ of s into $t+1$ nonnegative parts corresponds to a composition $r_s \ldots r_0$ of t into $s+1$ nonnegative parts. What composition corresponds to 10224000001010 under this correspondence?

▸ **5.** [*20*] What is a good way to generate all of the integer solutions to the following systems of inequalities?

a) $n > x_t \geq x_{t-1} > x_{t-2} \geq x_{t-3} > \cdots > x_1 \geq 0$, when t is odd.

b) $n \gg x_t \gg x_{t-1} \gg \cdots \gg x_2 \gg x_1 \gg 0$, where $a \gg b$ means $a \geq b + 2$.

6. [*M22*] How often is each step of Algorithm T performed?

7. [*22*] Design an algorithm that runs through the "dual" combinations $b_s \dots b_2 b_1$ in *decreasing* lexicographic order (see (5) and Table 1). Like Algorithm T, your algorithm should avoid redundant assignments and unnecessary searching.

8. [*M23*] Design an algorithm that generates all (s,t)-combinations $a_{n-1} \dots a_1 a_0$ lexicographically in bitstring form. The total running time should be $O\binom{n}{t}$, assuming that $st > 0$.

9. [*M26*] When all (s,t)-combinations $a_{n-1} \dots a_1 a_0$ are listed in lexicographic order, let $2A_{st}$ be the total number of bit changes between adjacent strings. For example, $A_{33} = 25$ because there are respectively

$$2+2+2+4+2+2+4+2+2+6+2+2+4+2+2+4+2+2+2 = 50$$

bit changes between the 20 strings in Table 1.

a) Show that $A_{st} = \min(s,t) + A_{(s-1)t} + A_{s(t-1)}$ when $st > 0$; $A_{st} = 0$ when $st = 0$.

b) Prove that $A_{st} < 2\binom{s+t}{t}$.

▸ **10.** [*21*] The "World Series" of baseball is traditionally a competition in which the American League champion (A) plays the National League champion (N) until one of them has beaten the other four times. What is a good way to list all possible scenarios AAAA, AAANA, AAANNA, ..., NNNN? What is a simple way to assign consecutive integers to those scenarios?

11. [*19*] Which of the scenarios in exercise 10 occurred most often during the 1900s? Which of them never occurred? [*Hint:* World Series scores are easily found on the Internet.]

12. [*HM32*] A set V of n-bit vectors that is closed under addition modulo 2 is called a *binary vector space*.

a) Prove that every such V contains 2^t elements, for some integer t, and can be represented as the set $\{x_1\alpha_1 \oplus \cdots \oplus x_t\alpha_t \mid 0 \le x_1, \dots, x_t \le 1\}$ where the vectors $\alpha_1, \dots, \alpha_t$ form a "canonical basis" with the following property: There is a t-combination $c_t \dots c_2 c_1$ of $\{0, 1, \dots, n-1\}$ such that, if α_k is the binary vector $a_{k(n-1)} \dots a_{k1} a_{k0}$, we have

$$a_{kc_j} = [j = k] \quad \text{for } 1 \le j,k \le t; \qquad\qquad a_{kl} = 0 \quad \text{for } 0 \le l < c_k,\ 1 \le k \le t.$$

For example, the canonical bases with $n = 9$, $t = 4$, and $c_4c_3c_2c_1 = 7641$ have the general form

$$\begin{aligned} \alpha_1 &= *\,0\,0\,*\,0\,*\,*\,1\,0, \\ \alpha_2 &= *\,0\,0\,*\,1\,0\,0\,0\,0, \\ \alpha_3 &= *\,0\,1\,0\,0\,0\,0\,0\,0, \\ \alpha_4 &= *\,1\,0\,0\,0\,0\,0\,0\,0; \end{aligned}$$

there are 2^8 ways to replace the eight asterisks by 0s and/or 1s, and each of these defines a canonical basis. We call t the dimension of V.

b) How many t-dimensional spaces are possible with n-bit vectors?

c) Design an algorithm to generate all canonical bases $(\alpha_1, \dots, \alpha_t)$ of dimension t. *Hint:* Let the associated combinations $c_t \dots c_1$ increase lexicographically as in Algorithm L.

d) What is the 1000000th basis visited by your algorithm when $n = 9$ and $t = 4$?

13. [*25*] A one-dimensional *Ising configuration* of length n, weight t, and energy r, is a binary string $a_{n-1} \dots a_0$ such that $\sum_{j=0}^{n-1} a_j = t$ and $\sum_{j=1}^{n-1} b_j = r$, where $b_j =$

$a_j \oplus a_{j-1}$. For example, $a_{12} \ldots a_0 = 1100100100011$ has weight 6 and energy 6, since $b_{12} \ldots b_1 = 010110110010$.

Design an algorithm to generate all such configurations, given n, t, and r.

14. [*26*] When the binary strings $a_{n-1} \ldots a_1 a_0$ of (s,t)-combinations are generated in lexicographic order, we sometimes need to change $2\min(s,t)$ bits to get from one combination to the next. For example, 011100 is followed by 100011 in Table 1. Therefore we apparently cannot hope to generate all combinations with a loopless algorithm unless we visit them in some other order.

Show, however, that there actually is a way to compute the lexicographic successor of a given combination in $O(1)$ steps, if each combination is represented indirectly in a doubly linked list as follows: There are arrays $l[0], \ldots, l[n]$ and $r[0], \ldots, r[n]$ such that $l[r[j]] = j$ for $0 \le j \le n$. If $x_0 = l[0]$ and $x_j = l[x_{j-1}]$ for $0 < j < n$, then $a_j = [x_j > s]$ for $0 \le j < n$.

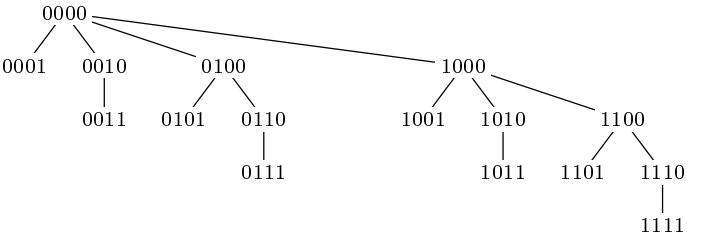
15. [*M22*] Use the fact that dual combinations $b_s \ldots b_2 b_1$ occur in reverse lexicographic order to prove that the sum $\binom{b_s}{s} + \cdots + \binom{b_2}{2} + \binom{b_1}{1}$ has a simple relation to the sum $\binom{c_t}{t} + \cdots + \binom{c_2}{2} + \binom{c_1}{1}$.

16. [*M21*] What is the millionth combination generated by Algorithm L when t is (a) 2? (b) 3? (c) 4? (d) 5? (e) 1000000?

17. [*HM25*] Given N and t, what is a good way to compute the combinatorial representation (20)?

▸ **18.** [*20*] What binary tree do we get when the binomial tree T_n is represented by "right child" and "left sibling" pointers as in exercise 2.3.2–5?

19. [*21*] Instead of labeling the branches of the binomial tree T_4 as shown in (22), we could label each node with the bit string of its corresponding combination:



If T_∞ has been labeled in this way, suppressing leading zeros, preorder is the same as the ordinary increasing order of binary notation; so the millionth node turns out to be 11111010000010001111111. But what is the millionth node of T_∞ in *postorder*?

20. [*M20*] Find generating functions g and h such that Algorithm F finds exactly $[z^N]\, g(z)$ feasible combinations and sets $t \leftarrow t+1$ exactly $[z^N]\, h(z)$ times.

21. [*M22*] Prove the alternating combination law (30).

22. [*M23*] What is the millionth revolving-door combination visited by Algorithm R when t is (a) 2? (b) 3? (c) 4? (d) 5? (e) 1000000?

23. [*M23*] Suppose we augment Algorithm R by setting $j \leftarrow t+1$ in step R1, and $j \leftarrow 1$ if R3 goes directly to R2. Find the probability distribution of j, and its average value. What does this imply about the running time of the algorithm?

▸ **24.** [*M25*] (W. H. Payne, 1974.) Continuing the previous exercise, let j_k be the value of j on the kth visit by Algorithm R. Show that $|j_{k+1} - j_k| \le 2$, and explain how to make the algorithm loopless by exploiting this property.

25. [*M35*] Let $c_t \dots c_2 c_1$ and $c'_t \dots c'_2 c'_1$ be the Nth and N'th combinations generated by the revolving-door method, Algorithm R. If the set $C = \{c_t, \dots, c_2, c_1\}$ has m elements not in $C' = \{c'_t, \dots, c'_2, c'_1\}$, prove that $|N - N'| > \sum_{k=1}^{m-1} \binom{2k}{k-1}$.

26. [*26*] Do elements of the *ternary* reflected Gray path have properties similar to the revolving-door Gray code Γ_{st}, if we extract only the n-tuples $a_{n-1} \dots a_1 a_0$ such that (a) $a_{n-1} + \cdots + a_1 + a_0 = t$? (b) $\{a_{n-1}, \dots, a_1, a_0\} = \{r \cdot 0, s \cdot 1, t \cdot 2\}$?

▸ **27.** [*25*] Show that there is a simple way to generate all combinations of *at most* t elements of $\{0, 1, \dots, n-1\}$, using only Gray-code-like transitions $0 \leftrightarrow 1$ and $01 \leftrightarrow 10$. (In other words, each step should either insert a new element, delete an element, or shift an element by ± 1.) For example,

0000, 0001, 0011, 0010, 0110, 0101, 0100, 1100, 1010, 1001, 1000

is one such sequence when $n = 4$ and $t = 2$. *Hint:* Think of Chinese rings.

28. [*M21*] True or false: A listing of (s,t)-combinations $a_{n-1} \dots a_1 a_0$ in bitstring form is in genlex order if and only if the corresponding index-form listings $b_s \dots b_2 b_1$ (for the 0s) and $c_t \dots c_2 c_1$ (for the 1s) are both in genlex order.

▸ **29.** [*M28*] (P. J. Chase.) Given a string on the symbols `+`, `-`, and `0`, say that an *R-block* is a substring of the form $\texttt{-}^{k+1}$ that is preceded by `0` and not followed by `-`; an *L-block* is a substring of the form $\texttt{+-}^{k}$ that is followed by `0`; in both cases $k \ge 0$. For example, the string `+00++-++-000-` has two L-blocks and one R-block, shown in gray. Notice that blocks cannot overlap.

We form the *successor* of such a string as follows, whenever at least one block is present: Replace the rightmost $\texttt{0-}^{k+1}$ by $\texttt{-+}^{k}\texttt{0}$, if the rightmost block is an R-block; otherwise replace the rightmost $\texttt{+-}^{k}\texttt{0}$ by $\texttt{0+}^{k+1}$. Also negate the first sign, if any, that appears to the right of the block that has been changed. For example,

$$\texttt{-+00++-} \to \texttt{-0+0-+-} \to \texttt{-0+--0--} \to \texttt{-0+--+0} \to \texttt{-0+--0+} \to \texttt{-00+++-},$$

where the notation $\alpha \to \beta$ means that β is the successor of α.

a) What strings have no blocks (and therefore no successor)?
b) Can there be a cycle of strings with $\alpha_0 \to \alpha_1 \to \cdots \to \alpha_{k-1} \to \alpha_0$?
c) Prove that if $\alpha \to \beta$ then $-\beta \to -\alpha$, where "$-$" means "negate all the signs." (Therefore every string has at most one predecessor.)
d) Show that if $\alpha_0 \to \alpha_1 \to \cdots \to \alpha_k$ and $k > 0$, the strings α_0 and α_k do not have all their `0`s in the same positions. (Therefore, if α_0 has s signs and t zeros, k must be less than $\binom{s+t}{t}$.)
e) Prove that every string α with s signs and t zeros belongs to exactly one chain $\alpha_0 \to \alpha_1 \to \cdots \to \alpha_{\binom{s+t}{t}-1}$.

30. [*M32*] The previous exercise defines 2^s ways to generate all combinations of s 0s and t 1s, via the mapping `+` $\mapsto$ 0, `-` $\mapsto$ 0, and `0` $\mapsto$ 1. Show that each of these ways is a homogeneous genlex sequence, definable by an appropriate recurrence. Is Chase's sequence (37) a special case of this general construction?

31. [*M23*] How many genlex listings of (s,t)-combinations are possible in (a) bitstring form $a_{n-1} \dots a_1 a_0$? (b) index-list form $c_t \dots c_2 c_1$?

▸ **32.** [*M30*] How many of the genlex listings of (s,t)-combination strings $a_{n-1}\ldots a_1a_0$ (a) have the revolving-door property? (b) are homogeneous?

33. [*HM31*] How many of the genlex listings in exercise 31(b) are near-perfect?

34. [*M30*] Continuing exercise 33, explain how to find such schemes that are as near as possible to perfection, in the sense that the number of "imperfect" transitions $c_j \leftarrow c_j \pm 2$ is minimized, when s and t are not too large.

35. [*M26*] How many steps of Chase's sequence C_{st} use an imperfect transition?

▸ **36.** [*M21*] Prove that method (39) performs the operation $j \leftarrow j+1$ a total of exactly $\binom{s+t}{t}-1$ times as it generates all (s,t)-combinations $a_{n-1}\ldots a_1a_0$, given any genlex scheme for combinations in bitstring form.

▸ **37.** [*27*] What algorithm results when the general genlex method (39) is used to produce (s,t)-combinations $a_{n-1}\ldots a_1a_0$ in (a) lexicographic order? (b) the revolving-door order of Algorithm R? (c) the homogeneous order of (31)?

38. [*26*] Design a genlex algorithm like Algorithm C for the *reverse* sequence C^R_{st}.

39. [*M21*] When $s=12$ and $t=14$, how many combinations precede the bit string 11001001000011111101101010 in Chase's sequence C_{st}? (See (41).)

40. [*M22*] What is the millionth combination in Chase's sequence C_{st}, when $s=12$ and $t=14$?

41. [*M27*] Show that there is a permutation $c(0)$, $c(1)$, $c(2)$, ... of the nonnegative integers such that the elements of Chase's sequence C_{st} are obtained by complementing the least significant $s+t$ bits of the elements $c(k)$ for $0\le k<2^{s+t}$ that have weight $\nu(c(k))=s$. (Thus the sequence $\bar c(0)$, ..., $\bar c(2^n-1)$ contains, as subsequences, all of the C_{st} for which $s+t=n$, just as Gray binary code $g(0)$, ..., $g(2^n-1)$ contains all the revolving-door sequences Γ_{st}.) Explain how to compute the binary representation $c(k)=(\ldots a_2a_1a_0)_2$ from the binary representation $k=(\ldots b_2b_1b_0)_2$.

42. [*HM34*] Use generating functions of the form $\sum_{s,t} g_{st}w^sz^t$ to analyze each step of Algorithm C.

43. [*20*] Prove or disprove: If $s(x)$ and $p(x)$ denote respectively the successor and predecessor of x in endo-order, then $s(x+1)=p(x)+1$.

▸ **44.** [*M21*] Let $C_t(n)-1$ denote the sequence obtained from $C_t(n)$ by striking out all combinations with $c_1=0$, then replacing $c_t\ldots c_1$ by $(c_t-1)\ldots(c_1-1)$ in the combinations that remain. Show that $C_t(n)-1$ is near-perfect.

45. [*32*] Exploit endo-order and the expansions sketched in (44) to generate the combinations $c_t\ldots c_2c_1$ of Chase's sequence $C_t(n)$ with a nonrecursive procedure.

▸ **46.** [*33*] Construct a nonrecursive algorithm for the dual combinations $b_s\ldots b_2b_1$ of Chase's sequence C_{st}, namely the positions of the zeros in $a_{n-1}\ldots a_1a_0$.

47. [*26*] Implement the near-perfect multiset permutation method of (46) and (47).

48. [*M21*] Suppose α_0, α_1, ..., α_{N-1} is any listing of the permutations of the multiset $\{s_1\cdot 1,\ldots,s_d\cdot d\}$, where α_k differs from α_{k+1} by the interchange of two elements. Let β_0, ..., β_{M-1} be any revolving-door listing for (s,t)-combinations, where $s=s_0$, $t=s_1+\cdots+s_d$, and $M=\binom{s+t}{t}$. Then let Λ_j be the list of M elements obtained by starting with $\alpha_j\uparrow\beta_0$ and applying the revolving-door exchanges; here $\alpha\uparrow\beta$ denotes the string obtained by substituting the elements of α for the 1s in β, preserving left-right order. For example, if β_0, ..., β_{M-1} is 0110, 0101, 1100, 1001, 0011, 1010, and if $\alpha_j=12$,

then Λ_j is 0120, 0102, 1200, 1002, 0012, 1020. (The revolving-door listing need *not* be homogeneous.)

Prove that the list (47) contains all permutations of $\{s_0 \cdot 0, s_1 \cdot 1, \ldots, s_d \cdot d\}$, and that adjacent permutations differ from each other by the interchange of two elements.

49. [*HM23*] If q is a primitive mth root of unity, such as $e^{2\pi i/m}$, show that

$$\binom{n}{k}_q = \binom{\lfloor n/m \rfloor}{\lfloor k/m \rfloor} \binom{n \bmod m}{k \bmod m}_q.$$

▸ **50.** [*HM25*] Extend the formula of the previous exercise to *q-multinomial* coefficients

$$\binom{n_1 + \cdots + n_t}{n_1, \ldots, n_t}_q.$$

51. [*25*] Find all Hamiltonian paths in the graph whose vertices are permutations of $\{0, 0, 0, 1, 1, 1\}$ related by adjacent transposition. Which of those paths are equivalent under the operations of interchanging 0s with 1s and/or left-right reflection?

52. [*M37*] Generalizing Theorem P, find a necessary and sufficient condition that all permutations of the multiset $\{s_0 \cdot 0, \ldots, s_d \cdot d\}$ can be generated by adjacent transpositions $a_j a_{j-1} \leftrightarrow a_{j-1} a_j$.

53. [*M46*] (D. H. Lehmer, 1965.) Suppose the N permutations of $\{s_0 \cdot 0, \ldots, s_d \cdot d\}$ cannot be generated by a perfect scheme, because $(N + x)/2$ of them have an even number of inversions, where $x \geq 2$. Is it possible to generate them all with a sequence of $N + x - 2$ adjacent interchanges $a_{\delta_k} \leftrightarrow a_{\delta_k - 1}$ for $1 \leq k < N + x - 1$, where $x - 1$ cases are "spurs" with $\delta_k = \delta_{k-1}$ that take us back to the permutation we've just seen? For example, a suitable sequence $\delta_1 \ldots \delta_{94}$ for the 90 permutations of $\{0, 0, 1, 1, 2, 2\}$, where $x = \binom{2+2+2}{2,2,2}_{-1} = 6$, is $234535432523451\alpha42\alpha^R51\alpha42\alpha^R51\alpha4$, where $\alpha = 45352542345355$, if we start with $a_5 a_4 a_3 a_2 a_1 a_0 = 221100$.

54. [*M40*] For what values of s and t can all (s, t)-combinations be generated if we allow end-around swaps $a_{n-1} \leftrightarrow a_0$ in addition to adjacent interchanges $a_j \leftrightarrow a_{j-1}$?

55. [*M49*] (Buck and Wiedemann, 1984.) Can all (t, t)-combinations $a_{2t-1} \ldots a_1 a_0$ be generated by repeatedly swapping a_0 with some other element?

▸ **56.** [*22*] (Frank Ruskey.) Can a piano player run through all possible 4-note chords that span at most one octave, changing only one finger at a time? This is the problem of generating all combinations $c_t \ldots c_1$ such that $n > c_t > \cdots > c_1 \geq 0$ and $c_t - c_1 < m$, where $t = 4$ and (a) $m = 8$, $n = 52$ if we consider only the white notes of a piano keyboard; (b) $m = 13$, $n = 88$ if we consider also the black notes.

