$$\binom{N-t-1}{n-m-1} \Big/ \binom{N-t}{n-m} = \frac{n-m}{N-t} \tag{1}$$

of these select the $(t+1)$st element.

The idea developed in the preceding paragraph leads immediately to the following algorithm:

Algorithm S (*Selection sampling technique*). To select n records at random from a set of N, where $0 < n \leq N$.

S1. [Initialize.] Set $t \leftarrow 0$, $m \leftarrow 0$. (During this algorithm, m represents the number of records selected so far, and t is the total number of input records we have dealt with.)

S2. [Generate U.] Generate a random number U, uniformly distributed between zero and one.

S3. [Test.] If $(N - t)U \geq n - m$, go to step S5.

S4. [Select.] Select the next record for the sample, and increase m and t by 1. If $m < n$, go to step S2; otherwise the sample is complete and the algorithm terminates.

S5. [Skip.] Skip the next record (do not include it in the sample), increase t by 1, and go to step S2. ∎

This algorithm may appear to be unreliable at first glance and, in fact, to be incorrect; but a careful analysis (see the exercises below) shows that it is completely trustworthy. It is not difficult to verify that

a) At most N records are input (we never run off the end of the file before choosing n items).

b) The sample is completely unbiased; in particular, the probability that any given element is selected, e.g., the last element of the file, is n/N.

Statement (b) is true in spite of the fact that we are *not* selecting the $(t+1)$st item with probability n/N, we select it with the probability in Eq. (1)! This has caused some confusion in the published literature. Can the reader explain this seeming contradiction?

(*Note:* When using Algorithm S, one should be careful to use a different source of random numbers U each time the program is run, to avoid connections between the samples obtained on different days. This can be done, for example, by choosing a different value of X_0 for the linear congruential method each time; X_0 could be set to the current date, or to the last X value generated on the previous run of the program.)

We will usually not have to pass over all N records; in fact, since (b) above says that the last record is selected with probability n/N, we will terminate the algorithm *before* considering the last record exactly $(1 - n/N)$ of the time. The average number of records considered when $n = 2$ is about $\frac{2}{3}N$, and the general formulas are given in exercises 5 and 6.

Algorithm S and a number of other sampling techniques are discussed in a paper by C. T. Fan, Mervin E. Muller, and Ivan Rezucha, *J. Amer. Stat. Assoc.* **57** (1962), 387–402. The method was independently discovered by T. G. Jones, *CACM* **5** (1962), 343.

A problem arises if we don't know the value of N in advance, since the precise value of N is crucial in Algorithm S. Suppose we want to select n items at random from a file, without knowing exactly how many are present in that file. We could first go through and count the records, then take a second pass to select them; but it is generally better to sample $m \geq n$ of the original items on the first pass, where m is much less than N, so that only m items must be considered on the second pass. The trick, of course, is to do this in such a way that the final result is a truly random sample of the original file.

Since we don't know when the input is going to end, we must keep track of a random sample of the input records seen so far, thus always being prepared for the end. As we read the input we will construct a "reservoir" that contains only those m records that have appeared among the previous samples. The first n records always go into the reservoir. When the $(t+1)$st record is being input, for $t \geq n$, we will have in memory a table of n indices pointing to those records in the reservoir that belong to the random sample we have chosen from the first t records. The problem is to maintain this situation with t increased by one, namely to find a new random sample from among the $t+1$ records now known to be present. It is not hard to see that we should include the new record in the new sample with probability $n/(t+1)$, and in such a case it should replace a random element of the previous sample.

Thus, the following procedure does the job:

Algorithm R (*Reservoir sampling*). To select n records at random from a file of unknown size $\geq n$, given $n > 0$. An auxiliary file called the "reservoir" contains all records that are candidates for the final sample. The algorithm uses a table of distinct indices $I[j]$ for $1 \leq j \leq n$, each of which points to one of the records in the reservoir.

R1. [Initialize.] Input the first n records and copy them to the reservoir. Set $I[j] \leftarrow j$ for $1 \leq j \leq n$, and set $t \leftarrow m \leftarrow n$. (If the file being sampled has fewer than n records, it will of course be necessary to abort the algorithm and report failure. During this algorithm, $\{I[1], \ldots, I[n]\}$ point to the records in the current sample, m is the size of the reservoir, and t is the number of input records dealt with so far.)

R2. [End of file?] If there are no more records to be input, go to step R6.

R3. [Generate and test.] Increase t by 1, then generate a random integer M between 1 and t (inclusive). If $M > n$, go to R5.

R4. [Add to reservoir.] Copy the next record of the input file to the reservoir, increase m by 1, and set $I[M] \leftarrow m$. (The record previously pointed to by $I[M]$ is being replaced in the sample by the new record.) Go back to R2.

R5. [Skip.] Skip over the next record of the input file (do not include it in the reservoir), and return to step R2.

R6. [Second pass.] Sort the I table entries so that $I[1] < \cdots < I[n]$; then go through the reservoir, copying the records with these indices into the output file that is to hold the final sample. ∎

Algorithm R is due to Alan G. Waterman. The reader may wish to work out the example of its operation that appears in exercise 9.

If the records are sufficiently short, it is of course unnecessary to have a reservoir at all; we can keep the n records of the current sample in memory at all times (see exercise 10).

The natural question to ask about Algorithm R is, "What is the expected size of the reservoir?" Exercise 11 shows that the average value of m is exactly $n(1 + H_N - H_n)$; this is approximately $n(1 + \ln(N/n))$. So if $N/n = 1000$, the reservoir will contain only about $\frac{1}{125}$ as many items as the original file.