57. [*20*] Consider the piano player's problem of exercise 56 with the additional condition that the chords don't involve adjacent notes. (In other words, $c_{j+1} > c_j + 1$ for $t > j \geq 1$.)

58. [*M25*] Is there a *perfect* solution to the piano player's problem, in which each step moves a finger to an *adjacent* key?

59. [*23*] Design an algorithm to generate all *bounded* compositions

$$t = r_s + \cdots + r_1 + r_0, \qquad \text{where } 0 \leq r_j \leq m_j \text{ for } s \geq j \geq 0.$$

60. [*32*] Show that all bounded compositions can be generated by changing only two of the parts at each step.

▸ **61.** [*M27*] A *contingency table* is an $m \times n$ matrix of nonnegative integers (a_{ij}) having given row sums $r_i = \sum_{j=1}^{n} a_{ij}$ and column sums $c_j = \sum_{i=1}^{m} a_{ij}$, where $r_1 + \cdots + r_m = c_1 + \cdots + c_n$.

a) Show that $2 \times n$ contingency tables are equivalent to bounded compositions.

b) What is the lexicographically largest contingency table for $(r_1, \ldots, r_m; c_1, \ldots, c_n)$, when matrix entries are read row-wise from left to right and top to bottom, namely in the order $(a_{11}, a_{12}, \ldots, a_{1n}, a_{21}, \ldots, a_{mn})$?

c) What is the lexicographically largest contingency table for $(r_1, \ldots, r_m; c_1, \ldots, c_n)$, when matrix entries are read column-wise from top to bottom and left to right, namely in the order $(a_{11}, a_{21}, \ldots, a_{m1}, a_{12}, \ldots, a_{mn})$?

d) What is the lexicographically smallest contingency table for $(r_1, \ldots, r_m; c_1, \ldots, c_n)$, in the row-wise and column-wise senses?

e) Explain how to generate all contingency tables for $(r_1, \ldots, r_m; c_1, \ldots, c_n)$ in lexicographic order.

62. [*M41*] Show that all contingency tables for $(r_1, \ldots, r_m; c_1, \ldots, c_n)$ can be generated by changing exactly four entries of the matrix at each step.

▸ **63.** [*M30*] Construct a genlex Gray code for all of the $2^s \binom{s+t}{t}$ *subcubes* that have s digits and t asterisks, using only the transformations $*0 \leftrightarrow 0*$, $*1 \leftrightarrow 1*$, $0 \leftrightarrow 1$. For example, one such cycle when $s = t = 2$ is

$$(00{**}, 01{**}, 0{*}1{*}, 0{**}1, 0{**}0, 0{*}0{*}, {*}00{*}, {*}01{*}, {*}0{*}1, {*}0{*}0, {**}00, {**}01,$$
$${**}11, {**}10, {*}1{*}0, {*}1{*}1, {*}11{*}, {*}10{*}, 1{*}0{*}, 1{**}0, 1{**}1, 1{*}1{*}, 11{**}, 10{**}).$$

64. [*M40*] Enumerate the total number of genlex Gray paths on subcubes that use only the transformations allowed in exercise 63. How many of those paths are cycles?

▸ **65.** [*22*] Given $n \geq t \geq 0$, show that there is a Gray path through all of the canonical bases $(\alpha_1, \ldots, \alpha_t)$ of exercise 12, changing just one bit at each step. For example, one such path when $n = 3$ and $t = 2$ is

$$\begin{array}{ccccccc} 001 & 101 & 101 & 001 & 001 & 011 & 010 \\ 010\,, & 010\,, & 110\,, & 110\,, & 100\,, & 100\,, & 100\,. \end{array}$$

66. [*46*] Consider the Ising configurations of exercise 13 for which $a_0 = 0$. Given n, t, and r, is there a Gray code for these configurations in which all transitions have the forms $0^k1 \leftrightarrow 10^k$ or $01^k \leftrightarrow 1^k0$? For example, in the case $n = 9$, $t = 5$, $r = 6$, there is a unique cycle

$$(010101110,\ 010110110,\ 011010110,\ 011011010,\ 011101010,\ 010111010).$$

67. [*M01*] If α is a t-combination, what is (a) $\partial^t\alpha$? (b) $\partial^{t+1}\alpha$?

▸ **68.** [*M22*] How large is the smallest set A of t-combinations for which $\|\partial A\| < \|A\|$?

69. [*M25*] What is the maximum value of $\kappa_t N - N$, for $N \geq 0$?

70. [*M20*] How many t-cliques can a million-edge graph have?

▸ **71.** [*M22*] Show that if N has the degree-t combinatorial representation (57), there is an easy way to find the degree-s combinatorial representation of the complementary number $M = \binom{s+t}{t} - N$, whenever $N < \binom{s+t}{t}$. Derive (63) as a consequence.

72. [*M23*] (A. J. W. Hilton, 1976.) Let A be a set of s-combinations and B a set of t-combinations, both contained in $U = \{0, \ldots, n-1\}$ where $n \geq s + t$. Show that if A and B are *cross-intersecting*, in the sense that $\alpha \cap \beta \neq \emptyset$ for all $\alpha \in A$ and $\beta \in B$, then so are the sets Q_{Mns} and Q_{Nnt} defined in Theorem K, where $M = \|A\|$ and $N = \|B\|$.

73. [*M21*] What are $\|\varrho P_{Nt}\|$ and $\|\varrho Q_{Nnt}\|$ in Theorem K?

74. [*M20*] The right-hand side of (6o) is not always the degree-$(t-1)$ combinatorial representation of $\kappa_t N$, because $v-1$ might be zero. Show, however, that a positive integer N has at most two representations if we allow $v=0$ in (57), and both of them yield the same value $\kappa_t N$ according to (6o). Therefore

$$\kappa_k\kappa_{k+1}\ldots\kappa_t N = \binom{n_t}{k-1} + \binom{n_{t-1}}{k-2} + \cdots + \binom{n_v}{k-1+v-t} \qquad \text{for } 1\le k\le t.$$

75. [*M20*] Find a simple formula for $\kappa_t(N+1)-\kappa_t N$.

▸ **76.** [*M26*] Prove the following properties of the κ functions by manipulating binomial coefficients, without assuming Theorem K:

a) $\kappa_t(M+N)\le\kappa_t M+\kappa_t N$.

b) $\kappa_t(M+N)\le\max(\kappa_t M,N)+\kappa_{t-1}N$.

Hint: $\binom{m_t}{t}+\cdots+\binom{m_1}{1}+\binom{n_t}{t}+\cdots+\binom{n_1}{1}$ is equal to $\binom{m_t\vee n_t}{t}+\cdots+\binom{m_1\vee n_1}{1}+\binom{m_t\wedge n_t}{t}+\cdots+\binom{m_1\wedge n_1}{1}$, where $\vee$ and $\wedge$ denote max and min.

77. [*M22*] Show that Theorem K follows easily from inequality (b) in the previous exercise. Conversely, both inequalities are simple consequences of Theorem K. *Hint:* Any set A of t-combinations can be written $A=A_1+A_0 0$, where $A_1=\{\alpha\in A\mid 0\notin\alpha\}$.

78. [*M23*] Prove that if $t\ge 2$, we have $M\ge\mu_t N$ if and only if $M+\lambda_{t-1}M\ge N$.

79. [*HM26*] (L. Lovász, 1979.) The function $\binom{x}{t}$ increases monotonically from 0 to ∞ as x increases from $t-1$ to ∞; hence we can define

$$\underline{\kappa}_t N = \binom{x}{t-1}, \qquad \text{if } N=\binom{x}{t} \text{ and } x\ge t-1.$$

Prove that $\kappa_t N\ge\underline{\kappa}_t N$ for all integers $t\ge 1$ and $N\ge 0$. *Hint:* Equality holds when x is an integer.

▸ **80.** [*M27*] Show that the minimum shadow sizes in Theorem M are given by (64).

81. [*HM31*] The Takagi function of Fig. 27 is defined for $0\le x\le 1$ by the formula

$$\tau(x)=\sum_{k=1}^{\infty}\int_0^x r_k(t)\,dt,$$

where $r_k(t)=(-1)^{\lfloor 2^k t\rfloor}$ is the Rademacher function of Eq. 7.2.1.1–(16).

a) Prove that $\tau(x)$ is continuous in the interval $[0\,..\,1]$, but its derivative does not exist at any point.

b) Show that $\tau(x)$ is the only continuous function that satisfies

$$\tau(\tfrac12 x) \;=\; \tau(1-\tfrac12 x) \;=\; \tfrac12 x+\tfrac12\tau(x) \qquad \text{for } 0\le x\le 1.$$

c) What is the asymptotic value of $\tau(\epsilon)$ when ϵ is small?

d) Prove that $\tau(x)$ is rational when x is rational.

e) Find all roots of the equation $\tau(x)=1/2$.

f) Find all roots of the equation $\tau(x)=\max_{0\le x\le 1}\tau(x)$.

82. [*HM46*] Determine the set R of all rational numbers r such that the equation $\tau(x)=r$ has uncountably many solutions. If $\tau(x)$ is rational and x is irrational, is it true that $\tau(x)\in R$?

83. [*HM27*] If $T = \binom{2t-1}{t}$, prove the asymptotic formula

$$\kappa_t N - N \;=\; \frac{T}{t}\Big(\tau\Big(\frac{N}{T}\Big) + O\Big(\frac{(\log t)^3}{t}\Big)\Big) \qquad \text{for } 0 \le N \le T.$$

84. [*HM21*] Relate the functions $\lambda_t N$ and $\mu_t N$ to the Takagi function $\tau(x)$.

85. [*M20*] Prove the law of spread/core duality, $X^{\sim+} = X^{\circ\sim}$.

86. [*M21*] True or false: (a) $X \subseteq Y^\circ$ if and only if $Y^\sim \subseteq X^{\sim\circ}$; (b) $X^{\circ+\circ} = X^\circ$; (c) $\alpha M \le N$ if and only if $M \le \beta N$.

87. [*M20*] Explain why cross order is useful, by completing the proof of Lemma S.

88. [*16*] Compute the α and β functions for the $2 \times 2 \times 3$ torus (69).

89. [*M22*] Prove the basic compression lemma, (85).

90. [*M24*] Prove Theorem W for two-dimensional toruses $T(l, m)$, $l \le m$.

91. [*M28*] Let $x = x_1 \dots x_{n-1}$ be the Nth element of the torus $T(m_1, \dots, m_{n-1})$, and let S be the set of all elements of $T(m_1, \dots, m_{n-1}, m)$ that are $\preceq x_1 \dots x_{n-1}(m-1)$ in cross order. If N_a elements of S have final component a, for $0 \le a < m$, prove that $N_{m-1} = N$ and $N_{a-1} = \alpha N_a$ for $1 \le a < m$, where α is the spread function for standard sets in $T(m_1, \dots, m_{n-1})$.

92. [*M25*] (a) Find an N for which the conclusion of Theorem W is false when the parameters $m_1, m_2, \dots, m_n$ have not been sorted into nondecreasing order. (b) Where does the proof of that theorem use the hypothesis that $m_1 \le m_2 \le \cdots \le m_n$?

93. [*M20*] Show that the ∂ half of Corollary C follows from the θ half. *Hint:* The complements of the multicombinations (91) with respect to U are 3211, 3210, 3200, 3110, 3100, 3000, 2110, 3100, 2000, 1000.

94. [*15*] Explain why Theorems K and M follow from Corollary C.

▸ **95.** [*M22*] If S is an infinite sequence $(s_0, s_1, s_2, \dots)$ of positive integers, let

$$\binom{S(n)}{k} = [z^k] \prod_{j=0}^{n-1} (1 + z + \cdots + z^{s_j});$$

thus $\binom{S(n)}{k}$ is the ordinary binomial coefficient $\binom{n}{k}$ if $s_0 = s_1 = s_2 = \cdots = 1$.

Generalizing the combinatorial number system, show that every nonnegative integer N has a unique representation

$$N = \binom{S(n_t)}{t} + \binom{S(n_{t-1})}{t-1} + \cdots + \binom{S(n_1)}{1}$$

where $n_t \ge n_{t-1} \ge \cdots \ge n_1 \ge 0$ and $\{n_t, n_{t-1}, \dots, n_1\} \subseteq \{s_0 \cdot 0, s_1 \cdot 1, s_2 \cdot 2, \dots\}$. Use this representation to give a simple formula for the numbers $\|\partial P_{Nt}\|$ in Corollary C.

▸ **96.** [*M26*] The text remarked that the vertices of a convex polyhedron can be perturbed slightly so that all of its faces are simplexes. In general, any set of combinations that contains the shadows of all its elements is called a *simplicial complex*; thus C is a simplicial complex if and only if $\alpha \subseteq \beta$ and $\beta \in C$ implies that $\alpha \in C$, if and only if C is an order ideal with respect to set inclusion.

The *size vector* of a simplicial complex C on n vertices is $(N_0, N_1, \dots, N_n)$ when C contains exactly N_t combinations of size t.

a) What are the size vectors of the five regular solids (the tetrahedron, cube, octahedron, dodecahedron, and icosahedron), when their vertices are slightly tweaked?

b) Construct a simplicial complex with size vector $(1, 4, 5, 2, 0)$.
c) Find a necessary and sufficient condition that a given size vector $(N_0, N_1, \ldots, N_n)$ is feasible.
d) Prove that $(N_0, \ldots, N_n)$ is feasible if and only its "dual" vector $(\overline{N}_0, \ldots, \overline{N}_n)$ is feasible, where we define $\overline{N}_t = \binom{n}{t} - N_{n-t}$.
e) List all feasible size vectors $(N_0, N_1, N_2, N_3, N_4)$ and their duals. Which of them are self-dual?

97. [*30*] Continuing exercise 96, find an efficient way to count the number of feasible size vectors $(N_0, N_1, \ldots, N_n)$ when $n \le 100$.

98. [*M25*] A *clutter* is a set C of combinations that are incomparable, in the sense that $\alpha \subseteq \beta$ and $\alpha, \beta \in C$ implies $\alpha = \beta$. The size vector of a clutter is defined as in exercise 96.
a) Find a necessary and sufficient condition that $(M_0, M_1, \ldots, M_n)$ is the size vector of a clutter.
b) List all such size vectors in the case $n = 4$.

▸ **99.** [*M30*] (Clements and Lindström.) Let A be a "simplicial multicomplex," a set of submultisets of the multiset U in Corollary C with the property that $\partial A \subseteq A$. How large can the total weight $\nu A = \sum\{\|\alpha\| \mid \alpha \in A\}$ be when $\|A\| = N$?

100. [*M25*] If $f(x_1, \ldots, x_n)$ is a Boolean formula, let $F(p)$ be the probability that $f(x_1, \ldots, x_n) = 1$ when each variable x_j independently is 1 with probability p.
a) Calculate $G(p)$ and $H(p)$ for the Boolean formulas $g(w, x, y, z) = wxz \vee wyz \vee xy\bar{z}$, $h(w, x, y, z) = \bar{w}yz \vee xyz$.
b) Show that there is a *monotone* Boolean function $f(w, x, y, z)$ such that $F(p) = G(p)$, but there is no such function with $F(p) = H(p)$. Explain how to test this condition in general.

101. [*HM35*] (F. S. Macaulay, 1927.) A *polynomial ideal* I in the variables $\{x_1 \ldots, x_s\}$ is a set of polynomials closed under the operations of addition, multiplication by a constant, and multiplication by any of the variables. It is called *homogeneous* if it consists of all linear combinations of a set of homogeneous polynomials, namely of polynomials like $xy + z^2$ whose terms all have the same degree. Let N_t be the maximum number of linearly independent elements of degree t in I. For example, if $s = 2$, the set of all $\alpha(x_0, x_1, x_2)(x_0x_1^2 - 2x_1x_2^2) + \beta(x_0, x_1, x_2)x_0x_1x_2^2$, where α and β run through all possible polynomials in $\{x_0, x_1, x_2\}$, is a homogeneous polynomial ideal with $N_0 = N_1 = N_2 = 0$, $N_3 = 1$, $N_4 = 4$, $N_5 = 9$, $N_6 = 15$, ...
a) Prove that for any such ideal I there is another ideal I' in which all homogeneous polynomials of degree t are linear combinations of N_t independent *monomials*. (A monomial is a product of variables, like $x_1^3x_2x_5^4$.)
b) Use Theorem M and (6_4) to prove that $N_{t+1} \ge N_t + \kappa_s N_t$ for all $t \ge 0$.
c) Show that $N_{t+1} > N_t + \kappa_s N_t$ occurs for only finitely many t. (This statement is equivalent to "Hilbert's basis theorem," proved by David Hilbert in *Göttinger Nachrichten* (1888), 450–457; *Math. Annalen* **36** (1890), 473–534.)

▸ **102.** [*M38*] The shadow of a subcube $a_1 \ldots a_n$, where each a_j is either 0 or 1 or $*$, is obtained by replacing some $*$ by 0 or 1. For example,

$$\partial 0{*}11{*}0 \;=\; \{0011{*}0,\ 011{*}0,\ 0{*}1100,\ 0{*}1110\}.$$

Find a set P_{Nst} such that, if A is any set of N subcubes $a_1 \ldots a_n$ having s digits and t asterisks, $\|\partial A\| \ge \|P_{Nst}\|$.

103. [*M41*] The shadow of a binary string $a_1 \ldots a_n$ is obtained by deleting one of its bits. For example,

$$\partial 110010010 = \{10010010,\ 11010010,\ 11000010,\ 11001000,\ 11001001\}.$$

Find a set P_{Nn} such that, if A is any set of N binary strings $a_1 \ldots a_n$, $\|\partial A\| \geq \|P_{Nn}\|$.

104. [*M20*] A *universal cycle of t-combinations* for $\{0, 1, \ldots, n-1\}$ is a cycle of $\binom{n}{t}$ numbers whose blocks of t consecutive elements run through every t-combination $\{c_1, \ldots, c_t\}$. For example,

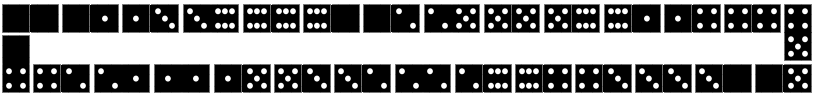
$$(0214506132051624315263042536 4103546)$$

is a universal cycle when $t = 3$ and $n = 7$.

Prove that no such cycle is possible unless $\binom{n}{t}$ is a multiple of n.

105. [*M21*] (L. Poinsot, 1809.) Find a "nice" universal cycle of 2-combinations for $\{0, 1, \ldots, 2m\}$. *Hint:* Consider the differences of consecutive elements, mod $(2m+1)$.

106. [*22*] (O. Terquem, 1849.) Poinsot's theorem implies that all 28 dominoes of a traditional "double-six" set can be arranged in a cycle so that the spots of adjacent dominoes match each other:



How many such cycles are possible?

107. [*M31*] Find universal cycles of 3-combinations for the sets $\{0, \ldots, n-1\}$ when $n \bmod 3 \neq 0$.

108. [*M31*] Find universal cycles of 3-*multicombinations* for $\{0, 1, \ldots, n-1\}$ when $n \bmod 3 \neq 0$ (namely for combinations $d_1 d_2 d_3$ with repetitions permitted).

▸ **109.** [*26*] *Cribbage* is a game played with 52 cards, where each card has a suit (♣, ♢, ♡, or ♠) and a face value (A, 2, 3, 4, 5, 6, 7, 8, 9, 10, J, Q, or K). One feature of the game is to compute the score of a 5-card combination $C = \{c_1, c_2, c_3, c_4, c_5\}$, where one card c_k is called the *starter*. The score is the sum of points computed as follows, for each subset S of C and each choice of k: Let $\|S\| = s$.

i) Fifteens: If $\sum\{v(c) \mid c \in S\} = 15$, where $\big(v(\texttt{A}), v(\texttt{2}), v(\texttt{3}), \ldots, v(\texttt{9}), v(\texttt{10}), v(\texttt{J}), v(\texttt{Q}), v(\texttt{K})\big) = (1, 2, 3, \ldots, 9, 10, 10, 10, 10)$, score two points.

ii) Pairs: If $s = 2$ and both cards have the same face value, score two points.

iii) Runs: If $s \geq 3$ and the face values are consecutive, and if C does not contain a run of length $s+1$, score s points.

iv) Flushes: If $s = 4$ and all cards of S have the same suit, and if $c_k \notin S$, score $4 + [c_k$ has the same suit as the others$]$.

v) Nobs: If $s = 1$ and $c_k \notin S$, score 1 if the card is J of the same suit as c_k.

For example, if you hold {J♣, 5♣, 5♢, 6♡} and if 4♣ is the starter, you score 4×2 for fifteens, 2 for a pair, 2×3 for runs, plus 1 for nobs, totalling 17.

Exactly how many combinations and starter choices lead to a score of x points, for $x = 0, 1, 2, \ldots$?

SECTION 7.2.1.3

1. Given a multiset, form the sequence $e_t \dots e_2 e_1$ from right to left by listing the distinct elements first, then those that appear twice, then those that appear thrice, etc. Let us set $e_{-j} \leftarrow s - j$ for $0 \le j \le s$, so that every element e_j for $1 \le j \le t$ is equal to some element to its right in the sequence $e_t \dots e_1 e_0 \dots e_{-s}$. If the first such element is $e_{c_j - s}$, we obtain a solution to (3). Conversely, every solution to (3) yields a unique multiset $\{e_1, \dots, e_t\}$, because $c_j < s + j$ for $1 \le j \le t$.

2. Start at the bottom left corner; then go up for each 0, go right for each 1. The result is  .

3. In this algorithm, variable r is the least positive index such that $q_r > 0$.

F1. [Initialize.] Set $q_j \leftarrow 0$ for $1 \le j \le t$, and $q_0 \leftarrow s$. (We assume that $st > 0$.)

F2. [Visit.] Visit the composition $q_t \dots q_0$. Go to F4 if $q_0 = 0$.

F3. [Easy case.] Set $q_0 \leftarrow q_0 - 1$, $r \leftarrow 1$, and go to F5.

F4. [Tricky case.] Terminate if $r = t$. Otherwise set $q_0 \leftarrow q_r - 1$, $q_r \leftarrow 0$, $r \leftarrow r + 1$.

F5. [Increase q_r.] Set $q_r \leftarrow q_r + 1$ and return to F2. ∎

[See *CACM* **11** (1968), 430; **12** (1969), 187. The task of generating such compositions in *decreasing* lexicographic order is more difficult.]

4. We can reverse the roles of 0 and 1 in (14), so that $0^{q_t} 10^{q_{t-1}} 1 \dots 10^{q_1} 10^{q_0} = 1^{r_s} 01^{r_{s-1}} 0 \dots 01^{r_1} 01^{r_0}$. This gives $0^1 10^0 10^2 10^2 10^4 10^0 10^0 10^0 10^0 10^0 10^1 10^0 10^1 10^0 = 1^0 01^2 01^0 01^1 01^0 01^1 01^0 01^0 01^0 01^6 01^2 01^1$. Lexicographic order of $a_{n-1} \dots a_1 a_0$ corresponds to lexicographic order of $r_s \dots r_1 r_0$.

Incidentally, there's also a multiset connection: $\{d_t, \dots, d_1\} = \{r_s \cdot s, \dots, r_0 \cdot 0\}$. For example, $\{10, 10, 8, 6, 2, 2, 2, 2, 2, 2, 1, 1, 0\} = \{0 \cdot 11, 2 \cdot 10, 0 \cdot 9, 1 \cdot 8, 0 \cdot 7, 1 \cdot 6, 0 \cdot 5, 0 \cdot 4, 0 \cdot 3, 6 \cdot 2, 2 \cdot 1, 1 \cdot 0\}$.

5. (a) Set $x_j = c_j - \lfloor (j-1)/2 \rfloor$ in each t-combination of $n + \lfloor t/2 \rfloor$. (b) Set $x_j = c_j + j + 1$ in each t-combination of $n - t - 2$.

(A similar approach finds all solutions $(x_t, \dots, x_1)$ to the inequalities $x_{j+1} \ge x_j + \delta_j$ for $0 \le j \le t$, given the values of x_{t+1}, $(\delta_t, \dots, \delta_1)$, and x_0.)

6. Assume that $t > 0$. We get to T3 when $c_1 > 0$; to T5 when $c_2 = c_1 + 1 > 1$; to T4 for $2 \le j \le t+1$ when $c_j = c_1 + j - 1 \ge j$. So the counts are: T1, 1; T2, $\binom{n}{t}$; T3, $\binom{n-1}{t}$; T4, $\binom{n-2}{t-1} + \binom{n-2}{t-2} + \cdots + \binom{n-t-1}{0} = \binom{n-1}{t-1}$; T5, $\binom{n-2}{t-1}$; T6, $\binom{n-1}{t-1} + \binom{n-2}{t-1} - 1$.

7. A procedure slightly simpler than Algorithm T suffices: Assume that $s < n$.

S1. [Initialize.] Set $b_j \leftarrow j + n - s - 1$ for $1 \le j \le s$; then set $j \leftarrow 1$.

S2. [Visit.] Visit the combination $b_s \dots b_2 b_1$. Terminate if $j > s$.

S3. [Decrease b_j.] Set $b_j \leftarrow b_j - 1$. If $b_j < j$, set $j \leftarrow j + 1$ and return to S2.

S4. [Reset $b_{j-1} \dots b_1$.] While $j > 1$, set $b_{j-1} \leftarrow b_j - 1$, $j \leftarrow j - 1$, and repeat until $j = 1$. Go to S2. ∎

(See S. Dvořák, *Comp. J.* **33** (1990), 188. Notice that if $x_k = n - b_k$ for $1 \le k \le s$, this algorithm runs through all combinations $x_s \dots x_2 x_1$ of $\{1, 2, \dots, n\}$ with $1 \le x_s < \cdots < x_2 < x_1 \le n$, in *increasing* lexicographic order.)

8. **A1.** [Initialize.] Set $a_n \dots a_0 \leftarrow 0^{s+1}1^t$, $q \leftarrow t$, $r \leftarrow 0$. (We assume that $0 < t < n$.)

A2. [Visit.] Visit the combination $a_{n-1} \dots a_1 a_0$. Go to A4 if $q = 0$.

A3. [Replace $\dots 01^q$ by $\dots 101^{q-1}$.] Set $a_q \leftarrow 1$, $a_{q-1} \leftarrow 0$, $q \leftarrow q - 1$; then if $q = 0$, set $r \leftarrow 1$. Return to A2.

A4. [Shift block of 1s.] Set $a_r \leftarrow 0$ and $r \leftarrow r + 1$. Then if $a_r = 1$, set $a_q \leftarrow 1$, $q \leftarrow q + 1$, and repeat step A4.

A5. [Carry to left.] Terminate if $r = n$; otherwise set $a_r \leftarrow 1$.

A6. [Odd?] If $q > 0$, set $r \leftarrow 0$. Return to A2. ∎

In step A2, q and r point respectively to the rightmost 0 and 1 in $a_{n-1} \dots a_0$. Steps A1, ..., A6 are executed with frequency 1, $\binom{n}{t}$, $\binom{n-1}{t-1}$, $\binom{n}{t} - 1$, $\binom{n-1}{t}$, $\binom{n-1}{t} - 1$.

9. (a) The first $\binom{n-1}{t}$ strings begin with 0 and have $2A_{(s-1)t}$ bit changes; the other $\binom{n-1}{t-1}$ begin with 1 and have $2A_{s(t-1)}$. And $\nu(01^t0^{s-1} \oplus 10^s1^{t-1}) = 2\min(s,t)$.

(b) Solution 1 (direct): Let $B_{st} = A_{st} + \min(s,t) + 1$. Then

$$B_{st} = B_{(s-1)t} + B_{s(t-1)} + [s=t] \quad \text{when } st > 0; \qquad B_{st} = 1 \quad \text{when } st = 0.$$

Consequently $B_{st} = \sum_{k=0}^{\min(s,t)} \binom{s+t-2k}{s-k}$. If $s \le t$ this is $\le \sum_{k=0}^{s} \binom{s+t-k}{s-k} = \binom{s+t+1}{s} = \binom{s+t}{s}\frac{s+t+1}{t+1} < 2\binom{s+t}{t}$.

Solution 2 (indirect): The algorithm in answer 8 makes $2(x+y)$ bit changes when steps (A3, A4) are executed (x, y) times. Thus $A_{st} \le \binom{n-1}{t-1} + \binom{n}{t} - 1 < 2\binom{n}{t}$.

[The comment in answer 7.2.1.1–3 therefore applies to combinations as well.]

10. Each scenario corresponds to a $(4,4)$-combination $b_4b_3b_2b_1$ or $c_4c_3c_2c_1$ in which A wins games $\{8-b_4, 8-b_3, 8-b_2, 8-b_1\}$ and N wins games $\{8-c_4, 8-c_3, 8-c_2, 8-c_1\}$, because we can assume that the losing team wins the remaining games in a series of 8. (Equivalently, we can generate all permutations of {A, A, A, A, N, N, N, N} and omit the trailing run of As or Ns.) The American League wins if and only if $b_1 \neq 0$, if and only if $c_1 = 0$. The formula $\binom{c_4}{4} + \binom{c_3}{3} + \binom{c_2}{2} + \binom{c_1}{1}$ assigns a unique integer between 0 and 69 to each scenario.

For example, ANANAA $\iff a_7 \dots a_1a_0 = 01010011 \iff b_4b_3b_2b_1 = 7532 \iff c_4c_3c_2c_1 = 6410$, and this is the scenario of rank $\binom{6}{4} + \binom{4}{3} + \binom{1}{2} + \binom{0}{1} = 19$ in lexicographic order. (Notice that the term $\binom{c_j}{j}$ will be zero if and only if it corresponds to a trailing N.)

11. AAAA (9 times), NNNN (8), and ANAAA (7) were most common. Exactly 27 of the 70 failed to occur, including all four beginning with NNNA. (We disregard the games that were tied because of darkness, in 1907, 1912, and 1922. The case ANNAAA should perhaps be excluded too, because it occurred only in 1920 as part of ANNAAAA in a best-of-nine series. The scenario NNAAANN occurred for the first time in 2001.)

12. (a) Let V_j be the subspace $\{a_{n-1} \dots a_0 \in V \mid a_k = 0 \text{ for } 0 \le k < j\}$, so that $\{0 \dots 0\} = V_n \subseteq V_{n-1} \subseteq \cdots \subseteq V_0 = V$. Then $\{c_1, \dots, c_t\} = \{c \mid V_c \neq V_{c+1}\}$, and α_k is the unique element $a_{n-1} \dots a_0$ of V with $a_{c_j} = [j=k]$ for $1 \le j \le t$.

Incidentally, the $t \times n$ matrix corresponding to a canonical basis is said to be in *reduced row-echelon form*. It can be found by a standard "triangulation" algorithm (see exercise 4.6.1–19 and Algorithm 4.6.2N).

(b) The 2-nomial coefficient $\binom{n}{t}_2 = 2^t\binom{n-1}{t}_2 + \binom{n-1}{t-1}_2$ of exercise 1.2.6–58 has the right properties, because $2^t\binom{n-1}{t}_2$ binary vector spaces have $c_t < n-1$ and $\binom{n-1}{t-1}_2$ have $c_t = n-1$. [In general the number of canonical bases with r asterisks is the number of

partitions of r into at most t parts, with no part exceeding $n-t$, and this is $[z^r]\binom{n}{t}_z$ by Eq. 7.2.1.4–(oo). See D. E. Knuth, *J. Combinatorial Theory* **10** (1971), 178–180.]

(c) The following algorithm assumes that $n > t > 0$ and that $a_{(t+1)j} = 0$ for $t \le j \le n$.

V1. [Initialize.] Set $a_{kj} \leftarrow [j = k-1]$ for $1 \le k \le t$ and $0 \le j < n$. Also set $q \leftarrow t$, $r \leftarrow 0$.

V2. [Visit.] (At this point we have $a_{k(k-1)} = 1$ for $1 \le k \le q$, $a_{(q+1)q} = 0$, and $a_{1r} = 1$.) Visit the canonical basis $(a_{1(n-1)} \ldots a_{11}a_{10}, \ldots, a_{t(n-1)} \ldots a_{t1}a_{t0})$. Go to V4 if $q > 0$.

V3. [Find block of 1s.] Set $q \leftarrow 1, 2, \ldots$, until $a_{(q+1)(q+r)} = 0$. Terminate if $q + r = n$.

V4. [Add 1 to column $q+r$.] Set $k \leftarrow 1$. If $a_{k(q+r)} = 1$, set $a_{k(q+r)} \leftarrow 0$, $k \leftarrow k+1$, and repeat until $a_{k(q+r)} = 0$. Then if $k \le q$, set $a_{k(q+r)} \leftarrow 1$; otherwise set $a_{q(q+r)} \leftarrow 1$, $a_{q(q+r-1)} \leftarrow 0$, $q \leftarrow q-1$.

V5. [Shift block right.] If $q = 0$, set $r \leftarrow r+1$. Otherwise, if $r > 0$, set $a_{k(k-1)} \leftarrow 1$ and $a_{k(r+k-1)} \leftarrow 0$ for $1 \le k \le q$, then set $r \leftarrow 0$. Go to V2. ∎

Step V2 finds $q > 0$ with probability $1 - (2^{n-t}-1)/(2^n-1) \approx 1 - 2^{-t}$, so we could save time by treating this case separately.

(d) Since $999999 = 4\binom{8}{4}_2 + 16\binom{7}{4}_2 + 5\binom{6}{3}_2 + 5\binom{5}{3}_2 + 8\binom{4}{3}_2 + 0\binom{3}{2}_2 + 4\binom{2}{2}_2 + 1\binom{1}{1}_2 + 2\binom{0}{1}_2$, the millionth output has binary columns 4, 16/2, 5, 5, 8/2, 0, 4/2, 1, 2/2, namely

$$\begin{aligned}
\alpha_1 &= 0\,0\,1\,1\,0\,0\,0\,1\,1,\\
\alpha_2 &= 0\,0\,0\,0\,0\,0\,1\,0\,0,\\
\alpha_3 &= 1\,0\,1\,1\,1\,0\,0\,0\,0,\\
\alpha_4 &= 0\,1\,0\,0\,0\,0\,0\,0\,0.
\end{aligned}$$

[*Reference:* E. Calabi and H. S. Wilf, *J. Combinatorial Theory* **A22** (1977), 107–109.]

13. Let $n = s + t$. There are $\binom{s-1}{\lceil (r-1)/2 \rceil}\binom{t-1}{\lfloor (r-1)/2 \rfloor}$ configurations beginning with 0 and $\binom{s-1}{\lfloor (r-1)/2 \rfloor}\binom{t-1}{\lceil (r-1)/2 \rceil}$ beginning with 1, because an Ising configuration that begins with 0 corresponds to a composition of s 0s into $\lceil (r+1)/2 \rceil$ parts and a composition of t 1s into $\lfloor (r+1)/2 \rfloor$ parts. We can generate all such pairs of compositions and weave them into configurations. [See E. Ising, *Zeitschrift für Physik* **31** (1925), 253–258; J. M. S. Simões Pereira, *CACM* **12** (1969), 562.]

14. Start with $l[j] \leftarrow j-1$ and $r[j-1] \leftarrow j$ for $1 \le j \le n$; $l[0] \leftarrow n$, $r[n] \leftarrow 0$. To get the next combination, assuming that $t > 0$, set $p \leftarrow s$ if $l[0] > s$, otherwise $p \leftarrow r[n]-1$. Terminate if $p \le 0$; otherwise set $q \leftarrow r[p]$, $l[q] \leftarrow l[p]$, and $r[l[p]] \leftarrow q$. Then if $r[q] > s$ and $p < s$, set $r[p] \leftarrow r[n]$, $l[r[n]] \leftarrow p$, $r[s] \leftarrow r[q]$, $l[r[q]] \leftarrow s$, $r[n] \leftarrow 0$, $l[0] \leftarrow n$; otherwise set $r[p] \leftarrow r[q]$, $l[r[q]] \leftarrow p$. Finally set $r[q] \leftarrow p$ and $l[p] \leftarrow q$.

[See Korsh and Lipschutz, *J. Algorithms* **25** (1997), 321–335, where the idea is extended to a loopless algorithm for multiset permutations. *Caution:* This exercise, like exercise 7.2.1.1–16, is more academic than practical, because the routine that visits the linked list might need a loop that nullifies any advantage of loopless generation.]

15. (The stated fact is true because lexicographic order of $c_t \ldots c_1$ corresponds to lexicographic order of $a_{n-1} \ldots a_0$, which is reverse lexicographic order of the complementary sequence $1 \ldots 1 \oplus a_{n-1} \ldots a_0$.) By Theorem L, the combination $c_t \ldots c_1$ is

visited *before* exactly $\binom{b_s}{s}+\cdots+\binom{b_2}{2}+\binom{b_1}{1}$ others have been visited, and we must have

$$\binom{b_s}{s}+\cdots+\binom{b_1}{1}+\binom{c_t}{t}+\cdots+\binom{c_1}{1} \;=\; \binom{s+t}{t}-1.$$

This general identity can be written

$$\sum_{j=0}^{n-1} x_j \binom{j}{x_0+\cdots+x_j} + \sum_{j=0}^{n-1} \bar{x}_j \binom{j}{\bar{x}_0+\cdots+\bar{x}_j} \;=\; \binom{n}{x_0+\cdots+x_{n-1}} - 1$$

when each x_j is 0 or 1, and $\bar{x}_j = 1 - x_j$; it follows also from the equation

$$x_n \binom{n}{x_0+\cdots+x_n} + \bar{x}_n \binom{n}{\bar{x}_0+\cdots+\bar{x}_n} \;=\; \binom{n+1}{x_0+\cdots+x_n} - \binom{n}{x_0+\cdots+x_{n-1}}.$$

16. Since $999999 = \binom{1414}{2}+\binom{1008}{1} = \binom{182}{3}+\binom{153}{2}+\binom{111}{1} = \binom{71}{4}+\binom{56}{3}+\binom{36}{2}+\binom{14}{1} = \binom{43}{5}+\binom{32}{4}+\binom{21}{3}+\binom{15}{2}+\binom{6}{1}$, the answers are (a) 1414 1008; (b) 182 153 111; (c) 71 56 36 14; (d) 43 32 21 15 6; (e) 1000000 999999 ... 2 0.

17. By Theorem L, n_t is the largest integer such that $N \geq \binom{n_t}{t}$; the remaining terms are the degree-$(t-1)$ representation of $N - \binom{n_t}{t}$.