Note that Algorithms S and R can be used to obtain samples for several independent categories simultaneously. For example, if we have a large file of names and addresses of U.S. residents, we could pick random samples of exactly 10 people from each of the 50 states without making 50 passes through the file, and without first sorting the file by state.

The sampling problem can be regarded as the computation of a random *combination*, according to the conventional definition of combinations of N things taken n at a time (see Section 1.2.6). Now let us consider the problem of computing a random *permutation* of t objects; we will call this the *shuffling problem*, since shuffling a deck of cards is nothing more than subjecting it to a random permutation.

A moment's reflection is enough to convince oneself that the approaches people traditionally use to shuffle cards are miserably inadequate; there is no hope of obtaining each of the $t!$ permutations with anywhere near equal probability by such methods. It has been said that expert bridge players make use of this fact when deciding whether or not to "finesse."

If t is small, we can obtain a random permutation very quickly by generating a random integer between 1 and $t!$. For example, when $t = 4$, a random number between 1 and 24 suffices to select a random permutation from a table of all possibilities. But for large t, it is necessary to be more careful if we want to claim that each permutation is equally likely, since $t!$ is much larger than the accuracy of individual random numbers.

A suitable shuffling procedure can be obtained by recalling Algorithm 3.3.2P, which gives a simple correspondence between each of the $t!$ possible permutations and a sequence of numbers $(c_1, c_2, \ldots, c_{t-1})$, with $0 \le c_j \le j$. It is easy to compute such a set of numbers at random, and we can use the correspondence to produce a random permutation.

Algorithm P (*Shuffling*). Let $X_1, X_2, \ldots, X_t$ be a set of t numbers to be shuffled.

P1. [Initialize.] Set $j \leftarrow t$.

P2. [Generate U.] Generate a random number U, uniformly distributed between zero and one.

P3. [Exchange.] Set $k \leftarrow \lfloor jU \rfloor + 1$. (Now k is a random integer, between 1 and j.) Exchange $X_k \leftrightarrow X_j$.

P4. [Decrease j.] Decrease j by 1. If $j > 1$, return to step P2. ∎

This algorithm was first published by L. E. Moses and R. V. Oakford, in *Tables of Random Permutations* (Stanford University Press, 1963); and by R. Durstenfeld, *CACM* **7** (1964), 420. It can also be modified to obtain a random permutation of a random combination (see exercise 14).

For a discussion of random combinatorial objects of other kinds (e.g., partitions), see Section 7.2 and/or the book *Combinatorial Algorithms* by Nijenhuis and Wilf (New York: Academic Press, 1975).

EXERCISES

1. [*M12*] Explain Eq. (1).

2. [*20*] Prove that Algorithm S never tries to read more than N records of its input file.

▶ **3.** [*22*] The $(t+1)$st item in Algorithm S is selected with probability $(n-m)/(N-t)$, not n/N, yet the text claims that the sample is unbiased—so each item should be selected with the *same* probability. How can both of these statements be true?

4. [*M23*] Let $p(m,t)$ be the probability that exactly m items are selected from among the first t in the selection sampling technique. Show directly from Algorithm S that

$$p(m,t) = \binom{t}{m}\binom{N-t}{n-m}\Big/\binom{N}{n}, \qquad \text{for } 0 \le t \le N.$$

5. [*M24*] What is the average value of t when Algorithm S terminates? (In other words, how many of the N records have been passed, on the average, before the sample is complete?)

6. [*M24*] What is the standard deviation of the value computed in the previous exercise?

▶ **7.** [*M25*] Prove that any *given* choice of n records from the set of N is obtained by Algorithm S with probability $1/\binom{N}{n}$. Therefore the sample is completely unbiased.

8. [*M46*] Algorithm S computes one uniform deviate for each input record it handles. Find a more efficient way to determine the number of input records to skip before the first is selected, assuming that N/n is rather large. (We could iterate this process to select the remaining $n-1$ records, thus reducing the number of necessary random deviates from order N to order n.)

9. [*12*] Let $n = 3$. If Algorithm R is applied to a file containing 20 records numbered 1 thru 20, and if the random numbers generated in step R3 are respectively

$$4, 1, 6, 7, 5, 3, 5, 11, 11, 3, 7, 9, 3, 11, 4, 5, 4,$$

which records go into the reservoir? Which are in the final sample?

10. [*15*] Modify Algorithm R so that the reservoir is eliminated, assuming that the n records of the current sample can be held in memory.

▶ **11.** [*M25*] Let p_m be the probability that exactly m elements are put into the reservoir during the first pass of Algorithm R. Determine the generating function $G(z) = \sum_m p_m z^m$, and find the mean and standard deviation. (Use the ideas of Section 1.2.10.)

12. [*M26*] The gist of Algorithm P is that any permutation π can be uniquely written as a product of transpositions in the form $\pi = (a_t t)\dots(a_3 3)(a_2 2)$, where $1 \le a_j \le j$ for $t \ge j > 1$. Prove that there is also a unique representation of the form $\pi = (b_2 2)(b_3 3)\dots(b_t t)$, where $1 \le b_j \le j$ for $1 < j \le t$, and design an algorithm that computes the b's from the a's in $O(t)$ steps.

13. [*M23*] (S. W. Golomb.) One of the most common ways to shuffle cards is to divide the deck into two parts as equal as possible, and to "riffle" them together. (See the discussion of card-playing etiquette in Hoyle's rules of card games; we read, "A shuffle of this sort should be made about three times to mix the cards thoroughly.") Consider a deck of $2n - 1$ cards $X_1, X_2, \dots, X_{2n-1}$; a "perfect shuffle" s divides this deck into $X_1, X_2, \dots, X_n$ and $X_{n+1}, \dots, X_{2n-1}$, then perfectly interleaves them to obtain $X_1, X_{n+1}, X_2, X_{n+2}, \dots, X_{2n-1}, X_n$. The "cut" operation c^j changes $X_1, X_2, \dots, X_{2n-1}$ into $X_{j+1}, \dots, X_{2n-1}, X_1, \dots, X_j$. Show that by combining perfect shuffles and cuts, at most $(2n - 1)(2n - 2)$ different arrangements of the deck are possible, if $n > 1$.

▶ **14.** [*30*] (Ole-Johan Dahl.) If $X_k = k$ for $1 \le k \le t$ at the start of Algorithm P, and if we terminate the algorithm when j reaches the value $t - n$, the sequence $X_{t-n+1}, \dots, X_t$ is a random permutation of a random combination of n elements. Show how to simulate the effect of this procedure using only $O(n)$ cells of memory.

▶ **15.** [*M25*] Devise a way to compute a random sample of n records from N, given N and n, based on the idea of hashing (Section 6.4). Your method should use $O(n)$ storage locations and an average of $O(n)$ units of time, and it should present the sample as a sorted set of integers $1 \le X_1 < X_2 < \cdots < X_n \le N$.

16. [*25*] Discuss the problem of *weighted* sampling, where each subset of n elements is obtained with probability proportional to the product of the weights of the elements.

3.5. WHAT IS A RANDOM SEQUENCE?

A. Introductory remarks. We have seen in this chapter how to generate sequences

$$\langle U_n \rangle = U_0, U_1, U_2, \ldots \tag{1}$$

of real numbers in the range $0 \le U_n < 1$, and we have called them "random" sequences even though they are completely deterministic in character. To justify this terminology, we claimed that the numbers "behave as if they are truly random." Such a statement may be satisfactory for practical purposes (at the present time), but it sidesteps a very important philosophical and theoretical question: Precisely what do we mean by "random behavior"? A quantitative definition is needed. It is undesirable to talk about concepts that we do not really understand, especially since many apparently paradoxical statements can be made about random numbers.

The mathematical theory of probability and statistics carefully sidesteps the question; it refrains from making absolute statements, and instead expresses everything in terms of how much *probability* is to be attached to statements involving random sequences of events. The axioms of probability theory are set up so that abstract probabilities can be computed readily, but nothing is said about what probability really signifies, or how this concept can be applied meaningfully to the actual world. In the book *Probability, Statistics, and Truth* (New York: Macmillan, 1957), R. von Mises discusses this situation in detail, and presents the view that a proper definition of probability depends on obtaining a proper definition of a random sequence.

Let us paraphrase here some statements made by two of the many authors who have commented on the subject.

> *D. H. Lehmer* (1951): "A random sequence is a vague notion embodying the idea of a sequence in which each term is unpredictable to the uninitiated and whose digits pass a certain number of tests, traditional with statisticians and depending somewhat on the uses to which the sequence is to be put."
>
> *J. N. Franklin* (1962): "The sequence (1) is random if it has every property that is shared by all infinite sequences of independent samples of random variables from the uniform distribution."

Franklin's statement essentially generalizes Lehmer's to say that the sequence must satisfy *all* statistical tests. His definition is not completely precise, and we will see later that a reasonable interpretation of his statement leads us to conclude that there is no such thing as a random sequence! So let us begin with Lehmer's less restrictive statement and attempt to make *it* precise. What we really want is a relatively short list of mathematical properties, each of which is satisfied by our intuitive notion of a random sequence; furthermore, the list is to be complete enough so that we are willing to agree that any sequence satisfying these properties is "random." In this section, we will develop what seems to be

an adequate definition of randomness according to these criteria, although many interesting questions remain to be answered.

Let u and v be real numbers, $0 \le u < v \le 1$. If U is a random variable that is uniformly distributed between 0 and 1, the probability that $u \le U < v$ is equal to $v - u$. For example, the probability that $\frac{1}{3} \le U < \frac{2}{3}$ is $\frac{1}{3}$. How can we translate this property of the single number U into a property of the infinite sequence $U_0, U_1, U_2, \ldots$? The obvious answer is to count how many times U_n lies between u and v, and the average number of times should equal $v - u$. Our intuitive idea of probability is based in this way on the frequency of occurrence.

More precisely, let $\nu(n)$ be the number of values of j, $0 \le j < n$, such that $u \le U_j < v$; we want the ratio $\nu(n)/n$ to approach the value $v - u$ as n approaches infinity:

$$\lim_{n\to\infty} \nu(n)/n = v - u. \tag{2}$$

If this condition holds for all choices of u and v, the sequence is said to be *equidistributed.*

Let $S(n)$ be a statement about the integer n and the sequence $U_1, U_2, \ldots$; for example, $S(n)$ might be the statement considered above, "$u \le U_n < v$." We can generalize the idea used in the preceding paragraph to define "the probability that $S(n)$ is true" with respect to a particular infinite sequence: Let $\nu(n)$ be the number of values of j, $0 \le j < n$, such that $S(j)$ is true.