A simple sequential method for $t > 1$ starts with $x = 1$, $c = t$, and sets $c \leftarrow c+1$, $x \leftarrow xc/(c-t)$ zero or more times until $x > N$; then we complete the first phase by setting $x \leftarrow x(c-t)/c$, $c \leftarrow c-1$, at which point we have $x = \binom{c}{t} \leq N < \binom{c+1}{t}$. Set $n_t \leftarrow c$, $N \leftarrow N - x$; terminate with $n_1 \leftarrow N$ if $t = 2$; otherwise set $x \leftarrow xt/c$, $t \leftarrow t-1$, $c \leftarrow c-1$; while $x > N$ set $x \leftarrow x(c-t)/c$, $c \leftarrow c-1$; repeat. This method requires $O(n)$ arithmetic operations if $N < \binom{n}{t}$, so it is suitable unless t is small and N is large.

When $t = 2$, exercise 1.2.4–41 tells us that $n_2 = \lfloor\sqrt{2N+2} + \frac{1}{2}\rfloor$. In general, n_t is $\lfloor x \rfloor$ where x is the largest root of $x^{\underline{t}} = t!\,N$; this root can be approximated by reverting the series $y = (x^{\underline{t}})^{1/t} = x - \frac{1}{2}(t-1) + \frac{1}{24}(t^2-1)x^{-1} + \cdots$ to get $x = y + \frac{1}{2}(t-1) + \frac{1}{24}(t^2-1)/y + O(y^{-3})$. Setting $y = (t!\,N)^{1/t}$ in this formula gives a good approximation, after which we can check that $\binom{\lfloor x\rfloor}{t} \leq N < \binom{\lfloor x\rfloor+1}{t}$ or make a final adjustment. [See A. S. Fraenkel and M. Mor, *Comp. J.* **26** (1983), 336–343.]

18. A complete binary tree of $2^n - 1$ nodes is obtained, with an extra node at the top, like the "tree of losers" in replacement selection sorting (Fig. 63 in Section 5.4.1). Therefore explicit links aren't necessary; the right child of node k is node $2k+1$, and the left sibling is node $2k$, for $1 \leq k < 2^{n-1}$.

This representation of a binomial tree has the curious property that node $k = (0^a 1\alpha)_2$ corresponds to the combination whose binary string is $0^a 1 \alpha^R$.

19. It is post(1000000), where $\text{post}(n) = 2^k + \text{post}(n - 2^k + 1)$ if $2^k \leq n < 2^{k+1}$, and $\text{post}(0) = 0$. So it is 11110100001001000100.

20. $f(z) = (1+z^{w_{n-1}})\ldots(1+z^{w_1})/(1-z)$, $g(z) = (1+z^{w_0})f(z)$, $h(z) = z^{w_0}f(z)$.

21. The rank of $c_t \ldots c_2 c_1$ is $\binom{c_t+1}{t}-1$ minus the rank of $c_{t-1}\ldots c_2 c_1$. [See H. Lüneburg, *Abh. Math. Sem. Hamburg* **52** (1982), 208–227.]

22. Since $999999 = \binom{1415}{2}-\binom{406}{1} = \binom{183}{3}-\binom{98}{2}+\binom{21}{1} = \binom{72}{4}-\binom{57}{3}+\binom{32}{2}-\binom{27}{1} = \binom{44}{5}-\binom{40}{4}+\binom{33}{3}-\binom{13}{2}+\binom{3}{1}$, the answers are (a) 1414 405; (b) 182 97 21; (c) 71 56 31 26; (d) 43 39 32 12 3; (e) 1000000 999999 999998 999996 ... 0.

23. There are $\binom{n-r}{t-r}$ combinations with $j > r$, for $r = 1, 2, \ldots, t$. (If $r = 1$ we have $c_2 = c_1 + 1$; if $r = 2$ we have $c_1 = 0$, $c_2 = 1$; if $r = 3$ we have $c_1 = 0$, $c_2 = 1$, $c_4 = c_3 + 1$; etc.) Thus the mean is $\big(\binom{n}{t}+\binom{n-1}{t-1}+\cdots+\binom{n-t}{0}\big)/\binom{n}{t} = \binom{n+1}{t}/\binom{n}{t} = (n+1)/(n+1-t)$.

The average running time per step is approximately proportional to this quantity; thus the algorithm is quite fast when t is small, but slow if t is near n.

24. In fact $j_k - 2 \le j_{k+1} \le j_k + 1$ when $j_k \equiv t$ (modulo 2) and $j_k - 1 \le j_{k+1} \le j_k + 2$ when $j_k \not\equiv t$, because R5 is performed only when $c_i = i - 1$ for $1 \le i < j$.

Thus we could say, "If $j \ge 4$, set $j \leftarrow j-1-[j \text{ odd}]$ and go to R5" at the end of R2, if t is odd; "If $j \ge 3$, set $j \leftarrow j-1-[j \text{ even}]$ and go to R5" if t is even. The algorithm will then be loopless, since R4 and R5 will be performed at most twice per visit.

25. Assume that $N > N'$ and $N - N'$ is minimum; furthermore let c_t be minimum, subject to those assumptions. Then $c_t > c'_t$.

If there is an element $x \notin C \cup C'$ with $0 \le x < c_t$, map each t-combination of $C \cup C'$ by changing $j \mapsto j-1$ for $j > x$; or, if there is an element $x \in C \cap C'$, map each t-combination that contains x into a $(t-1)$-combination by omitting x and changing $j \mapsto x - j$ for $j < x$. In either case the mapping preserves alternating lexicographic order; hence $N - N'$ must exceed the number of combinations between the images of C and C'. But c_t is minimum, so no such x can exist. Consequently $t = m$ and $c_t = 2m - 1$.

Now if $c'_m < c_m - 1$, we could decrease $N - N'$ by increasing c'_m. Therefore $c'_m = 2m-2$, and the problem has been reduced to finding the *maximum* of $\operatorname{rank}(c_{m-1} \dots c_1) - \operatorname{rank}(c'_{m-1} \dots c'_1)$, where rank refers to Gray binary code.

Let $f(s,t) = \max\bigl(\operatorname{rank}(b_s \dots b_1) - \operatorname{rank}(c_t \dots c_1)\bigr)$ over all $\{b_s, \dots, b_1, c_t \dots, c_1\} = \{0, \dots, s+t-1\}$. Then $f(s,t)$ satisfies the curious recurrence

$$f(s,0) = f(0,t) = 0; \qquad f(1,t) = t;$$
$$f(s,t) = \tbinom{s+t-1}{s} + \max\bigl(f(t-1,s-1), f(s-2,t)\bigr) \quad \text{if } st > 0.$$

When $s + t = 2u + 2$ the solution turns out to be

$$f(s,t) = \binom{2u+1}{t-1} + \sum_{j=1}^{u-r} \binom{2u+1-2j}{r} + \sum_{j=0}^{r-1} \binom{2j+1}{j}, \qquad r = \min(s-2, t-1),$$

with the maximum occurring at $f(t-1,s-1)$ when $s \le t$ and at $f(s-2,t)$ when $s \ge t+2$.

Therefore the minimum $N - N'$ occurs for

$$C = \{2m-1\} \cup \{2m-2-x \mid 1 \le x \le 2m-2, \quad x \bmod 4 \le 1\},$$
$$C' = \{2m-2\} \cup \{2m-2-x \mid 1 \le x \le 2m-2, \quad x \bmod 4 \ge 2\};$$

and it equals $\binom{2m-1}{m-1} - \sum_{k=0}^{m-2} \binom{2k+1}{k} = 1 + \sum_{k=1}^{m-1} \binom{2k}{k-1}$. [A. J. van Zanten, *IEEE Trans.* **IT-37** (1991), 1229–1233.]

26. (a) Yes: The first is $0^{n-\lceil t/2 \rceil} 1^{t \bmod 2} 2^{\lfloor t/2 \rfloor}$ and the last is $2^{\lfloor t/2 \rfloor} 1^{t \bmod 2} 0^{n-\lceil t/2 \rceil}$; transitions are substrings of the forms $02^a1 \leftrightarrow 12^a0$, $02^a2 \leftrightarrow 12^a1$, $10^a1 \leftrightarrow 20^a0$, $10^a2 \leftrightarrow 20^a1$.

(b) No: If $s = 0$ there is a big jump from 02^t0^{r-1} to 20^r2^{t-1}.

27. The following procedure extracts all combinations $c_1 \dots c_k$ of Γ_n that have weight $\le t$: Begin with $k \leftarrow 0$ and $c_0 \leftarrow n$. Visit $c_1 \dots c_k$. If k is even and $c_k = 0$, set $k \leftarrow k-1$; if k is even and $c_k > 0$, set $c_k \leftarrow c_k - 1$ if $k = t$, otherwise $k \leftarrow k+1$ and $c_k \leftarrow 0$. On the other hand if k is odd and $c_k + 1 = c_{k-1}$, set $k \leftarrow k-1$ and $c_k \leftarrow c_{k+1}$ (but terminate if $k = 0$); if k is odd and $c_k + 1 < c_{k-1}$, set $c_k \leftarrow c_k + 1$ if $k = t$, otherwise $k \leftarrow k+1$, $c_k \leftarrow c_{k-1}$, $c_{k-1} \leftarrow c_k + 1$. Repeat.

(This loopless algorithm reduces to that of exercise 7.2.1.1–12(b) when $t = n$, with slight changes of notation.)

28. True. Bit strings $a_{n-1}\ldots a_0=\alpha\beta$ and $a'_{n-1}\ldots a'_0=\alpha\beta'$ correspond to index lists $(b_s\ldots b_1=\theta\chi,\ c_t\ldots c_1=\phi\psi)$ and $(b'_s\ldots b'_1=\theta\chi',\ c'_t\ldots c'_1=\phi\psi')$ such that everything between $\alpha\beta$ and $\alpha\beta'$ begins with α if and only if everything between $\theta\chi$ and $\theta\chi'$ begins with θ and everything between $\phi\psi$ and $\phi\psi'$ begins with ϕ. For example, if $n=10$, the prefix $\alpha=01101$ corresponds to prefixes $\theta=96$ and $\phi=875$.

(But just having $c_t\ldots c_1$ in genlex order is a much weaker condition. For example, *every* such sequence is genlex when $t=1$.)

29. (a) $\texttt{-}^k\texttt{0}^{l+1}$ or $\texttt{-}^k\texttt{0}^{l+1}\texttt{+}\pm^m$ or $\pm^k$, for $k,l,m\ge 0$.

(b) No; the successor is always smaller in balanced ternary notation.

(c) For all α and all $k,l,m\ge 0$ we have $\alpha\texttt{0-}^{k+1}\texttt{0}^{l}\texttt{+}\pm^m\to\alpha\texttt{-+}^k\texttt{0}^{l+1}\texttt{-}\pm^m$ and $\alpha\texttt{+-}^k\texttt{0}^{l+1}\texttt{+}\pm^m\to\alpha\texttt{0+}^{k+1}\texttt{0}^{l}\texttt{-}\pm^m$; also $\alpha\texttt{0-}^{k+1}\texttt{0}^{l}\to\alpha\texttt{-+}^k\texttt{0}^{l+1}$ and $\alpha\texttt{+-}^k\texttt{0}^{l+1}\to\alpha\texttt{0+}^{k+1}\texttt{0}^{l}$.

(d) Let the jth sign of α_i be $(-1)^{a_{ij}}$, and let it be in position b_{ij}. Then we have $(-1)^{a_{ij}+b_{i(j-1)}}=(-1)^{a_{(i+1)j}+b_{(i+1)(j-1)}}$ for $0\le i<k$ and $1\le j\le t$, if we let $b_{i0}=0$.

(e) By parts (a), (b), and (c), α belongs to some chain $\alpha_0\to\cdots\to\alpha_k$, where α_k is final (has no successor) and α_0 is initial (has no predecessor). By part (d), every such chain has at most $\binom{s+t}{t}$ elements. But there are 2^s final strings, by (a), and there are $2^s\binom{s+t}{t}$ strings with s signs and t zeros; so k must be $\binom{s+t}{t}-1$.

Reference: *SICOMP* **2** (1973), 128–133.

30. Assume that $t>0$. Initial strings are the negatives of final strings. Let σ_j be the initial string $\texttt{0}^t\texttt{-}\tau_j$ for $0\le j<2^{s-1}$, where the kth character of τ_j for $1\le k<s$ is $(-1)^{a_k}$ when j is the binary number $(a_{s-1}\ldots a_1)_2$; thus $\sigma_0=\texttt{0}^t\texttt{-++}\ldots\texttt{+}$, $\sigma_1=\texttt{0}^t\texttt{--+}\ldots\texttt{+}$, $\ldots$, $\sigma_{2^{s-1}-1}=\texttt{0}^t\texttt{---}\ldots\texttt{-}$. Let ρ_j be the final string obtained by inserting $\texttt{-0}^t$ after the first run of minus signs in τ_j; thus $\rho_0=\texttt{-0}^t\texttt{++}\ldots\texttt{+}$, $\rho_1=\texttt{--0}^t\texttt{+}\ldots\texttt{+}$, $\ldots$, $\rho_{2^{s-1}-1}=\texttt{--}\ldots\texttt{-0}^t$. We also let $\sigma_{2^{s-1}}=\sigma_0$ and $\rho_{2^{s-1}}=\rho_0$. Then we can prove by induction that the chain beginning with σ_j ends with ρ_j when t is even, with ρ_{j-1} when t is odd, for $1\le j\le 2^{s-1}$. Therefore the chain beginning with $-\rho_j$ ends with $-\sigma_j$ or $-\sigma_{j+1}$.

Let $A_j(s,t)$ be the sequence of (s,t)-combinations derived by mapping the chain that starts with σ_j, and let $B_j(s,t)$ be the analogous sequence derived from $-\rho_j$. Then, for $1\le j\le 2^{s-1}$, the reverse sequence $A_j(s,t)^R$ is $B_j(s,t)$ when t is even, $B_{j-1}(s,t)$ when t is odd. The corresponding recurrences when $st>0$ are

$$A_j(s,t)=\begin{cases}1A_j(s,t-1),\ 0A_{\lfloor(2^{s-1}-1-j)/2\rfloor}(s-1,t)^R, & \text{if } t \text{ is even;}\\ 1A_j(s,t-1),\ 0A_{\lfloor j/2\rfloor}(s-1,t), & \text{if } t \text{ is even;}\end{cases}$$

and when $st>0$ all 2^{s-1} of these sequences are distinct.

Chase's sequence C_{st} is $A_{\lfloor 2^s/3\rfloor}(s,t)$, and $\widehat{C}_{st}$ is $A_{\lfloor 2^{s-1}/3\rfloor}(s,t)$. Incidentally, the homogeneous sequence K_{st} of (31) is $A_{2^{s-1}-[t\text{ even}]}(s,t)^R$.

31. (a) $2^{\binom{s+t}{t}-1}$ solves the recurrence $f(s,t)=2f(s-1,t)f(s,t-1)$ when $f(s,0)=f(0,t)=1$. (b) Now $f(s,t)=(s+1)!\,f(s,t-1)\ldots f(0,t-1)$ has the solution

$$(s+1)!^t\,s!^{\binom{t}{2}}(s-1)!^{\binom{t+1}{3}}\ldots 2!^{\binom{s+t-2}{s}}\;=\;\prod_{r=1}^{s}(r+1)!^{\binom{s+t-1-r}{t-2}+[r=s]}.$$

32. (a) No simple formula seems to exist, but the listings can be counted for small s and t by systematically computing the number of genlex paths that run through all weight-t strings from a given starting point to a given ending point via revolving-door

moves. The totals for $s+t \le 6$ are

$$\begin{array}{ccccccccccccc}
 & & & & & & 1 & & & & & & \\
 & & & & & 1 & & 1 & & & & & \\
 & & & & 1 & & 2 & & 1 & & & & \\
 & & & 1 & & 4 & & 4 & & 4 & & & \\
 & & 1 & & 8 & & 20 & & 8 & & 1 & & \\
 & 1 & & 16 & & 160 & & 160 & & 16 & & 1 & \\
1 & & 32 & & 2264 & & 17152 & & 2264 & & 32 & & 1
\end{array}$$

and $f(4,4) = 95{,}304{,}112{,}865{,}280$; $f(5,5) \approx 5.92646 \times 10^{48}$. [This class of combination generators was first studied by G. Ehrlich, *JACM* **20** (1973), 500–513, but he did not attempt to enumerate them.]

(b) By extending the proof of Theorem N, one can show that all such listings or their reversals must run from 1^t0^s to $0^a1^t0^{s-a}$ for some a, $1 \le a \le s$. Moreover, the number n_{sta} of possibilities, given s, t, and a, satisfies

$$n_{sta} = \begin{cases} n_{s(t-1)1}\, n_{(s-1)t(a-1)}, & \text{if } a > 1, \\ n_{s(t-1)2}\, n_{(s-1)t1} + \cdots + n_{s(t-1)s}\, n_{(s-1)t(s-1)}, & \text{if } a = 1 < s, \end{cases}$$

when $st > 0$. This recurrence has the remarkable solution $n_{sta} = 2^{m(s,t,a)}$, where

$$m(s,t,a) = \begin{cases} \binom{s+t-3}{t} + \binom{s+t-5}{t-2} + \cdots + \binom{s-1}{2}, & \text{if } t \text{ is even;} \\ \binom{s+t-3}{t} + \binom{s+t-5}{t-2} + \cdots + \binom{s}{3} + s - a - [a<s], & \text{if } t \text{ is odd.} \end{cases}$$

33. Consider first the case $t = 1$: The number of near-perfect paths from i to $j > i$ is $f\big(j-i-[i>0]-[j<n-1]\big)$, where $\sum_j f(j)z^j = 1/(1-z-z^3)$. (By coincidence, the same sequence $f(j)$ arises in Caron's polyphase merge on 6 tapes, Table 5.4.2–2.) The sum over $0 \le i < j < n$ is $3f(n) + f(n-1) + f(n-2) + 2 - n$; and we must double this, to cover cases with $j > i$.

When $t > 1$ we can construct $\binom{n}{t} \times \binom{n}{t}$ matrices that tell how many genlex listings begin and end with particular combinations. The entries of these matrices are sums of products of matrices for the case $t-1$, summed over all paths of the type considered for $t = 1$. The totals for $s+t \le 6$ turn out to be

$$\begin{array}{ccccccccccc}
 & & & & 1 & & & & & & \\
 & & & 1 & & 1 & & & & & \\
 & & 1 & & 2 & & 1 & & & & \\
 & 1 & & 6 & & 2 & & 1 & & & \\
1 & & 12 & & 10 & & 2 & & 1 & & \\
 & 20 & & 44 & & 10 & & 2 & & 1 & \\
34 & & 238 & & 68 & & 10 & & 2 & & 1
\end{array}
\qquad
\begin{array}{ccccccccccc}
 & & & & 1 & & & & & & \\
 & & & 1 & & 1 & & & & & \\
 & & 1 & & 2 & & 1 & & & & \\
 & 1 & & 2 & & 0 & & 1 & & & \\
1 & & 2 & & 2 & & 0 & & 1 & & \\
 & 1 & & 2 & & 0 & & 0 & & 1 & \\
1 & & 2 & & 6 & & 0 & & 0 & & 1
\end{array}$$

where the right-hand triangle shows the number of *cycles*, $g(s,t)$. Further values include $f(4,4) = 17736$; $f(5,5) = 9{,}900{,}888{,}879{,}984$; $g(4,4) = 96$; $g(5,5) = 30{,}961{,}456{,}320$.

There are exactly 10 such schemes when $s = 2$ and $n \ge 4$. For example, when $n = 7$ they run from 43210 to 65431 or 65432, or from 54321 to 65420 or 65430 or 65432, or the reverse.