Definition A. *We say* $\Pr(S(n)) = \lambda$, *if* $\lim_{n\to\infty} \nu(n)/n = \lambda$. (Read, "The probability that $S(n)$ is true equals λ, if the limit as n tends to infinity of $\nu(n)/n$ equals λ.")

In terms of this notation, the sequence $U_0, U_1, \ldots$ is equidistributed if and only if $\Pr(u \le U_n < v) = v - u$, for all real numbers u, v with $0 \le u < v \le 1$.

A sequence may be equidistributed without being random. For example, if $U_0, U_1, \ldots$ and $V_0, V_1, \ldots$ are equidistributed sequences, it is not hard to show that the sequence

$$W_0, W_1, W_2, W_3, \ldots = \tfrac{1}{2}U_0,\ \tfrac{1}{2}+\tfrac{1}{2}V_0,\ \tfrac{1}{2}U_1,\ \tfrac{1}{2}+\tfrac{1}{2}V_1,\ \ldots \tag{3}$$

is also equidistributed, since the subsequence $\frac{1}{2}U_0, \frac{1}{2}U_1, \ldots$ is equidistributed between 0 and $\frac{1}{2}$, while the alternate terms $\frac{1}{2} + \frac{1}{2}V_0, \frac{1}{2} + \frac{1}{2}V_1, \ldots$, are equidistributed between $\frac{1}{2}$ and 1. In the sequence of W's, a value less than $\frac{1}{2}$ is always followed by a value greater than or equal to $\frac{1}{2}$, and conversely; hence the sequence is not random by any reasonable definition. A stronger property than equidistribution is needed.

A natural generalization of the equidistribution property, which removes the objection stated in the preceding paragraph, is to consider adjacent pairs of numbers of our sequence. We can require the sequence to satisfy the condition

$$\Pr(u_1 \le U_n < v_1 \quad \text{and} \quad u_2 \le U_{n+1} < v_2) = (v_1 - u_1)(v_2 - u_2) \tag{4}$$

for any four numbers u_1, v_1, u_2, v_2 with $0 \le u_1 < v_1 \le 1$, $0 \le u_2 < v_2 \le 1$. In

general, for any positive integer k we can require our sequence to be *k-distributed* in the following sense:

Definition B. *The sequence* (1) *is said to be k-distributed if*

$$\Pr(u_1 \le U_n < v_1, \ldots, u_k \le U_{n+k-1} < v_k) = (v_1 - u_1)\ldots(v_k - u_k) \tag{5}$$

for all choices of real numbers u_j, v_j, *with* $0 \le u_j < v_j \le 1$, *for* $1 \le j \le k$.

An equidistributed sequence is a 1-distributed sequence. Note that if $k > 1$, a k-distributed sequence is always $(k-1)$-distributed, since we may set $u_k = 0$ and $v_k = 1$ in Eq. (5). Thus, in particular, any sequence that is known to be 4-distributed must also be 3-distributed, 2-distributed, and equidistributed. We can investigate the largest k for which a given sequence is k-distributed; and this leads us to formulate

Definition C. *A sequence is said to be* ∞*-distributed if it is k-distributed for all positive integers k.*

So far we have considered "$[0,1)$ sequences," i.e., sequences of real numbers lying between zero and one. The same ideas apply to integer-valued sequences; let us say a sequence $\langle X_n \rangle = X_0, X_1, X_2, \ldots$ is a "b-ary sequence" if each X_n is one of the integers $0, 1, \ldots, b-1$. Thus, a 2-ary (binary) sequence is a sequence of zeros and ones.

We also say that a k-digit "b-ary number" is a string of k integers $x_1 x_2 \ldots x_k$, where $0 \le x_j < b$ for $1 \le j \le k$.

Definition D. *A b-ary sequence is said to be k-distributed if*

$$\Pr(X_n X_{n+1} \ldots X_{n+k-1} = x_1 x_2 \ldots x_k) = 1/b^k \tag{6}$$

for all b-ary numbers $x_1 x_2 \ldots x_k$.

It is clear from this definition that if $U_0, U_1, \ldots$ is a k-distributed $[0,1)$ sequence, then the sequence $\lfloor bU_0 \rfloor, \lfloor bU_1 \rfloor, \ldots$ is a k-distributed b-ary sequence. (If we set $u_j = x_j/b$, $v_j = (x_j + 1)/b$, $X_n = \lfloor bU_n \rfloor$, Eq. (5) becomes Eq. (6).) Furthermore, every k-distributed b-ary sequence is also $(k-1)$-distributed, if $k > 1$: we add together the probabilities for the b-ary numbers $x_1 \ldots x_{k-1}\,0$, $x_1 \ldots x_{k-1}\,1, \ldots, x_1 \ldots x_{k-1}\,(b-1)$ to obtain

$$\Pr(X_n \ldots X_{n+k-2} = x_1 \ldots x_{k-1}) = 1/b^{k-1}.$$

(Probabilities for disjoint events are additive; see exercise 5.) It therefore is natural to speak of an ∞-distributed b-ary sequence, as in Definition C above.

The representation of a positive real number in the radix-b number system may be regarded as a b-ary sequence; for example, π corresponds to the 10-ary

sequence 3, 1, 4, 1, 5, 9, 2, 6, 5, 3, 5, 8, 9, ... It has been conjectured that this sequence is ∞-distributed, but nobody has yet been able to prove that it is even 1-distributed.