34. The minimum can be computed as in the previous answer, but using min-plus matrix multiplication $c_{ij} = \min_k(a_{ik} + b_{kj})$ instead of ordinary matrix multiplication $c_{ij} = \sum_k a_{ik}b_{kj}$. (When $s = t = 5$, the genlex path in Fig. 26(e) with only 49 imperfect transitions is essentially unique. There is a genlex cycle for $s = t = 5$ that has only 55 imperfections.)

35. From the recurrences (35) we have $a_{st} = b_{s(t-1)} + [s>1][t>0] + a_{(s-1)t}$, $b_{st} = a_{s(t-1)} + a_{(s-1)t}$; consequently $a_{st} = b_{st} + [s>1][t\,\text{odd}]$ and $a_{st} = a_{s(t-1)} + a_{(s-1)t} + [s>1][t\,\text{odd}]$. The solution is

$$a_{st} = \sum_{k=0}^{t/2} \binom{s+t-2-2k}{s-2} - [s>1][t\,\text{even}];$$

this sum is approximately $s/(s+2t)$ times $\binom{s+t}{t}$.

36. Consider the binary tree with root node (s,t) and with recursively defined subtrees rooted at $(s-1,t)$ and $(s,t-1)$ whenever $st>0$; the node (s,t) is a leaf if $st=0$. Then the subtree rooted at (s,t) has $\binom{s+t}{t}$ leaves, corresponding to all (s,t)-combinations $a_{n-1}\ldots a_1a_0$. Nodes on level l correspond to prefixes $a_{n-1}\ldots a_{n-l}$, and leaves on level l are combinations with $r=n-l$.

Any genlex algorithm for combinations $a_{n-1}\ldots a_1a_0$ corresponds to preorder traversal of such a tree, after the children of the $\binom{s+t}{t}-1$ branch nodes have been ordered in any desired way; that, in fact, is why there are $2^{\binom{s+t}{t}-1}$ such genlex schemes (exercise 31(a)). And the operation $j\leftarrow j+1$ is performed exactly once per branch node, namely after both children have been processed.

Incidentally, exercise 7.2.1.2–6(a) implies that the average value of r is $s/(t+1)+t/(s+1)$, which can be $\Omega(n)$; thus the extra time needed to keep track of r is worthwhile.

37. (a) In the lexicographic case we needn't maintain the w_j table, since a_j is active for $j\ge r$ if and only if $a_j=0$. After setting $a_j\leftarrow 1$ and $a_{j-1}\leftarrow 0$ there are two cases to consider if $j>1$: If $r=j$, set $r\leftarrow j-1$; otherwise set $a_{j-2}\ldots a_0\leftarrow 0^r1^{j-1-r}$ and $r\leftarrow j-1-r$ (or $r\leftarrow j$ if r was $j-1$).

(b) Now the transitions to be handled when $j>1$ are to change $a_j\ldots a_0$ as follows: $01^r\to 1101^{r-2}$, $010^r\to 10^{r+1}$, $010^a1^r\to 110^{a+1}1^{r-1}$, $10^r\to 010^{r-1}$, $110^r\to 010^{r-1}1$, $10^a1^r\to 0^a1^{r+1}$; these six cases are easily distinguished. The value of r should change appropriately.

(c) Again the case $j=1$ is trivial. Otherwise $01^a0^r\to 101^{a-1}0^r$; $0^a1^r\to 10^a1^{r-1}$; $101^a0^r\to 01^{a+1}0^r$; $10^a1^r\to 0^a1^{r+1}$; and there is also an ambiguous case, which can occur only if $a_{n-1}\ldots a_{j+1}$ contains at least one 0: Let $k>j$ be minimal with $a_k=0$. Then $10^r\to 010^{r-1}$ if k is odd, $10^r\to 0^r1$ if k is even.

38. The same algorithm works, except that (i) step C1 sets $a_{n-1}\ldots a_0\leftarrow 01^t0^{s-1}$ if n is odd or $s=1$, $a_{n-1}\ldots a_0\leftarrow 001^t0^{s-2}$ if n is even and $s>1$, with an appropriate value of r; (ii) step C3 interchanges the roles of even and odd; (iii) step C5 goes to C4 also if $j=1$.

39. In general, start with $r\leftarrow 0$, $j\leftarrow s+t-1$, and repeat the following steps until $st=0$:

$$r\leftarrow r+[w_j=0]\binom{s+t-a_j}{s-a_j},\quad s\leftarrow s-[a_j=0],\quad t\leftarrow t-[a_j=1],\quad j\leftarrow j-1.$$

Then r is the rank of $a_{n-1}\ldots a_1a_0$. So the rank of 11001001000011111101101010 is $\binom{25}{11}+\binom{24}{11}+\binom{20}{10}+\binom{19}{9}+\binom{18}{7}+\binom{15}{6}+\binom{7}{4}+\binom{6}{2}+\binom{5}{2}+\binom{2}{2}=2390131$.

40. We start with $N\leftarrow 999999$, $v\leftarrow 0$, and repeat the following steps until $st=0$: If $v=0$, set $t\leftarrow t-1$ and $a_{s+t}\leftarrow 1$ if $N<\binom{s+t-1}{s}$, otherwise set $N\leftarrow N-\binom{s+t-1}{s}$, $v\leftarrow (s+t) \bmod 2$, $s\leftarrow s-1$, $a_{s+t}\leftarrow 0$. If $v=1$, set $v\leftarrow (s+t) \bmod 2$, $s\leftarrow s-1$, and $a_{s+t}\leftarrow 0$ if $N<\binom{s+t-1}{t}$, otherwise set $N\leftarrow N-\binom{s+t-1}{t}$, $t\leftarrow t-1$, $a_{s+t}\leftarrow 1$.

Finally if $s = 0$, set $a_{t-1} \ldots a_0 \leftarrow 1^t$; if $t = 0$, set $a_{s-1} \ldots a_0 \leftarrow 0^s$. The answer is $a_{25} \ldots a_0 = 11101001111111010100100001$.

41. Let $c(0), \ldots, c(2^n - 1) = C_n$ where $C_{2n} = 0C_{2n-1}$, $1C_{2n-1}$; $C_{2n+1} = 0C_{2n}$, $1\widehat{C}_{2n}$; $\widehat{C}_{2n} = 1C_{2n-1}$, $0\widehat{C}_{2n-1}$; $\widehat{C}_{2n+1} = 1\widehat{C}_{2n}$, $0\widehat{C}_{2n}$; $C_0 = \widehat{C}_0 = \epsilon$. Then $a_j \oplus b_j = b_{j+1} \wedge (b_{j+2} \vee (b_{j+3} \wedge (b_{j+4} \vee \cdots)))$ if j is even, $b_{j+1} \vee (b_{j+2} \wedge (b_{j+3} \vee (b_{j+4} \wedge \cdots)))$ if j is odd. Curiously we also have the inverse relation $c\big((\ldots \bar{a}_5 a_4 \bar{a}_3 a_2 \bar{a}_1 a_0)_2\big) = (\ldots \bar{b}_5 b_4 \bar{b}_3 b_2 \bar{b}_1 b_0)$.

42. Equation (40) shows that the left context $a_{n-1} \ldots a_{l+1}$ does not affect the behavior of the algorithm on $a_{l-1} \ldots a_0$ if $a_l = 0$ and $l > r$. Therefore we can analyze Algorithm C by counting combinations that end with certain bit patterns, and it follows that the number of times each operation is performed can be represented as $[w^s z^t]\, p(w,z)/(1-w^2)^2(1-z^2)^2(1-w-z)$ for an appropriate polynomial $p(w,z)$.

For example, the algorithm goes from C5 to C4 once for each combination that ends with $01^{2a+1}01^{2b+1}$ or has the form $1^{a+1}01^{2b+1}$, for integers $a, b \ge 0$; the corresponding generating functions are $w^2z^2/(1-z^2)^2(1-w-z)$ and $w(z^2+z^3)/(1-z^2)^2$.

Here are the polynomials $p(w,z)$ for key operations. Let $W = 1 - w^2$, $Z = 1 - z^2$.

C3 → C4:	$wzW(1+wz)(1-w-z^2)$:	C5($r \leftarrow 1$):	$w^2zW^2Z(1-wz-z^2)$:
C3 → C5:	$wzW(w+z)(1-wz-z^2)$:	C5($r \leftarrow j-1$):	$w^2z^3W^2(1-wz-z^2)$:
C3 → C6:	$w^2z^2W(w+z)$:	C6($j = 1$):	w^2zW^2Z:
C3 → C7:	$w^2zW(1+wz)$:	C6($r \leftarrow j-1$):	$w^2z^3W^2$:
C4($j = 1$):	$wzW^2Z(1-w-z^2)$:	C6($r \leftarrow j$):	w^3z^2WZ:
C4($r \leftarrow j-1$):	$w^3zWZ(1-w-z^2)$:	C7 → C6:	w^2zW^2:
C4($r \leftarrow j$):	$wz^2W^2(1+z-2wz-z^2-z^3)$:	C7($r \leftarrow j$):	w^4zWZ:
C5 → C4:	$wz^2W^2(1-wz-z^2)$:	C7($r \leftarrow j-2$):	$w^3z^2W^2$:
C5($r \leftarrow j-2$):	$w^4zWZ(1-wz-z^2)$:		

The asymptotic value is $\binom{s+t}{t}\big(p(1-x,x)/(2x-x^2)^2(1-x^2)^2 + O(n^{-1})\big)$, for fixed $0 < x < 1$, if $t = xn + O(1)$ as $n \to \infty$. Thus we find, for example, that the four-way branching in step C3 takes place with relative frequencies $x + x^2 - x^3 : 1 : x : 1 + x - x^2$.

Incidentally, the number of cases with j odd exceeds the number of cases with j even by

$$\sum_{k,l \ge 1} \binom{s+t-2k-2l}{s-2k} [2k+2l \le s+t] + [s \text{ odd}][t \text{ odd}],$$

in *any* genlex scheme that uses (39). This quantity has the interesting generating function $wz/(1+w)(1+z)(1-w-z)$.

43. The identity is true for all nonnegative integers x, except when $x = 1$.

44. In fact, $C_t(n) - 1 = \widehat{C}_t(n-1)^R$, and $\widehat{C}_t(n) - 1 = C_t(n-1)^R$. (Hence $C_t(n) - 2 = C_t(n-2)$, etc.)

45. In the following algorithm, r is the least subscript with $c_r \ge r$.

CC1. [Initialize.] Set $c_j \leftarrow n - t - 1 + j$ and $z_j \leftarrow 0$ for $1 \le j \le t+1$. Also set $r \leftarrow 1$. (We assume that $0 < t < n$.)

CC2. [Visit.] Visit the combination $c_t \ldots c_2 c_1$. Then set $j \leftarrow r$.

CC3. [Branch.] Go to CC5 if $z_j \ne 0$.

CC4. [Try to decrease c_j.] Set $x \leftarrow c_j + (c_j \bmod 2) - 2$. If $x \ge j$, set $c_j \leftarrow x$, $r \leftarrow 1$; otherwise if $c_j = j$, set $c_j \leftarrow j - 1$, $z_j \leftarrow c_{j+1} - \big((c_{j+1} + 1) \bmod 2\big)$, $r \leftarrow j$; otherwise if $c_j < j$, set $c_j \leftarrow j$, $z_j \leftarrow c_{j+1} - \big((c_{j+1} + 1) \bmod 2\big)$, $r \leftarrow \max(1, j-1)$; otherwise set $c_j \leftarrow x$, $r \leftarrow j$. Return to CC2.

CC5. [Try to increase c_j.] Set $x \leftarrow c_j + 2$. If $x < z_j$, set $c_j \leftarrow x$; otherwise if $x = z_j$ and $z_j \neq 0$, set $c_j \leftarrow x - (c_{j+1} \bmod 2)$; otherwise set $z_j \leftarrow 0$, $j \leftarrow j + 1$, and go to CC3 (but terminate if $j > t$). If $c_1 > 0$, set $r \leftarrow 1$; otherwise set $r \leftarrow j - 1$. Return to CC2. ▮

46. Eq. (40) implies that $u_k = (b_j + k + 1) \bmod 2$ when j is minimal with $b_j > k$. Then (37) and (38) yield the following algorithm, where we assume for convenience that $3 \le s < n$.

CB1. [Initialize.] Set $b_j \leftarrow j - 1$ for $1 \le j \le s$; also set $z \leftarrow s + 1$, $b_z \leftarrow 1$. (When subsequent steps examine the value of z, it is the smallest index such that $b_z \neq z - 1$.)

CB2. [Visit.] Visit the dual combination $b_s \ldots b_2 b_1$.

CB3. [Branch.] If b_2 is odd: Go to CB4 if $b_2 \neq b_1 + 1$, otherwise to CB5 if $b_1 > 0$, otherwise to CB6 if b_z is odd. Go to CB9 if b_2 is even and $b_1 > 0$. Otherwise go to CB8 if $b_{z+1} = b_z + 1$, otherwise to CB7.

CB4. [Increase b_1.] Set $b_1 \leftarrow b_1 + 1$ and return to CB2.

CB5. [Slide b_1 and b_2.] If b_3 is odd, set $b_1 \leftarrow b_1 + 1$ and $b_2 \leftarrow b_2 + 1$; otherwise set $b_1 \leftarrow b_1 - 1$, $b_2 \leftarrow b_2 - 1$, $z \leftarrow 3$. Go to CB2.

CB6. [Slide left.] If z is odd, set $z \leftarrow z - 2$, $b_{z+1} \leftarrow z + 1$, $b_z \leftarrow z$; otherwise set $z \leftarrow z - 1$, $b_z \leftarrow z$. Go to CB2.

CB7. [Slide b_z.] If b_{z+1} is odd, set $b_z \leftarrow b_z + 1$ and terminate if $b_z \ge n$; otherwise set $b_z \leftarrow b_z - 1$, then if $b_z < z$ set $z \leftarrow z + 1$. To CB2.

CB8. [Slide b_z and b_{z+1}.] If b_{z+2} is odd, set $b_z \leftarrow b_{z+1}$, $b_{z+1} \leftarrow b_z + 1$, and terminate if $b_{z+1} \ge n$. Otherwise set $b_{z+1} \leftarrow b_z$, $b_z \leftarrow b_z - 1$, then if $b_z < z$ set $z \leftarrow z + 2$. To CB2.

CB9. [Decrease b_1.] Set $b_1 \leftarrow b_1 - 1$, $z \leftarrow 2$, and return to CB2. ▮

Notice that this algorithm is *loopless*. Chase gave a similar procedure for the sequence $\widehat{C}^R_{st}$ in *Cong. Num.* **69** (1989), 233–237. It is truly amazing that this algorithm defines precisely the complements of the indices $c_t \ldots c_1$ produced by the algorithm in the previous exercise.

47. We can, for example, use Algorithm C and its reverse (exercise 38), with w_j replaced by a d-bit number whose bits represent activity at different levels of the recursion. Separate pointers r_0, r_1, ..., r_{d-1} are needed to keep track of the r-values on each level. (Many other solutions are possible.)

48. There are permutations $\pi_1, \ldots, \pi_M$ such that the kth element of Λ_j is $\pi_k \alpha_j \uparrow \beta_{k-1}$. And $\pi_k \alpha_j$ runs through all permutations of $\{s_1 \cdot 1, \ldots, s_d \cdot d\}$ as j varies from 0 to $N - 1$.

Historical note: The first publication of a homogeneous revolving-door scheme for (s,t)-combinations was by Éva Török, *Matematikai Lapok* **19** (1968), 143–146, who was motivated by the generation of multiset permutations. Many authors have subsequently relied on the homogeneity condition for similar constructions, but this exercise shows that homogeneity is not necessary.

49. We have $\lim_{z\to q}(z^{km+r} - 1)/(z^{lm+r} - 1) = 1$ when $0 < r < m$, and the limit is $\lim_{z\to q}(kmz^{km-1})/(lmz^{lm-1}) = k/l$ when $r = 0$. So we can pair up factors of the numerator $\prod_{n-k<a\le n}(z^a - 1)$ with factors of the denominator $\prod_{0<b\le k}(z^b - 1)$ when $a \equiv b$ (modulo m).

Notes: In the special case $m = 2$, $q = -1$, the second factor vanishes only when n is even and k is odd. The formula $\binom{n}{k}_q = \binom{n}{n-k}_q$ holds for all $n \ge 0$, but $\binom{\lfloor n/m \rfloor}{\lfloor k/m \rfloor}$ is *not*

always equal to $\binom{\lfloor n/m\rfloor}{\lfloor (n-k)/m\rfloor}$. We do, however, have $\lfloor k/m\rfloor + \lfloor (n-k)/m\rfloor = \lfloor n/m\rfloor$ in the case when $n \bmod m \geq k \bmod m$; otherwise the second factor is zero.

50. The stated coefficient is zero when $n_1 \bmod m + \cdots + n_t \bmod m \geq m$. Otherwise it equals

$$\binom{\lfloor (n_1+\cdots+n_t)/m\rfloor}{\lfloor n_1/m\rfloor,\ldots,\lfloor n_t/m\rfloor}\binom{(n_1+\cdots+n_t) \bmod m}{n_1 \bmod m,\ldots,n_t \bmod m}_q,$$

by Eq. 1.2.6–(43); here each upper index is the sum of the lower indices.

51. All paths clearly run between 000111 and 111000, since those vertices have degree 1. Fourteen total paths reduce to four under the stated equivalences. The path in (50), which is equivalent to itself under reflection-and-reversal, can be described by the delta sequence $A = 3452132523414354123$; the other three classes are $B = 3452541453414512543$, $C = 3452541453252154123$, $D = 3452134145341432543$. D. H. Lehmer found path C [*AMM* **72** (1965), part II, 36–46]; D is essentially the path constructed by Eades, Hickey, and Read.

(Incidentally, perfect schemes aren't really rare, although they seem to be difficult to construct systematically. The case $s = 3$, $t = 5$ has 4,050,046 of them.)

52. We may assume that each s_j is nonzero and that $d > 1$. Then the difference between permutations with an even and odd number of inversions is $\binom{\lfloor (s_0+\cdots+s_d)/2\rfloor}{\lfloor s_0/2\rfloor,\ldots,\lfloor s_d/2\rfloor} \geq 2$, by exercise 50, unless at least two of the multiplicities s_j are odd.

Conversely, if at least two multiplicities are odd, a general construction by G. Stachowiak [*SIAM J. Discrete Math.* **5** (1992), 199–206] shows that a perfect scheme exists. Indeed, his construction applies to a variety of topological sorting problems; in the special case of multisets it gives a Hamiltonian circuit in all cases with $d > 1$ and $s_0 s_1$ odd, except when $d = 2$, $s_0 = s_1 = 1$, and s_2 is even.

53. See *AMM* **72** (1965), Part II, 36–46.

54. Assuming that $st \neq 0$, a Hamiltonian path exists if and only if s and t are not both even; a Hamiltonian circuit exists if and only if, in addition, ($s \neq 2$ and $t \neq 2$) or $n = 5$. [T. C. Enns, *Discrete Math.* **122** (1993), 153–165.]

55. [*Discrete Math.* **48** (1984), 163–171.] This problem is equivalent to the "middle levels conjecture," which states that there is a Gray path through all binary strings of length $2t-1$ and weights $\{t-1, t\}$. In fact, such strings can almost certainly be generated by a delta sequence of the special form $\alpha_0\alpha_1\ldots\alpha_{2t-2}$ where the elements of α_k are those of α_0 shifted by k, modulo $2t-1$. For example, when $t = 3$ we can start with $a_5a_4a_3a_2a_1a_0 = 000111$ and repeatedly swap $a_0 \leftrightarrow a_\delta$, where δ runs through the cycle (4134 5245 1351 2412 3523). The middle levels conjecture is known to be true for $t \leq 15$ [see I. Shields and C. D. Savage, *Cong. Num.* **140** (1999), 161–178].