Let us analyze these concepts a little more closely in the case when k equals a million. A binary sequence that is 1000000-distributed is going to have runs of a million zeros in a row! Similarly, a $[0,1)$ sequence that is 1000000-distributed is going to have runs of a million consecutive values each of which is less than $\frac{1}{2}$. It is true that this will happen only $(\frac{1}{2})^{1000000}$ of the time, on the average, but the fact is that it *does* happen. Indeed, this phenomenon will occur in any truly random sequence, using our intuitive notion of "truly random." One can easily imagine that such a situation will have a drastic effect if this set of a million "truly random" numbers is being used in a computer-simulation experiment; there would be good reason to complain about the random number generator. However, if we have a sequence of numbers that never has runs of a million consecutive U's less than $\frac{1}{2}$, the sequence is not random, and it will not be a suitable source of numbers for other conceivable applications that use extremely long blocks of U's as input. In summary, *a truly random sequence will exhibit local nonrandomness.* Local nonrandomness is necessary in some applications, but it is disastrous in others. We are forced to conclude that no sequence of "random" numbers can be adequate for every application.

In a similar vein, one may argue that there is no way to judge whether a *finite* sequence is random or not; any particular sequence is just as likely as any other one. These facts are definitely stumbling blocks if we are ever to have a useful definition of randomness, but they are not really cause for alarm. It is still possible to give a definition for the randomness of infinite sequences of real numbers in such a way that the corresponding theory (viewed properly) will give us a great deal of insight concerning the ordinary finite sequences of rational numbers that are actually generated on a computer. Furthermore, we shall see later in this section that there are several plausible definitions of randomness for finite sequences.

B. ∞-distributed sequences. Let us now undertake a brief study of the theory of sequences that are ∞-distributed. To describe the theory adequately, we will need to use a bit of higher mathematics, so we assume in the remainder of this subsection that the reader knows the material ordinarily taught in an "advanced calculus" course.

First it is convenient to generalize Definition A, since the limit appearing there does not exist for all sequences. Let us define

$$\overline{\Pr}(S(n)) = \limsup_{n\to\infty} (\nu(n)/n), \qquad \underline{\Pr}(S(n)) = \liminf_{n\to\infty} (\nu(n)/n). \tag{7}$$

Then $\Pr(S(n))$, if it exists, is the common value of $\underline{\Pr}(S(n))$ and $\overline{\Pr}(S(n))$.

We have seen that a k-distributed $[0,1)$ sequence leads to a k-distributed b-ary sequence, if U is replaced by $\lfloor bU \rfloor$. Our first theorem shows that a converse result is also true.

Theorem A. *Let $\langle U_n\rangle = U_0, U_1, U_2, \ldots$ be a $[0,1)$ sequence. If the sequence*

$$\langle \lfloor b_j U_n \rfloor \rangle = \lfloor b_j U_0 \rfloor, \lfloor b_j U_1 \rfloor, \lfloor b_j U_2 \rfloor, \ldots$$

is a k-distributed b_j-ary sequence for all b_j in an infinite sequence of integers $1 < b_1 < b_2 < b_3 < \cdots$, then the original sequence $\langle U_n\rangle$ is k-distributed.

As an example of this theorem, suppose that $b_j = 2^j$. The sequence $\lfloor 2^j U_0 \rfloor, \lfloor 2^j U_1 \rfloor, \ldots$ is essentially the sequence of the first j bits of the binary representations of $U_0, U_1, \ldots$. If all these integer sequences are k-distributed, in the sense of Definition D, then the real-valued sequence $U_0, U_1, \ldots$ must also be k-distributed in the sense of Definition B.

Proof of Theorem A. If the sequence $\lfloor bU_0 \rfloor, \lfloor bU_1 \rfloor, \ldots$ is k-distributed, it follows by the addition of probabilities that Eq. (5) holds whenever each u_j and v_j is a rational number with denominator b. Now let u_j, v_j be any real numbers, and let u'_j, v'_j be rational numbers with denominator b such that

$$u'_j \le u_j < u'_j + 1/b, \qquad v'_j \le v_j < v'_j + 1/b.$$

Let $S(n)$ be the statement that $u_1 \le U_n < v_1, \ldots, u_k \le U_{n+k-1} < v_k$. We have

$$\begin{aligned}\overline{\Pr}(S(n)) &\le \Pr\left(u'_1 \le U_n < v'_1 + \frac{1}{b}, \ldots, u'_k \le U_{n+k-1} < v'_k + \frac{1}{b}\right)\\ &= \left(v'_1 - u'_1 + \frac{1}{b}\right)\ldots\left(v'_k - u'_k + \frac{1}{b}\right);\\ \underline{\Pr}(S(n)) &\ge \Pr\left(u'_1 + \frac{1}{b} \le U_n < v'_1, \ldots, u'_k + \frac{1}{b} \le U_{n+k-1} < v'_k\right)\\ &= \left(v'_1 - u'_1 - \frac{1}{b}\right)\ldots\left(v'_k - u'_k - \frac{1}{b}\right).\end{aligned}$$

Now $|(v'_j - u'_j \pm 1/b) - (v_j - u_j)| \le 2/b$; since our inequalities hold for all $b = b_j$, and since $b_j \to \infty$ as $j \to \infty$, we have

$$(v_1 - u_1)\ldots(v_k - u_k) \le \underline{\Pr}(S(n)) \le \overline{\Pr}(S(n)) \le (v_1 - u_1)\ldots(v_k - u_k). \quad \blacksquare$$

The next theorem is our main tool for proving things about k-distributed sequences.