56. Yes; there is a near-perfect genlex solution for all m, n, and t when $n \geq m > t$. One such scheme, in bitstring notation, is $1A_{(m-t)(t-1)}0^{n-m}$, $01A_{(m-t)(t-1)}0^{n-m-1}$, $\ldots$, $0^{n-m}1A_{(m-t)(t-1)}$, $0^{n-m+1}1A_{(m-1-t)(t-1)}$, $\ldots$, $0^{n-t}1A_{0(t-1)}$, using the sequences A_{st} of (35).

57. Solve the previous problem with m and n reduced by $t-1$, then add $j-1$ to each c_j. (Case (a), which is particularly simple, was probably known to Czerny.)

58. The generating function $G_{mnt}(q) = \sum g_{mntk}q^k$ for the number g_{mntk} of chords reachable in k steps from $0^{n-t}1^t$ satisfies $G_{mmt}(q) = \binom{m}{t}_q$ and $G_{m(n+1)t}(q) = G_{mnt}(q) + q^{tn-(t-1)m}\binom{m-1}{t-1}_q$, because the latter term accounts for cases with $c_t = n$ and $c_1 > n-m$. A perfect scheme is possible only if $|G_{mnt}(-1)| \leq 1$. But if $n \geq m > t \geq 2$, this

condition holds only when $m = t + 1$ or $(n - t)t$ is odd, by exercise 49. So there is no perfect solution when $t = 4$ and $m > 5$. (Many chords have only two neighbors when $n = t + 2$, so one can easily rule out that case. All cases with $n \geq m > 5$ and $t = 3$ apparently do have perfect paths when n is even.)

59. The following solution uses lexicographic order, taking care to ensure that the average amount of computation per step is bounded. We may assume that $stm_s \ldots m_0 \neq 0$ and $t \leq m_s + \cdots + m_1 + m_0$.

Q1. [Initialize.] Set $q_j \leftarrow 0$ for $1 \leq j \leq s$, and $x = t$.

Q2. [Distribute.] Set $j \leftarrow 0$. Then while $x > m_j$, set $q_j \leftarrow m_j$, $x \leftarrow x - m_j$, $j \leftarrow j + 1$, and repeat until $x \leq m_j$. Finally set $q_j \leftarrow x$.

Q3. [Visit.] Visit the bounded composition $q_s \ldots q_1 q_0$.

Q4. [Pick up the rightmost units.] If $j = 0$, set $x \leftarrow q_0 - 1$, $j \leftarrow 1$. Otherwise if $q_0 = 0$, set $x \leftarrow q_j - 1$, $q_j \leftarrow 0$, and $j \leftarrow j + 1$. Otherwise go to Q7.

Q5. [Full?] Terminate if $j > s$. Otherwise if $q_j = m_j$, set $x \leftarrow x + m_j$, $q_j \leftarrow 0$, $j \leftarrow j + 1$, and repeat this step.

Q6. [Increase q_j.] Set $q_j \leftarrow q_j + 1$. Then if $x = 0$, set $q_0 \leftarrow 0$ and return to Q3. Otherwise go to Q2.

Q7. [Increase and decrease.] While $q_j = m_j$, set $j \leftarrow j+1$ and repeat until $q_j < m_j$ (but terminate if $j > s$). Then set $q_j \leftarrow q_j + 1$, $j \leftarrow j - 1$, $q_j \leftarrow q_j - 1$. If $q_0 = 1$, set $j \leftarrow 1$. Return to Q3. ∎

For example, if $m_s = \cdots = m_0 = 9$, the successors of the composition $3{+}9{+}9{+}7{+}0{+}0$ are $4{+}0{+}0{+}6{+}9{+}9$, $4{+}0{+}0{+}7{+}8{+}9$, $4{+}0{+}0{+}7{+}9{+}8$, $4{+}0{+}0{+}8{+}7{+}9$, ...

60. Let $F_s(t) = \emptyset$ if $t < 0$ or $t > m_s + \cdots + m_0$; otherwise let $F_0(t) = t$, and

$$F_s(t) = 0{+}F_{s-1}(t),\ 1{+}F_{s-1}(t-1)^R,\ 2{+}F_{s-1}(t-2),\ \ldots,\ m_s{+}F_{s-1}(t-m_s)^{R^{m_s}}$$

when $s > 0$. This sequence can be shown to have the required properties; it is, in fact, equivalent to the compositions defined by the homogeneous sequence K_{st} of (31) under the correspondence of exercise 4, when restricted to the subsequence defined by the bounds $m_s, \ldots, m_0$. [See T. Walsh, *J. Combinatorial Math. and Combinatorial Computing* **33** (2000), 323–345, who has implemented it looplessly.]

61. (a) A $2 \times n$ contingency table with row sums r and $c_1 + \cdots + c_n - r$ is equivalent to solving $r = a_1 + \cdots + a_n$ with $0 \leq a_1 \leq c_1, \ldots, 0 \leq a_n \leq c_n$.

(b) We can compute it sequentially by setting $a_{ij} \leftarrow \min(r_i - a_{i1} - \cdots - a_{i(j-1)}, c_j - a_{1j} - \cdots - a_{(i-1)j})$ for $j = 1, \ldots, n$, for $i = 1, \ldots, m$. Alternatively, if $r_1 \leq c_1$, set $a_{11} \leftarrow r_1$, $a_{12} \leftarrow \cdots \leftarrow a_{1n} \leftarrow 0$, and do the remaining rows with c_1 decreased by r_1; if $r_1 > c_1$, set $a_{11} \leftarrow c_1$, $a_{21} \leftarrow \cdots \leftarrow a_{m1} \leftarrow 0$, and do the remaining columns with r_1 decreased by c_1. The second approach shows that at most $m + n - 1$ of the entries are nonzero. We can also write down the explicit formula

$$a_{ij} = \max\bigl(0, \min(r_i, c_j, r_1 + \cdots + r_i - c_1 - \cdots - c_{j-1}, c_1 + \cdots + c_j - r_1 - \cdots - r_{i-1})\bigr).$$

(c) The same matrix is obtained as in (b).

(d) Reverse left and right in (b) and (c), obtaining

$$a_{ij} = \max\bigl(0, \min(r_i, c_j, r_{i+1} + \cdots + r_m - c_1 - \cdots - c_{j-1}, c_1 + \cdots + c_j - r_i - \cdots - r_m)\bigr)$$

in both cases.

(e) Here we choose, say, row-wise order: Generate the first row just as for bounded compositions of r_1, with bounds $(c_1,\ldots,c_n)$; and for each row $(a_{11},\ldots,a_{1n})$, generate the remaining rows recursively in the same way, but with the column sums $(c_1-a_{11},\ldots,c_n-a_{1n})$. Most of the action takes place on the bottom two rows, but when a change is made to an earlier row the later rows must be re-initialized.

62. If a_{ij} and a_{kl} are positive, we obtain another contingency table by setting $a_{ij}\leftarrow a_{ij}-1$, $a_{il}\leftarrow a_{il}+1$, $a_{kj}\leftarrow a_{kj}+1$, $a_{kl}\leftarrow a_{kl}-1$. We want to show that the graph G whose vertices are the contingency tables for $(r_1,\ldots,r_m;c_1,\ldots,c_n)$, adjacent if they can be obtained from each other by such a transformation, has a Hamiltonian path.

When $m=n=2$, G is a simple path. When $m=2$ and $n=3$, G has a two-dimensional structure from which we can see that every vertex is the starting point of at least two Hamiltonian paths, having distinct endpoints. When $m=2$ and $n\ge4$ we can show, inductively, that G actually has Hamiltonian paths from any vertex to any other.

When $m\ge3$ and $n\ge3$, we can reduce the problem from m to $m-1$ as in answer 61(e), if we are careful not to "paint ourselves into a corner." Namely, we must avoid reaching a state where the nonzero entries of the bottom two rows have the form $\left(\begin{smallmatrix}1&a&0\\0&b&c\end{smallmatrix}\right)$ for some a, b, $c>0$ and a change to row $m-2$ forces this to become $\left(\begin{smallmatrix}0&a&1\\0&b&c\end{smallmatrix}\right)$. The previous round of changes to rows $m-1$ and m can avoid such a trap unless $c=1$ and it begins with $\left(\begin{smallmatrix}0&a+1&0\\1&b-1&1\end{smallmatrix}\right)$ or $\left(\begin{smallmatrix}1&a-1&1\\0&b+1&0\end{smallmatrix}\right)$. But that situation can be avoided too.

(A genlex method based on exercise 60 would be considerably simpler, and it almost always would make only four changes per step. But it would occasionally need to update $2\min(m,n)$ entries at a time.)

63. When $x_1\ldots x_s$ is a binary string and A is a list of subcubes, let $A\oplus x_1\ldots x_s$ denote replacing the digits $(a_1,\ldots,a_s)$ in each subcube of A by $(a_1\oplus x_1,\ldots,a_s\oplus x_s)$, from left to right. For example, $0{*}1{*}{*}10\oplus1010=1{*}1{*}{*}00$. Then the following mutual recursions define a Gray code, because A_{st} gives a Gray path from $0^s{*}^t$ to $10^{s0}1{*}^t$ and B_{st} gives a Gray path from $0^s{*}^t$ to ${*}01^{s-1}{*}^{t-1}$, when $st>0$:

$$\begin{aligned}A_{st}&=0B_{(s-1)t},\ {*}A_{s(t-1)}\oplus001^{s-2},\ 1B^R_{(s-1)t};\\B_{st}&=0A_{(s-1)t},\ 1B_{(s-1)t}\oplus010^{s-2},\ 1A_{s(t-1)}\oplus1^s.\end{aligned}$$

The strings 001^{s-2} and 010^{s-2} are simply 0^s when $s<2$; A_{s0} is Gray binary code; $A_{0t}=B_{0t}={*}^t$.

Incidentally, the somewhat simpler construction

$$G_{st}=\ {*}G_{s(t-1)},\ a_tG_{(s-1)t},\ a_{t-1}G^R_{(s-1)t},\qquad a_t=t \bmod 2,$$

defines a pleasant Gray *path* from ${*}^t0^s$ to $a_{t-1}{*}^t0^{s-1}$.

64. If a path P is considered equivalent to P^R and to $P\oplus x_1\ldots x_s$, the total number can be computed systematically as in exercise 33, with the following results for $s+t\le6$:

paths	cycles
1	1
1 1	1 1
1 2 1	1 1 1
1 3 3 1	1 1 1 1
1 5 10 4 1	1 2 1 1 1
1 6 36 35 5 1	1 2 3 1 1 1
1 9 310 4630 218 6 1	1 3 46 4 1 1 1

In general there are $t+1$ paths when $s=1$ and $\binom{\lceil s/2\rceil+2}{2}-(s \bmod 2)$ when $t=1$. The cycles for $s\le 2$ are unique. When $s=t=5$ there are approximately 6.869×10^{170} paths and 2.495×10^{70} cycles.

65. Let $G(n,0)=\epsilon$; $G(n,t)=\emptyset$ when $n<t$; and for $1\le t\le n$, let $G(n,t)$ be

$$\hat g(0)G(n-1,t),\ \hat g(1)G(n-1,t)^R,\ \ldots,\ \hat g(2^t-1)G(n-1,t)^R,\ \hat g(2^t-1)G(n-1,t-1),$$

where $\hat g(k)$ is a t-bit column containing the Gray binary number $g(k)$ with its least significant bit at the top. In this general formula we implicitly add a row of zeros below the bases of $G(n-1,t-1)$.

This remarkable rule gives ordinary Gray binary code when $t=1$, omitting $0\ldots00$. A cyclic Gray code is impossible because $\binom{n}{t}_2$ is odd.

66. A Gray path for compositions corresponding to Algorithm C implies that there is a path in which all transitions are $0^k1^l\leftrightarrow1^l0^k$ with $\min(k,l)\le2$. Perhaps there is, in fact, a cycle with $\min(k,l)=1$ in each transition.

67. (a) $\{\emptyset\}$; (b) $\emptyset$.

68. The least N with $\kappa_tN<N$ is $\binom{2t-1}{t}+\binom{2t-3}{t-1}+\cdots+\binom{1}{1}+1=\frac12\big(\binom{2t}{t}+\binom{2t-2}{t-1}+\cdots+\binom{0}{0}+1\big)$, because $\binom{n}{t-1}\le\binom{n}{t}$ if and only if $n\ge2t-1$.

69. From the identity

$$\kappa_t\big(\tbinom{2t-3}{t}+N'\big)-\big(\tbinom{2t-3}{t}+N'\big)=\kappa_t\big(\tbinom{2t-2}{t}+N'\big)-\big(\tbinom{2t-2}{t}+N'\big)=\tbinom{2t-2}{t}\tfrac{1}{t-1}+\kappa_{t-1}N'-N'$$

when $N'<\binom{2t-3}{t}$, we conclude that the maximum is $\binom{2t-2}{t}\frac1t+\binom{2t-4}{t-1}\frac{1}{t-2}+\cdots+\binom{2}{2}\frac11$, and it occurs at 2^{t-1} values of N when $t>1$.

70. Let C_t be the t-cliques. The first $\binom{1414}{t}+\binom{1009}{t-1}$ t-combinations visited by Algorithm L define a graph on 1415 vertices with 1000000 edges. If $\|C_t\|$ were larger, $\|\partial^{t-2}C_t\|$ would exceed 1000000. Thus the single graph defined by $P_{(1000000)_2}$ has the maximum number of t-cliques for all $t\ge2$.

71. $M=\binom{m_s}{s}+\cdots+\binom{m_u}{u}$ for $m_s>\cdots>m_u\ge u\ge1$, where $\{m_s,\ldots,m_u\}=\{s+t-1,\ldots,n_v\}\setminus\{n_t,\ldots,n_{v+1}\}$. (Compare with exercise 15, which gives $\binom{s+t}{t}-1-N$.)

If $\alpha=a_{n-1}\ldots a_0$ is the bit string corresponding to the combination $n_t\ldots n_1$, then v is 1 plus the number of trailing 1s in α, and u is the length of the rightmost run of 0s. For example, when $\alpha=1010001111$ we have $s=4$, $t=6$, $M=\binom84+\binom63$, $u=3$, $N=\binom96+\binom75$, $v=5$.

72. A and B are cross-intersecting $\iff\alpha\not\subseteq U\setminus\beta$ for all $\alpha\in A$ and $\beta\in B\iff A\cap\partial^{n-s-t}B^-=\emptyset$, where $B^-=\{U\setminus\beta\mid\beta\in B\}$ is a set of $(n-t)$-combinations. Since $Q^-_{Nnt}=P_{N(n-t)}$, we have $\|\partial^{n-s-t}B^-\|\ge\|\partial^{n-s-t}P_{N(n-t)}\|$, and $\partial^{n-s-t}P_{N(n-t)}=P_{N's}$ where $N'=\kappa_{s+1}\ldots\kappa_{n-t}N$. Thus if A and B are cross-intersecting we have $M+N'\le\|A\|+\|\partial^{n-s-t}B^-\|\le\binom ns$, and $Q_{Mns}\cap P_{N's}=\emptyset$.

Conversely, if $Q_{Mns}\cap P_{N's}\ne\emptyset$ we have $\binom ns<M+N'\le\|A\|+\|\partial^{n-s-t}B^-\|$, so A and B cannot be cross-intersecting.

73. $\|\varrho Q_{Nnt}\|=\kappa_{n-t}N$ (see exercise 93). Also, arguing as in (58) and (59), we find $\varrho P_{N5}=(n-1)P_{N5}\cup\cdots\cup10P_{N5}\cup\{543210,\ldots,987654\}$ in that particular case; and $\|\varrho P_{Nt}\|=(n+1-n_t)N+\binom{n_t+1}{t+1}$ in general.

74. The identity $\binom{n+1}{k}=\binom nk+\binom{n-1}{k-1}+\cdots+\binom{n-k}{0}$, Eq. 1.2.6–(10), gives another representation if $n_v>v$. But (60) is unaffected, since we have $\binom{n+1}{k-1}=\binom{n}{k-1}+\binom{n-1}{k-2}+\cdots+\binom{n-k+1}{0}$.

75. Represent $N+1$ by adding $\binom{v-1}{v-1}$ to (57); then use the previous exercise to deduce that $\kappa_t(N+1)-\kappa_t N=\binom{v-1}{v-2}=v-1$.

76. [D. E. Daykin, *Nanta Math.* **8**, 2 (1975), 78–83.] We work with extended representations $M=\binom{m_t}{t}+\cdots+\binom{m_u}{u}$ and $N=\binom{n_t}{t}+\cdots+\binom{n_v}{v}$ as in exercise 74, calling them *improper* if the final index u or v is zero. Call N *flexible* if it has both proper and improper representations, that is, if $n_v>v>0$.

(a) Given an integer S, find $M+N$ such that $M+N=S$ and $\kappa_t M+\kappa_t N$ is minimum, with M as large as possible. If $N=0$, we're done. Otherwise the max-min operation preserves both $M+N$ and $\kappa_t M+\kappa_t N$, so we can assume that $v\ge u\ge 1$ in the proper representations of M and N. If N is inflexible, $\kappa_t(M+1)+\kappa_t(N-1)=(\kappa_t M+u-1)+(\kappa_t N-v)<\kappa_t M+\kappa_t N$, by exercise 75; therefore N must be flexible. But then we can apply the max-min operation to M and the improper representation of N, increasing M: Contradiction.

This proof shows that equality holds if and only if $MN=0$, a fact that was noted in 1927 by F. S. Macaulay.

(b) Now we try to minimize $\max(\kappa_t M,N)+\kappa_{t-1}N$ when $M+N=S$, this time representing N as $\binom{n_{t-1}}{t-1}+\cdots+\binom{n_v}{v}$. The max-min operation can still be used if $n_{t-1}<m_t$; leaving m_t unchanged, it preserves $M+N$ and $\kappa_t M+\kappa_{t-1}N$ as well as the relation $\kappa_t M>N$. We arrive at a contradiction as in (a) if $N\ne 0$, so we can assume that $n_{t-1}\ge m_t$.

If $n_{t-1}>m_t$ we have $N>\kappa_t M$ and also $\lambda_t N>M$; hence $M+N<\lambda_t N+N=\binom{n_{t-1}+1}{t}+\cdots+\binom{n_v+1}{v}$, and we have $\kappa_t(M+N)\le\kappa_t(\lambda_t N+N)=N+\kappa_{t-1}N$.

Finally if $n_{t-1}=m_t=a$, let $M=\binom{a}{t}+M'$ and $N=\binom{a}{t-1}+N'$. Then $\kappa_t(M+N)=\binom{a+1}{t-1}+\kappa_{t-1}(M'+N')$, $\kappa_t M=\binom{a}{t-1}+\kappa_{t-1}M'$, and $\kappa_{t-1}N=\binom{a}{t-2}+\kappa_{t-2}N'$; the result follows by induction on t.

77. [A. J. W. Hilton, *Periodica Math. Hung.* **10** (1979), 25–30.] Let $M=\|A_1\|$ and $N=\|A_0\|$; we can assume that $t>0$ and $N>0$. Then $\|\partial A\|=\|\partial A_1\cup A_0\|+\|\partial A_0\|\ge\max(\|\partial A_1\|,\|A_0\|)+\|\partial A_0\|\ge\max(\kappa_t M,N)+\kappa_{t-1}N\ge\kappa_t(M+N)=\|P_{\|A\|t}\|$, by induction on $m+n+t$.