Theorem B. *Let $\langle U_n\rangle$ be a k-distributed $[0,1)$ sequence, and let $f(x_1, x_2, \ldots, x_k)$ be a Riemann-integrable function of k variables; then*

$$\begin{aligned}\lim_{n\to\infty} \frac{1}{n} \sum_{0\le j<n} & f(U_j, U_{j+1}, \ldots, U_{j+k-1})\\ &= \int_0^1 \cdots \int_0^1 f(x_1, x_2, \ldots, x_k)\, dx_1 \ldots dx_k.\end{aligned} \tag{8}$$

Proof. The definition of a k-distributed sequence states that this result is true in the special case that

$$f(x_1,\ldots,x_k)=\begin{cases}1, & \text{if } u_1\le x_1<v_1,\ldots,u_k\le x_k<v_k;\\ 0, & \text{otherwise.}\end{cases} \tag{9}$$

Therefore Eq. (8) is true whenever $f=a_1f_1+a_2f_2+\cdots+a_mf_m$ and when each f_j is a function of type (9); in other words, Eq. (8) holds whenever f is a "step-function" obtained by (i) partitioning the unit k-dimensional cube into subcells whose faces are parallel to the coordinate axes, and (ii) assigning a constant value to f on each subcell.

Now let f be any Riemann-integrable function. If ϵ is any positive number, we know (by the definition of Riemann-integrability) that there exist step functions $\underline{f}$ and $\overline{f}$ such that $\underline{f}(x_1,\ldots,x_k)\le f(x_1,\ldots,x_k)\le\overline{f}(x_1,\ldots,x_k)$, and such that the difference of the integrals of $\underline{f}$ and $\overline{f}$ is less than ϵ. Since Eq. (8) holds for $\underline{f}$ and $\overline{f}$, and since

$$\begin{aligned}\frac{1}{n}\sum_{0\le j<n}\underline{f}(U_j,\ldots,U_{j+k-1})&\le\frac{1}{n}\sum_{0\le j<n}f(U_j,\ldots,U_{j+k-1})\\&\le\frac{1}{n}\sum_{0\le j<n}\overline{f}(U_j,\ldots,U_{j+k-1}),\end{aligned}$$

we conclude that Eq. (8) is true also for f. ∎

Theorem B can be applied, for example, to the *permutation test* of Section 3.3.2. Let $(p_1,p_2,\ldots,p_k)$ be any permutation of the numbers $\{1,2,\ldots,k\}$; we want to show that

$$\Pr(U_{n+p_1-1}<U_{n+p_2-1}<\cdots<U_{n+p_k-1})=1/k!. \tag{10}$$

To prove this, assume that the sequence $\langle U_n\rangle$ is k-distributed, and let

$$f(x_1,\ldots,x_k)=\begin{cases}1, & \text{if } x_{p_1}<x_{p_2}<\cdots<x_{p_k};\\ 0, & \text{otherwise.}\end{cases}$$

We have

$$\begin{aligned}&\Pr(U_{n+p_1-1}<U_{n+p_2-1}<\cdots<U_{n+p_k-1})\\&\quad=\int_0^1\cdots\int_0^1 f(x_1,\ldots,x_k)\,dx_1\ldots dx_k\\&\quad=\int_0^1 dx_{p_k}\int_0^{x_{p_k}}\cdots\int_0^{x_{p_3}}dx_{p_2}\int_0^{x_{p_2}}dx_{p_1}=\frac{1}{k!}.\end{aligned}$$

Corollary P. *If a $[0,1)$ sequence is k-distributed, it satisfies the permutation test of order k, in the sense of Eq.* (10). ∎

We can also show that the *serial correlation test* is satisfied:

Corollary S. *If a* $[0,1)$ *sequence is* $(k+1)$*-distributed, the serial correlation coefficient between* U_n *and* U_{n+k} *tends to zero:*

$$\lim_{n\to\infty} \frac{\frac{1}{n}\sum U_jU_{j+k} - (\frac{1}{n}\sum U_j)(\frac{1}{n}\sum U_{j+k})}{\sqrt{(\frac{1}{n}\sum U_j^2 - (\frac{1}{n}\sum U_j)^2)(\frac{1}{n}\sum U_{j+k}^2 - (\frac{1}{n}\sum U_{j+k})^2)}} = 0.$$

(All summations here are for $0 \le j < n$.)

Proof. By Theorem B, the quantities

$$\tfrac{1}{n}\sum U_jU_{j+k}, \qquad \tfrac{1}{n}\sum U_j^2, \qquad \tfrac{1}{n}\sum U_{j+k}^2, \qquad \tfrac{1}{n}\sum U_j, \qquad \tfrac{1}{n}\sum U_{j+k}$$

tend to the respective limits $\frac{1}{4}, \frac{1}{3}, \frac{1}{3}, \frac{1}{2}, \frac{1}{2}$ as $n \to \infty$. ∎

Let us now consider some slightly more general distribution properties of sequences. We have defined the notion of k-distribution by considering all of the adjacent k-tuples; for example, a sequence is 2-distributed if and only if the points

$$(U_0,U_1),\ (U_1,U_2),\ (U_2,U_3),\ (U_3,U_4),\ (U_4,U_5),\ \ldots$$

are equidistributed in the unit square. It is quite possible, however, that this can happen while alternate pairs of points (U_1,U_2), (U_3,U_4), (U_5,U_6), ... are *not* equidistributed; if the density of points (U_{2n-1},U_{2n}) is deficient in some area, the other points (U_{2n},U_{2n+1}) might compensate. For example, the periodic binary sequence

$$\langle X_n\rangle = 0,0,0,1,\ 0,0,0,1,\ 1,1,0,1,\ 1,1,0,1,\ 0,0,0,1,\ \ldots, \tag{11}$$

with a period of length 16, is seen to be 3-distributed; yet the sequence of even-numbered elements $\langle X_{2n}\rangle = 0, 0, 0, 0, 1, 0, 1, 0, \ldots$ has three times as many zeros as ones, while the subsequence of odd-numbered elements $\langle X_{2n+1}\rangle = 0, 1, 0, 1, 1, 1, 1, 1, \ldots$ has three times as many ones as zeros.