Conversely, let $A_1=P_{Mt}+1$ and $A_0=P_{N(t-1)}+1$; this notation means, for example, that $\{210,320\}+1=\{321,431\}$. Then $\kappa_t(M+N)\le\|\partial A\|=\|\partial A_1\cup A_0\|+\|(\partial A_0)0\|=\max(\kappa_t M,N)+\kappa_{t-1}N$, because $\partial A_1=P_{(\kappa_t M)(t-1)}+1$. [Schützenberger observed in 1959 that $\kappa_t(M+N)\le\kappa_t M+\kappa_{t-1}N$ if and only if $\kappa_t M\ge N$.]

For the first inequality, let A and B be disjoint sets of t-combinations with $\|A\|=M$, $\|\partial A\|=\kappa_t M$, $\|B\|=N$, $\|\partial B\|=\kappa_t N$. Then $\kappa_t(M+N)=\kappa_t\|A\cup B\|\le\|\partial(A\cup B)\|=\|\partial A\cup\partial B\|=\|\partial A\|+\|\partial B\|=\kappa_t M+\kappa_t N$.

78. In fact, $\mu_t(M+\lambda_{t-1}M)=M$, and $\mu_t N+\lambda_{t-1}\mu_t N=N+(n_2-n_1)[v=1]$ when N is given by (57).

79. If $N>0$ and $t>1$, represent N as in (57) and let $N=N_0+N_1$, where

$$N_0=\binom{n_t-1}{t}+\cdots+\binom{n_v-1}{v},\qquad N_1=\binom{n_t-1}{t-1}+\cdots+\binom{n_v-1}{v-1}.$$

Let $N_0=\binom{y}{t}$ and $N_1=\binom{z}{t-1}$. Then, by induction on t and $\lfloor x\rfloor$, we have $\binom{x}{t}=N_0+\kappa_t N_0\ge\binom{y}{t}+\binom{y}{t-1}=\binom{y+1}{t}$; $N_1=\binom{x}{t}-\binom{y}{t}\ge\binom{x}{t}-\binom{x-1}{t}=\binom{x-1}{t-1}$; and $\kappa_t N=N_1+\kappa_{t-1}N_1\ge\binom{z}{t-1}+\binom{z}{t-2}=\binom{z+1}{t-1}\ge\binom{x}{t-1}$.

Lovász actually proved a stronger result [*Combinatorial Problems and Exercises*, (Akadémiai Kiadó, 1979), problem 13.31(a)], which was strengthened further by R. M. Redheffer [*AMM* **103** (1996), 62–64]: Suppose $\binom{u}{t}=\binom{v}{t}+\binom{w}{t-1}$ where $u\ge t-1$,

$v \ge t-1$, and $w \ge t-2$. Then for $1 \le k < t$ we have $\binom{u}{k} \le \binom{v}{k} + \binom{w}{k-1}$ if and only if $v \ge w$; for $t < k \le \min(v+1, w+2)$ we have $\binom{u}{k} \le \binom{v}{k} + \binom{w}{k-1}$ if and only if $v \le w$.

80. For example, if the largest element of $\widehat{P}_{N5}$ is 66433, we have

$$\widehat{P}_{N5} = \{00000,\ldots,55555\} \cup \{60000,\ldots,65555\} \cup \{66000,\ldots,66333\} \cup \{66400,\ldots,66433\}$$

so $N = \binom{10}{5} + \binom{9}{4} + \binom{6}{3} + \binom{5}{2}$. Its lower shadow is

$$\partial\widehat{P}_{N5} = \{0000,\ldots,5555\} \cup \{6000,\ldots,6555\} \cup \{6600,\ldots,6633\} \cup \{6640,\ldots,6643\},$$

of size $\binom{9}{4} + \binom{8}{3} + \binom{5}{2} + \binom{4}{1}$.

If the smallest element of Q_{N95} is 66433, we have

$$\widehat{Q}_{N95} = \{99999,\ldots,70000\} \cup \{66666,\ldots,66500\} \cup \{66444,\ldots,66440\} \cup \{66433\}$$

so $N = \big(\binom{13}{9}+\binom{12}{8}+\binom{11}{7}\big) + \big(\binom{8}{6}+\binom{7}{5}\big) + \binom{5}{4} + \binom{3}{3}$. Its upper shadow is

$$\partial\widehat{Q}_{N95} = \{999999,\ldots,700000\} \cup \{666666,\ldots,665000\} \cup \{664444,\ldots,664400\} \cup \{664333,\ldots,664330\},$$

of size $\big(\binom{14}{9}+\binom{13}{8}+\binom{12}{7}\big) + \big(\binom{9}{6}+\binom{8}{5}\big) + \binom{6}{4} + \binom{4}{3} = N + \kappa_9 N$. The size, t, of each combination is essentially irrelevant, as long as $N \le \binom{s+t}{t}$; for example, the smallest element of $\widehat{Q}_{N98}$ is 99966433 in the case we have considered.

81. (a) The derivative would have to be $\sum_{k>0} r_k(x)$, but that series diverges.

[Informally, the graph of $\tau(x)$ shows "pits" of relative magnitude 2^{-k} at all odd multiples of 2^{-k}. Takagi's original publication, in *Proc. Physico-Math. Soc. Japan* (2) **1** (1903), 176–177, has been translated into English in his *Collected Papers* (Iwanami Shoten, 1973).]

(b) Since $r_k(1-t) = (1)^{\lceil 2^k t\rceil}$ when $k > 0$, we have $\int_0^{1-x} r_k(t)\,dt = \int_x^1 r_k(1-u)\,du = -\int_x^1 r_k(u)\,du = \int_0^x r_k(u)\,du$. The second equation follows from the fact that $r_k(\frac{1}{2}t) = r_{k-1}(t)$. Part (d) shows that these two equations suffice to define $\tau(x)$ when x is rational.

(c) Since $\tau(2^{-a}x) = a2^{-a}x + 2^{-a}\tau(x)$ for $0 \le x \le 1$, we have $\tau(\epsilon) = a\epsilon + O(\epsilon)$ when $2^{-a-1} \le \epsilon \le 2^{-a}$. Therefore $\tau(\epsilon) = \epsilon \lg \frac{1}{\epsilon} + O(\epsilon)$ for $0 < \epsilon \le 1$.

(d) Suppose $0 \le p/q \le 1$. If $p/q \le 1/2$ we have $\tau(p/q) = p/q + \tau(2p/q)/2$; otherwise $\tau(p/q) = (q-p)/q + \tau(2(q-p)/q)/2$. Therefore we can assume that q is odd. When q is odd, let $p' = p/2$ when p is even, $p' = (q-p)/2$ when p is odd. Then $\tau(p/q) = 2\tau(p'/q) - 2p'/q$ for $0 < p < q$; this system of $q-1$ equations has a unique solution. For example, the values for $q = 3, 4, 5, 6, 7$ are $2/3,\ 2/3;\ 1/2,\ 1/2,\ 1/2;\ 8/15,\ 2/3,\ 2/3,\ 8/15;\ 1/2,\ 2/3,\ 1/2,\ 2/3,\ 1/2;\ 22/49,\ 30/49,\ 32/49,\ 32/49,\ 30/49,\ 22/49$.

(e) The solutions $< \frac{1}{2}$ are $x = \frac{1}{4},\ \frac{1}{4} - \frac{1}{16},\ \frac{1}{4} - \frac{1}{16} - \frac{1}{64},\ \frac{1}{4} - \frac{1}{16} - \frac{1}{64} - \frac{1}{256},\ \ldots,\ \frac{1}{3}$.

(f) The value $\frac{2}{3}$ is achieved for $x = \frac{1}{2} \pm \frac{1}{8} \pm \frac{1}{32} \pm \frac{1}{128} \pm \cdots$, an uncountable set.

82. Consider paths starting from 0 in the digraph

$$\begin{array}{ccccccccccccc}
0 & \leftarrow & 1 & \leftarrow & 2 & \leftarrow & 3 & \leftarrow & 4 & \leftarrow & 5 & \leftarrow & \cdots \\
\updownarrow & & \updownarrow & & \updownarrow & & \updownarrow & & \updownarrow & & \updownarrow & & \\
1 & \rightarrow & 2 & \rightarrow & 3 & \rightarrow & 4 & \rightarrow & 5 & \rightarrow & 6 & \rightarrow & \cdots
\end{array}$$

Compute an associated value v, starting with $v \leftarrow -p$; horizontal moves change $v \leftarrow 2v$, vertical moves from node a change $v \leftarrow 2(qa - v)$. The path stops if we reach a node twice with the same value v. Transitions are not allowed to upper nodes with $-v \le -q$

or $v \ge qa$; they are not allowed to lower nodes with $v \le 0$ or $v \ge q(a+1)$. These restrictions force most steps of the path. (Node a in the upper row means, "Solve $\tau(x) = ax - v/q$"; in the lower row it means, "Solve $\tau(x) = v/q - ax$.") Empirical tests suggest that, for all integers $q > p > 0$, at least one such path exists, and that all such paths are finite. The equation $\tau(x) = p/q$ then has solutions $x = x_0$ defined by the sequence x_0, x_1, x_2, ... where $x_{k+1} = \frac{1}{2}x_k$ on a horizontal step and $x_{k+1} = 1 - \frac{1}{2}x_k$ on a vertical step; these are all the solutions to $\tau(x) = p/q$ when $x < \frac{1}{2}$, when q is not a power of 2.

For example, this procedure establishes that $\tau(x) = \frac{1}{5}$ only when x or $1-x$ is $3459/87040$; there are, similarly, just two solutions to $\tau(x) = 3/5$, having denominator $2^{46}(2^{56}-1)/3$.

Moreover, it appears that all cycles in the digraph that pass through node 0 define values of p and q such that $\tau(x) = p/q$ has uncountably many solutions. Such values are, for example, $2/3$, $8/15$, $8/21$, corresponding to the cycles (01), (0121), (012321). The value $32/63$ corresponds to (012121) and also to (0121012345454321), as well as to two other paths that do not return to 0.

83. [Frankl, Matsumoto, Ruzsa, and Tokushige, *J. Combinatorial Theory* **A69** (1995), 125–148.] If $a \le b$ we have

$$\binom{2t-1-b}{t-a} \Big/ T = t^{\underline{a}}(t-1)^{\underline{b-a}}/(2t-1)^{\underline{b}} = 2^{-b}\big(1 + f(a,b)t^{-1} + O(b^4/t^2)\big),$$

where $f(a,b) = a(1+b) - a^2 - b(1+b)/4 = f(a+1,b) - b + 2a$. Therefore if N has the combinatorial representation (57), and if we set $n_j = 2t - 1 - b_j$, we have

$$\frac{t}{T}\Big(\kappa_t N - N\Big) = \frac{b_t}{2^{b_t}} + \frac{b_{t-1}-2}{2^{b_{t-1}}} + \frac{b_{t-2}-4}{2^{b_{t-2}}} + \cdots + \frac{O(\log t)^3}{t},$$

the terms being negligible when b_j exceeds $2\lg t$. And one can show that

$$\tau\Big(\sum_{j=0}^{l} 2^{-e_j}\Big) \;=\; \sum_{j=0}^{l} (e_j - 2j)2^{-e_j}.$$

84. $N - \lambda_{t-1}N$ has the same asymptotic form as $\kappa_t N - N$, by (63), since $\tau(x) = \tau(1-x)$. So does $2\mu_t N - N$, up to $O\big(T(\log t)^3/t^2\big)$, because $\binom{2t-1-b}{t-a} = 2\binom{2t-2-b}{t-a}\big(1 + O(\log t)/t\big)$ when $b < 2\lg t$.

85. $x \in X^{\circ\sim} \iff \bar{x} \notin X^{\circ} \iff \bar{x} \notin X$ or $\bar{x} \notin X + e_1$ or $\cdots$ or $\bar{x} \notin X + e_n \iff x \in X^{\sim}$ or $x \in X^{\sim} - e_1$ or $\cdots$ or $x \in X^{\sim} - e_n \iff x \in X^{\sim+}$.

86. All three are true, using the fact that $X \subseteq Y^{\circ}$ if and only if $X^{+} \subseteq Y$: (a) $X \subseteq Y^{\circ} \iff X^{\sim} \supseteq Y^{\circ\sim} = Y^{\sim+} \iff Y^{\sim} \subseteq X^{\sim\circ}$. (b) $X^{+} \subseteq X^{+} \implies X \subseteq X^{+\circ}$; hence $X^{\circ} \subseteq X^{\circ+\circ}$. Also $X^{\circ} \subseteq X^{\circ} \implies X^{\circ+} \subseteq X$; hence $X^{\circ+\circ} \subseteq X^{\circ}$. (c) $\alpha M \le N \iff S_M^{+} \subseteq S_N \iff S_M \subseteq S_N^{\circ} \iff M \le \beta N$.

87. If $\nu x < \nu y$ then $\nu(x - e_k) < \nu(y - e_j)$, so we can assume that $\nu x = \nu y$ and $x < y$. We must have $y_j > 0$; otherwise $\nu(y - e_j)$ would exceed $\nu(x - e_k)$. If $x_i = y_i$ for $1 \le i \le j$, clearly $k > j$ and $x - e_k \prec y - e_j$. Otherwise $x_i > y_i$ for some $i \le j$; again we have $x - e_k \prec y - e_j$, unless $x - e_k = y - e_j$.

88. From the table

j =	0	1	2	3	4	5	6	7	8	9	10	11
$e_j + e_1$ =	e_1	e_0	e_4	e_5	e_2	e_3	e_8	e_9	e_6	e_7	e_{11}	e_{10}
$e_j + e_2$ =	e_2	e_4	e_0	e_6	e_1	e_8	e_3	e_{10}	e_5	e_{11}	e_7	e_9
$e_j + e_3$ =	e_3	e_5	e_6	e_7	e_8	e_9	e_{10}	e_0	e_{11}	e_1	e_2	e_4

we find $(\alpha 0, \alpha 1, \ldots, \alpha 12) = (0, 4, 6, 7, 8, 9, 10, 11, 11, 12, 12, 12, 12)$; $(\beta 0, \beta 1, \ldots, \beta 12) = (0, 0, 0, 0, 1, 1, 2, 3, 4, 5, 6, 8, 12)$.

89. Let $Y = X^+$ and $Z = C_k X$, and let $N_a = \|X_k(a)\|$ for $0 \le a < m_k$. Then

$$\|Y\| = \sum_{a=0}^{m_k-1} \|Y_k(a)\| = \sum_{a=0}^{m_k-1} \big\|(X_k(a-1) + e_k) \cup (X_k(a) + E_k(0))\big\| \\ \ge \sum_{a=0}^{m_k-1} \max(N_{a-1}, \alpha N_a),$$

where $a - 1$ stands for $(a - 1) \bmod m_k$ and the α function comes from the $(n - 1)$-dimensional torus, because $\|X_k(a) + E_k(0)\| \ge \alpha N_a$ by induction. Also

$$\|Z^+\| = \sum_{a=0}^{m_k-1} \|Z_k^+(a)\| = \sum_{a=0}^{m_k-1} \big\|(Z_k(a-1) + e_k) \cup (Z_k(a) + E_k(0))\big\| \\ = \sum_{a=0}^{m_k-1} \max(N_{a-1}, \alpha N_a),$$

because both $Z_k(a - 1) + e_k$ and $Z_k(a) + E_k(0)$ are standard in $n - 1$ dimensions.

90. Let there be N_a points in row a of a totally compressed array, where row 0 is at the bottom; thus $l = N_{-1} \ge N_0 \ge \cdots \ge N_{m-1} \ge N_m = 0$. We show first that there is an optimum X for which the "bad" condition $N_a = N_{a+1}$ never occurs except when $N_a = 0$ or $N_a = l$. For if a is the smallest bad subscript, suppose $N_{a-1} > N_a = N_{a+1} = \cdots = N_{a+k} > N_{a+k+1}$. Then we can always decrease N_{a+k} by 1 and add 1 to some N_b for $b \le a$ without increasing $\|X^+\|$, except in cases where $k = 1$ and $N_{a+2} = N_{a+1} - 1$ and $N_b = N_a + a - b$ for $0 \le b \le a$. Exploring such cases further, we can find a subscript d such that $N_c = N_{a+1} + a + 1 - c > 0$ for $a < c < d$, and either $N_d = 0$ or $N_d < N_{d+1} - 1$. Then it is OK to decrease N_c by 1 for $a < c < d$ and increase N_b by 1 for $0 \le b < d - a - 1$. (It is important to note that if $N_d = 0$ we have $N_0 \ge d - 1$; hence $d = m$ implies $l = m$.)

Repeating such transformations until $N_a > N_{a+1}$ whenever $N_a \ne l$ and $N_{a+1} \ne 0$, we reach situation (86), and the proof can be completed as in the text.

91. Let $x + k$ denote the lexicographically smallest element of $T(m_1, \ldots, m_{n-1})$ that exceeds x and has weight $\nu x + k$, if any such element exists. For example, if $m_1 = m_2 = m_3 = 4$ and $x = 211$, we have $x+1 = 212$, $x+2 = 213$, $x+3 = 223$, $x+4 = 233$, $x+5 = 333$, and $x + 6$ does not exist; in general, $x + k + 1$ is obtained from $x + k$ by increasing the rightmost component that can be increased. If $x + k = (m_1 - 1, \ldots, m_{n-1} - 1)$, let us set $x + k + 1 = x + k$. Then if $S(k)$ is the set of all elements of $T(m_1, \ldots, m_{n-1})$ that are $\le x + k$, we have $S(k + 1) = S(k)^+$. Furthermore, the elements of S that end in a are those whose first $n - 1$ components are in $S(m - 1 - a)$.

The result of this exercise can be stated more intuitively: As we generate n-dimensional standard sets S_1, S_2, ..., the $(n - 1)$-dimensional standard sets on each layer become spreads of each other just after each point is added to layer $m - 1$. Similarly, they become cores of each other just before each point is added to layer 0.

92. (a) Suppose the parameters are $2 \le m'_1 \le m'_2 \le \cdots \le m'_n$ when sorted properly, and let k be minimal with $m_k \ne m'_k$. Then take $N = 1 + \mathrm{rank}(0, \ldots, 0, m'_k - 1, 0, \ldots, 0)$. (We must assume that $\min(m_1, \ldots, m_n) \ge 2$, since parameters equal to 1 can be placed anywhere.)

(b) Only in the proof for $n = 2$, buried inside the answer to exercise 90. That proof is incorporated by induction when n is larger.

93. Complementation reverses lexicographic order and changes ϱ to ∂.

94. For Theorem K, let $d = n - 1$ and $s_0 = \cdots = s_d = 1$. For Theorem M, let $d = s$ and $s_0 = \cdots = s_d = t + 1$.

95. In such a representation, N is the number of t-multicombinations of $\{s_0 \cdot 0, s_1 \cdot 1, s_2 \cdot 2, \dots\}$ that precede $n_t n_{t-1} \dots n_1$ in lexicographic order, because the generalized coefficient $\binom{S(n)}{t}$ counts the multicombinations whose leftmost component is $< n$.

If we truncate the representation by stopping at the rightmost nonzero term $\binom{S(n_v)}{v}$, we obtain a nice generalization of (6o):

$$\|\partial P_{N_t}\| = \binom{S(n_t)}{t-1} + \binom{S(n_{t-1})}{t-2} + \cdots + \binom{S(n_v)}{v-1}.$$

[See G. F. Clements, *J. Combinatorial Theory* **A37** (1984), 91–97. The inequalities $s_0 \ge s_1 \ge \cdots \ge s_d$ are needed for the validity of Corollary C, but not for the calculation of $\|\partial P_{N_t}\|$. Some terms $\binom{S(n_k)}{k}$ for $t \ge k > v$ may be zero. For example, when $N = 1$, $t = 4$, $s_0 = 3$, and $s_1 = 2$, we have $N = \binom{S(1)}{4} + \binom{S(1)}{3} = 0 + 1$.]