If a sequence $\langle U_n\rangle$ is ∞-distributed, example (11) shows that it is not at all obvious that the subsequence of alternate terms $\langle U_{2n}\rangle = U_0, U_2, U_4, U_6, \ldots$ will be ∞-distributed or even 1-distributed. But we shall see that $\langle U_{2n}\rangle$ is, in fact, ∞-distributed, and much more is true.

Definition E. *A* $[0,1)$ *sequence* $\langle U_n\rangle$ *is said to be* (m,k)*-distributed if*

$$\Pr(u_1 \le U_{mn+j} < v_1,\ u_2 \le U_{mn+j+1} < v_2,\ \ldots,\ u_k \le U_{mn+j+k-1} < v_k) = (v_1-u_1)\ldots(v_k-u_k)$$

for all choices of real numbers u_r, v_r *with* $0 \le u_r < v_r \le 1$ *for* $1 \le r \le k$, *and for all integers* j *with* $0 \le j < m$.

Thus a k-distributed sequence is the special case $m = 1$ in Definition E; the case $m = 2$ means that the k-tuples starting in even positions must have the same density as the k-tuples starting in odd positions, etc.

Several properties of Definition E are obvious:

An (m, k)-distributed sequence is (m, κ)-distributed for $1 \le \kappa \le k$. (12)

An (m, k)-distributed sequence is (d, k)-distributed for all divisors d of m. (13)

We can also define the concept of an (m, k)-distributed b-ary sequence, as in Definition D; and the proof of Theorem A remains valid for (m, k)-distributed sequences.

The next theorem, which is in many ways rather surprising, shows that the property of being ∞-distributed is very strong indeed, much stronger than we imagined it to be when we first considered the definition of the concept.

Theorem C (Ivan Niven and H. S. Zuckerman). *An ∞-distributed sequence is (m, k)-distributed for all positive integers m and k.*

Proof. It suffices to prove the theorem for b-ary sequences, by using the generalization of Theorem A just mentioned. Furthermore, we may assume that $m = k$, because (12) and (13) tell us that the sequence will be (m, k)-distributed if it is (mk, mk)-distributed.

So we will prove that *any ∞-distributed b-ary sequence $X_0, X_1, \ldots$ is (m, m)-distributed for all positive integers m.* Our proof is a simplified version of the original one given by Niven and Zuckerman in *Pacific J. Math.* **1** (1951), 103–109.

The key idea we shall use is an important technique that applies to many situations in mathematics: "If the sum of m quantities and the sum of their squares are both consistent with the hypothesis that the m quantities are equal, then that hypothesis is true." In a strong form, this principle may be stated as follows:

Lemma E. *Given m sequences of numbers $\langle y_{jn} \rangle = y_{j0}, y_{j1}, \ldots$ for $1 \le j \le m$, suppose that*

$$\begin{aligned} \lim_{n\to\infty} (y_{1n} + y_{2n} + \cdots + y_{mn}) &= m\alpha, \\ \limsup_{n\to\infty} (y_{1n}^2 + y_{2n}^2 + \cdots + y_{mn}^2) &\le m\alpha^2. \end{aligned} \tag{14}$$

Then for each j, $\lim_{n\to\infty} y_{jn}$ exists and equals α.

An incredibly simple proof of this lemma is given in exercise 9. ∎

Resuming our proof of Theorem C, let $x = x_1 x_2 \ldots x_m$ be a b-ary number, and say that x *occurs* at position p if $X_{p-m+1} X_{p-m+2} \ldots X_p = x$. Let $\nu_j(n)$ be the number of occurrences of x at position p when $p < n$ and $p \bmod m = j$. Let $y_{jn} = \nu_j(n)/n$; we wish to prove that

$$\lim_{n\to\infty} y_{jn} = 1/mb^m. \tag{15}$$

First we know that

$$\lim_{n\to\infty}(y_{0n}+y_{1n}+\cdots+y_{(m-1)n})=1/b^m, \tag{16}$$

since the sequence is m-distributed. By Lemma E and Eq. (16), the theorem will be proved if we can show that

$$\limsup_{n\to\infty}(y_{0n}^2+y_{1n}^2+\cdots+y_{(m-1)n}^2)\le 1/mb^{2m}. \tag{17}$$

This inequality is not obvious yet; some rather delicate maneuvering is necessary before we can prove it. Let q be a multiple of m, and consider

$$C(n)=\sum_{0\le j<m}\binom{\nu_j(n)-\nu_j(n-q)}{2}. \tag{18}$$

This is the number of pairs of occurrences of x in positions p_1,p_2 with $n-q\le p_1<p_2<n$ and with p_2-p_1 a multiple of m. Consider now the sum

$$S_N=\sum_{1\le n\le N+q}C(n). \tag{19}$$

Each pair of occurrences of x in positions p_1,p_2 with $p_1<p_2<p_1+q$, where p_2-p_1 is a multiple of m and $p_1\le N$, is counted p_1+q-p_2 times in the total S_N (namely, when $p_2<n\le p_1+q$); and the pairs of such occurrences with $N<p_1<p_2<N+q$ are counted $N+q-p_2$ times.