96. (a) The tetrahedron has four vertices, six edges, four faces: $(N_0, \dots, N_4) = (1, 4, 6, 4, 1)$. The octahedron, similarly, has $(N_0, \dots, N_6) = (1, 6, 8, 8, 0, 0, 0)$, and the icosahedron has $(N_0, \dots, N_{12}) = (1, 12, 30, 20, 0, \dots, 0)$. The hexahedron, aka the 3-cube, has eight vertices, 12 edges, and six square faces; perturbation breaks each square face into two triangles and introduces new edges, so we have $(N_0, \dots, N_8) = (1, 8, 18, 12, 0, \dots, 0)$. Finally, the perturbed pentagonal faces of the dodecahedron lead to $(N_0, \dots, N_{20}) = (1, 20, 54, 36, 0, \dots, 0)$.

(b) $\{210, 310\} \cup \{10, 20, 21, 30, 31\} \cup \{0, 1, 2, 3\} \cup \{\epsilon\}$.

(c) $0 \le N_t \le \binom{n}{t}$ for $0 \le t \le n$ and $N_{t-1} \ge \kappa_t N_t$ for $1 \le t \le n$. The second condition is equivalent to $\lambda_{t-1} N_{t-1} \ge N_t$ for $1 \le t \le n$, if we define $\lambda_0 1 = \infty$. These conditions are necessary for Theorem K, and sufficient if $A = \bigcup P_{N_t t}$.

(d) The complements of the elements not in a simplicial complex, namely the sets $\{\{0, \dots, n-1\} \setminus \alpha \mid \alpha \notin C\}$, form a simplicial complex. (We can also verify that the necessary and sufficient condition holds: $N_{t-1} \ge \kappa_t N_t \iff \lambda_{t-1} N_{t-1} \ge N_t \iff \kappa_{n-t+1} \overline{N}_{n-t+1} \le \overline{N}_{n-t}$, because $\kappa_{n-t} \overline{N}_{n-t+1} = \binom{n}{t} - \lambda_{t-1} N_{t-1}$ by exercise 93.)

(e) 00000 ↔ 14641; 10000 ↔ 14640; 11000 ↔ 14630; 12000 ↔ 14620; 13000 ↔ 14610; 14000 ↔ 14600; 12100 ↔ 14520; 13100 ↔ 14510; 14100 ↔ 14500; 13200 ↔ 14410; 14200 ↔ 14400; 13300 ↔ 14400; and the self-dual cases 14300, 13310.

97. The following procedure by S. Linusson [*Combinatorica* **19** (1999), 255–266], who considered also the more general problem for multisets, is considerably faster than a more obvious approach. Let $L(n, h, l)$ count feasible vectors with $N_t = \binom{n}{t}$ for $0 \le t \le l$, $N_{t+1} < \binom{n}{t+1}$, and $N_t = 0$ for $t > h$. Then $L(n, h, l) = 0$ unless $-1 \le l \le h \le n$; also $L(n, h, h) = L(n, h, -1) = 1$, and $L(n, n, l) = L(n, n-1, l)$ for $l < n$. When $n > h \ge l \ge 0$ we can compute $L(n, h, l) = \sum_{j=l}^{h} L(n-1, h, j) L(n-1, j-1, l-1)$, a recurrence that follows from Theorem K. (Each size vector corresponds to the complex $\bigcup P_{N_t t}$, with $L(n-1, h, j)$ representing combinations that do not contain the maximum element $n-1$ and $L(n-1, j-1, l-1)$ representing those that do.) Finally the grand total is $L(n) = \sum_{l=1}^{n} L(n, n, l)$.

We have $L(0)$, $L(1)$, $L(2)$, $\dots$ $= 2, 3, 5, 10, 26, 96, 553, 5461, 100709, 3718354, 289725509, \dots$; $L(100) \approx 3.2299 \times 10^{1842}$.

98. The maximal elements of a simplicial complex form a clutter; conversely, the combinations contained in elements of a clutter form a simplicial complex. Thus the two concepts are essentially equivalent.

(a) If $(M_0, M_1, \ldots, M_n)$ is the size vector of a clutter, then $(N_0, N_1, \ldots, N_n)$ is the size vector of a simplicial complex if $N_n = M_n$ and $N_t = M_t + \kappa_{t+1}N_{t+1}$ for $0 \le t < n$. Conversely, every such $(N_0, \ldots, N_n)$ yields an $(M_0, \ldots, M_n)$ if we use the lexicographically first N_t t-combinations. [G. F. Clements extended this result to general multisets in *Discrete Math.* **4** (1973), 123–128.]

(b) In the order of answer 96(e) they are 00000, 00001, 10000, 00040, 01000, 00030, 02000, 00120, 03000, 00310, 04000, 00600, 00100, 00020, 01100, 00210, 02100, 00500, 00200, 00110, 01200, 00400, 00300, 01010, 01300, 00010. Notice that $(M_0, \ldots, M_n)$ is feasible if and only if $(M_n, \ldots, M_0)$ is feasible, so we have a different sort of duality in this interpretation.

99. Represent A as a subset of $T(m_1, \ldots, m_n)$ as in the proof of Corollary C. Then the maximum value of νA is obtained when A consists of the N lexicographically smallest points $x_1 \ldots x_n$.

The proof starts by reducing to the case that A is compressed, in the sense that its t-multicombinations are $P_{\|A\cap T_t\|t}$ for each t. Then if y is the largest element $\in A$ and if x is the smallest element $\notin A$, we prove that $x < y$ implies $\nu x > \nu y$, hence $\nu(A \setminus \{y\} \cup \{x\}) > \nu A$. For if $\nu x = \nu y - k$ we could find an element of $\partial^k y$ that is greater than x, contradicting the assumption that A is compressed.

100. In general, $F(p) = N_0p^n + N_1p^{n-1}(1-p) + \cdots + N_n(1-p)^n$ when $f(x_1, \ldots, x_n)$ is satisfied by exactly N_t binary strings $x_1 \ldots x_n$ of weight t. Thus we find $G(p) = p^4 + 3p^3(1-p) + p^2(1-p)^2$; $H(p) = p^4 + p^3(1-p) + p^2(1-p)^2$.

(b) A monotone formula f is equivalent to a simplicial complex C under the correspondence $f(x_1, \ldots, x_n) = 1 \iff \{j-1 \mid x_j = 0\} \in C$. Therefore the functions $f(p)$ of monotone Boolean functions are those that satisfy the condition of exercise 96(c), and we obtain a suitable function by choosing the lexicographically last N_{n-t} t-combinations (which are complements of the first N_s s-combinations): $\{3210\}$, $\{321, 320, 310\}$, $\{32\}$ gives $f(w,x,y,z) = wxyz \vee xyz \vee wyz \vee wxz \vee yz = wxz \vee yz$.

M. P. Schützenberger observed that we can find the parameters N_t values easily from $f(p)$ by noting that $f\big(1/(1+u)\big) = (N_0 + N_1u + \cdots + N_nu^n)/(1+u)^n$. One can show that $H(p)$ is not equivalent to a monotone formula in any number of variables, because $(1+u+u^2)/(1+u)^4 = (N_0+N_1u+\cdots+N_nu^n)/(1+u)^n$ implies that $N_1 = n-3$, $N_2 = \binom{n-3}{2} + 1$, and $\kappa_2 N_2 = n-2$.

But the task of deciding this question is not so simple in general. For example, the function $(1 + 5u + 5u^2 + 5u^3)/(1+u)^5$ does not match any monotone formula in five variables, because $\kappa_3 5 = 7$; but it equals $(1 + 6u + 10u^2 + 10u^3 + 5u^4)/(1+u)^6$, which works fine with six.

101. (a) Choose N_t linearly independent polynomials of degree t in I; order their terms lexicographically, and take linear combinations so that the lexicographically smallest terms are distinct monomials. Let I' consist of all multiples of those monomials.

(b) Each monomial of degree t in I' is essentially a t-multicombination; for example, $x_1^3x_2x_5^4$ corresponds to 55552111. If M_t is the set of independent monomials for degree t, the ideal property is equivalent to saying that $M_{t+1} \supseteq \partial M_t$.

In the given example, $M_3 = \{x_0x_1^2\}$; $M_4 = \partial M_3 \cup \{x_0x_1x_2^2\}$; $M_5 = \partial M_4 \cup \{x_1x_2^4\}$, since $x_2^2(x_0x_1^2 - 2x_1x_2^2) - x_1(x_0x_1x_2^2) = -2x_1x_2^4$; and $M_{t+1} = \partial M_t$ thereafter.

(c) By Theorem M we can assume that $M_t = \widehat{Q}_{Mst}$. Let $N_t = \binom{n_{ts}}{s} + \cdots + \binom{n_{t2}}{2} + \binom{n_{t1}}{1}$, where $s+t \ge n_{ts} > \cdots > n_{t2} > n_{t1} \ge 0$; then $n_{ts} = s+t$ if and only if $n_{t(s-1)} = s-2, \ldots, n_{t1} = 0$. Furthermore we have

$$N_{t+1} \ge N_t + \kappa_s N_t = \binom{n_{ts} + [n_{ts} \ge s]}{s} + \cdots + \binom{n_{t2} + [n_{t2} \ge 2]}{2} + \binom{n_{t1} + [n_{t1} \ge 1]}{1}.$$

Therefore the sequence $(n_{ts} - t - \infty[n_{ts} < s], \ldots, n_{t2} - t - \infty[n_{t2} < 2], n_{t1} - t - \infty[n_{t1} < 1])$ is lexicographically nondecreasing as t increases, where we insert '$-\infty$' in components that have $n_{tj} = j-1$. Such a sequence cannot increase infinitely many times without exceeding the maximum value $(s, -\infty, \ldots, -\infty)$, by exercise 1.2.1–15(d).

102. Let P_{Nst} be the first N elements of a sequence determined as follows: For each binary string $x = x_{s+t-1} \ldots x_0$, in lexicographic order, write down $\binom{\nu x}{t}$ subcubes by changing t of the 1s to $*$s in all possible ways, in lexicographic order (considering $1 < *$). For example, if $x = 0101101$ and $t = 2$, we generate the subcubes 0101*0*, 010*10*, 010**01, 0*0110*, 0*01*01, 0*0*101.

[See B. Lindström, *Arkiv för Mat.* **8** (1971), 245–257; a generalization analogous to Corollary C appears in K. Engel, *Sperner Theory* (Cambridge Univ. Press, 1997), Theorem 8.1.1.]

103. The first N strings in cross order have the desired property. [T. N. Danh and D. E. Daykin, *J. London Math. Soc.* (2) **55** (1997), 417–426.]

Notes: Beginning with the observation that the "1-shadow" of the N lexicographically first strings of weight t (namely the strings obtained by deleting 1 bits only) consists of the first $\mu_t N$ strings of weight t, R. Ahlswede and N. Cai extended the Danh–Daykin theorem to allow insertion, deletion, and/or transposition of bits [*Combinatorica* **17** (1997), 11–29; *Applied Math. Letters* **11**,5 (1998), 121–126]. Uwe Leck has proved that no total ordering of *ternary strings* has the analogous minimum-shadow property [Preprint 98/6 (Univ. Rostock, 1998), 6 pages].

104. Every number must occur the same number of times in the cycle. Equivalently, $\binom{n-1}{t-1}$ must be a multiple of t. This necessary condition appears to be sufficient as well, provided that n is not too small with respect to t; but such a result may well be true yet impossible to prove. [See Chung, Graham, and Diaconis, *Discrete Math.* **110** (1992), 55–57.]

The next few exercises consider the cases $t = 2$ and $t = 3$, when elegant results are known. Similar but more complicated results have been derived for $t = 4$ and $t = 5$, and the case $t = 6$ has been partially resolved. The case $(n, t) = (12, 6)$ is currently the smallest for which the existence of a universal cycle is unknown.

105. Let the differences mod $(2m+1)$ be $1, 2, \ldots, m, 1, 2, \ldots, m, \ldots$, repeated $2m+1$ times; for example, the cycle for $m = 3$ is (013602561450346235124). This works because $1 + \cdots + m = \binom{m+1}{2}$ is relatively prime to $2m+1$. [*J. École Polytechnique* **4**, Cahier 10 (1810), 16–48.]

106. The seven doubles ⚅⚅, ⚅⚄, ..., ⚃⚃ can be inserted in 3^7 ways into any universal cycle of 3-combinations for $\{0, 1, 2, 3, 4, 5, 6\}$. The number of such universal cycles is the number of Eulerian circuits of the complete graph K_7, which can be shown to be 129,976,320 if we regard $(a_0 a_1 \ldots a_{20})$ as equivalent to $(a_1 \ldots a_{20} a_0)$ but not to the reverse-order cycle $(a_{20} \ldots a_1 a_0)$. So the answer is 284,258,211,840.

[This problem was first solved in 1859 by M. Reiss, whose method was so complicated that people doubted the result; see *Nouvelles Annales de Mathématiques* **8**

(1849), 74; **11** (1852), 115; *Annali di Matematica Pura ed Applicata* (2) **5** (1871–1873), 63–120. A considerably simpler solution, confirming Reiss's claim, was found by P. Jolivald and G. Tarry, who also enumerated the Eulerian circuits of K_9; see *Comptes Rendus Association Française pour l'Avancement des Sciences* **15**, part 2 (1886), 49–53; É. Lucas, *Récréations Mathématiques* **4** (1894), 123–151. Brendan D. McKay and Robert W. Robinson found an approach that is better still, enabling them to continue the enumeration through K_{21} by using the fact that the number of circuits is

$$(m-1)!^{2m+1}\ [z_0^{2m} z_1^{2m-2} \dots z_{2m}^{2m-2}]\ \det(a_{jk}) \prod_{1\le j<k\le 2m} (z_j^2 + z_k^2),$$

where $a_{jk} = -1/(z_j^2 + z_k^2)$ when $j \ne k$; $a_{jj} = -1/(2z_j^2) + \sum_{0\le k\le 2m} 1/(z_j^2 + z_k^2)$; see *Combinatorics, Probability, and Computing* **7** (1998), 437–449.]

C. Flye Sainte-Marie, in L'*Intermédiaire des Mathématiciens* **1** (1894), 164–165, noted that the Eulerian circuits of K_7 include 2×720 that have 7-fold symmetry under permutation of $\{0, 1, \dots, 6\}$ (namely Poinsot's cycle and its reverse), plus 32×1680 with 3-fold symmetry, plus 25778×5040 cycles that are asymmetric.

107. No solution is possible for $n < 7$, except in the trivial case $n = 4$. When $n = 7$ there are $12{,}255{,}208 \times 7!$ universal cycles, not considering $(a_0 a_1 \dots a_{34})$ to be the same as $(a_1 \dots a_{34} a_0)$, including cases with 5-fold symmetry like the example cycle in exercise 104.

When $n \ge 8$ we can proceed systematically as suggested by B. Jackson in *Discrete Math.* **117** (1993), 141–150; see also G. Hurlbert, *SIAM J. Disc. Math.* **7** (1994), 598–604: Put each 3-combination into the "standard cyclic order" $c_1 c_2 c_3$ where $c_2 = (c_1 + \delta) \bmod n$, $c_3 = (c_2 + \delta') \bmod n$, $0 < \delta, \delta' < n/2$, and either $\delta = \delta'$ or $\max(\delta, \delta') < n - \delta - \delta' \ne (n-1)/2$ or $(1 < \delta < n/4$ and $\delta' = (n-1)/2)$ or $(\delta = (n-1)/2$ and $1 < \delta' < n/4)$. For example, when $n = 8$ the allowable values of (δ, δ') are $(1,1)$, $(1,2)$, $(1,3)$, $(2,1)$, $(2,2)$, $(3,1)$, $(3,3)$; when $n = 11$ they are $(1,1)$, $(1,2)$, $(1,3)$, $(1,4)$, $(2,1)$, $(2,2)$, $(2,3)$, $(2,5)$, $(3,1)$, $(3,2)$, $(3,3)$, $(4,1)$, $(4,4)$, $(5,2)$, $(5,5)$. Then construct the digraph with vertices (c, δ) for $0 \le c < n$ and $1 < \delta < n/2$, and with arcs $(c_1, \delta) \to (c_2, \delta')$ for every combination $c_1 c_2 c_3$ in standard cyclic order. This digraph is connected and balanced, so it has an Eulerian circuit by Theorem 2.3.4.2D. (The peculiar rules about $(n-1)/2$ make the digraph connected when n is odd. The Eulerian circuit can be chosen to have n-fold symmetry when $n = 8$, but not when $n = 12$.)

108. When $n = 1$ the cycle (000) is trivial; when $n = 2$ there is no cycle; and there are essentially only two when $n = 4$, namely (0001112223330202 1313) and (0001112020333222 1313). When $n \ge 5$, let the multicombination $d_1 d_2 d_3$ be in standard cyclic order if $d_2 = (d_1 + \delta - 1) \bmod n$, $d_3 = (d_2 + \delta' - 1) \bmod n$, and (δ, δ') is allowable for $n + 3$ in the previous answer. Construct the digraph with vertices (d, δ) for $0 \le d < n$ and $1 < \delta < (n+3)/2$, and with arcs $(d_1, \delta) \to (d_2, \delta')$ for every multicombination $d_1 d_2 d_3$ in standard cyclic order; then find an Eulerian circuit.

Perhaps a universal cycle of t-multicombinations exists for $\{0, 1, \dots, n-1\}$ if and only if a universal cycle of t-combinations exists for $\{0, 1, \dots, n+t-1\}$.

109. A nice way to check for runs is to compute the numbers $b(S) = \sum\{2^{p(c)} \mid c \in S\}$ where $\big(p(\mathtt{A}), \dots, p(\mathtt{K})\big) = (1, \dots, 13)$; then set $l \leftarrow b(S) \wedge -b(S)$ and check that $b(S) + l = l \ll s$, and also that $\big((l \ll s) \vee (l \gg 1)\big) \wedge a = 0$, where $a = 2^{p(c_1)} \vee \dots \vee 2^{p(c_5)}$. The values of $b(S)$ and $\sum\{v(c) \mid c \in S\}$ are easily maintained as S runs through all 31 nonempty subsets in Gray-code order. The answers are (1009008, 99792, 2813796, 505008, 2855676, 697508, 1800268, 751324, 1137236, 361224, 388740, 51680, 317340,

19656, 90100, 9168, 58248, 11196, 2708, 0, 8068, 2496, 444, 356, 3680, 0, 0, 0, 76, 4) for $x = (0, \ldots, 29)$; thus the mean score is ≈ 4.769 and the variance is ≈ 9.768.

Note: A four-card flush is not allowed in the "crib." Then the distribution is a bit easier to compute, and it turns out to be (1022208, 99792, 2839800, 508908, 2868960, 703496, 1787176, 755320, 1118336, 358368, 378240, 43880, 310956, 16548, 88132, 9072, 57288, 11196, 2264, 0, 7828, 2472, 444, 356, 3680, 0, 0, 0, 76, 4); the mean and variance decrease to approximately 4.735 and 9.667.

INDEX AND GLOSSARY

When an index entry refers to a page containing a relevant exercise, see also the *answer* to that exercise for further information. An answer page is not indexed here unless it refers to a topic not included in the statement of the exercise.