Let $d_t(n)$ be the number of pairs of occurrences of x in positions p_1,p_2 with $p_1+t=p_2<n$. The analysis above shows that

$$\sum_{0<t<q/m}(q-mt)d_{mt}(N+q)\ge S_N\ge\sum_{0<t<q/m}(q-mt)d_{mt}(N). \tag{20}$$

Since the original sequence is q-distributed,

$$\lim_{N\to\infty}\frac{1}{N}d_{mt}(N)=1/b^{2m} \tag{21}$$

for all t, $0<t<q/m$, and therefore by (20) we have

$$\lim_{N\to\infty}\frac{S_N}{N}=\sum_{0<t<q/m}(q-mt)/b^{2m}=q(q-m)/2mb^{2m}. \tag{22}$$

This fact will prove the theorem, after some manipulation.

By definition,

$$2S_N = \sum_{1\le n\le N+q} \sum_{0\le j<m} \big((\nu_j(n) - \nu_j(n-q))^2 - (\nu_j(n) - \nu_j(n-q))\big),$$

and we can remove the unsquared terms by applying (16) to get

$$\lim_{N\to\infty} \frac{T_N}{N} = q(q-m)/mb^{2m} + q/b^m, \tag{23}$$

where

$$T_N = \sum_{1\le n\le N+q} \sum_{0\le j<m} \big(\nu_j(n) - \nu_j(n-q)\big)^2.$$

Using the inequality

$$\frac{1}{r}\Big(\sum_{1\le j\le r} a_j\Big)^2 \le \sum_{1\le j\le r} a_j^2$$

(cf. exercise 1.2.3–30), we find that

$$\limsup_{N\to\infty} \sum_{0\le j<m} \frac{1}{N(N+q)}\Big(\sum_{1\le n\le N+q} \big(\nu_j(n) - \nu_j(n-q)\big)\Big)^2 \le q(q-m)/mb^{2m} + q/b^m. \tag{24}$$

We also have

$$q\,\nu_j(N) \le \sum_{N<n\le N+q} \nu_j(n) = \sum_{1\le n\le N+q} \big(\nu_j(n) - \nu_j(n-q)\big) \le q\,\nu_j(N+q),$$

and putting this into (24) gives

$$\limsup_{N\to\infty} \sum_{0\le j<m} \big(\nu_j(N)/N\big)^2 \le (q-m)/qmb^{2m} + 1/qb^m. \tag{25}$$

This formula has been established whenever q is a multiple of m; and if we let $q \to \infty$ we obtain (17), completing the proof.

For a possibly simpler proof, see J. W. S. Cassels, *Pacific J. Math.* **2** (1952), 555–557. ∎

Exercises 29 and 30 illustrate the nontriviality of this theorem, and they also demonstrate the fact that a q-distributed sequence will have probabilities deviating from the true (m, m)-distribution probabilities by essentially $1/\sqrt{q}$ at most. (Cf. (25).) The full hypothesis of ∞-distribution is necessary for the proof of the theorem.

As a result of Theorem C, we can prove that an ∞-distributed sequence passes the serial test, the maximum-of-t test, the collision test, and the tests on subsequences mentioned in Section 3.3.2; it is not hard to show that the gap test, the poker test, and the run test are also satisfied (see exercises 12 through 14). The coupon collector's test is considerably more difficult to deal with, but it too is satisfied (see exercises 15 and 16).

The existence of ∞-distributed sequences of a rather simple type is guaranteed by the next theorem.

Theorem F (J. Franklin). *The* $[0,1)$ *sequence* $U_0, U_1, \ldots,$ *with*

$$U_n = \theta^n \bmod 1 \tag{26}$$

is ∞*-distributed for almost all real numbers* $\theta > 1$. *That is, the set*

$$\{\theta \mid \theta > 1 \text{ and (26) is not } \infty\text{-distributed}\}$$

is of measure zero.

The proofs of this theorem and some generalizations are given in Franklin's paper cited below. ∎

Franklin has shown that θ must be a transcendental number for (26) to be ∞-distributed. The powers $(\pi^n \bmod 1)$ have been laboriously computed for $n \leq 10000$, using multiple-precision arithmetic, and the most significant 35 bits of each of these numbers, stored on a disk file, have successfully been used as a source of uniform deviates. According to Theorem F, the probability that the powers $(\pi^n \bmod 1)$ are ∞-distributed is equal to 1; yet because there are uncountably many real numbers, this gives us no information as to whether the sequence is really ∞-distributed or not. It is a fairly safe bet that nobody in our lifetimes will ever *prove* that this particular sequence is *not* ∞-distributed; but it might not be. Because of these considerations, one may legitimately wonder if there is any *explicit* sequence that is ∞-distributed; i.e., *is there an algorithm to compute real numbers* U_n *for all* $n \geq 0$, *such that the sequence* $\langle U_n \rangle$ *is* ∞*-distributed?* The answer is yes, as shown for example by D. E. Knuth in *BIT* **5** (1965), 246–250. The sequence constructed there consists entirely of rational numbers; in fact, each number U_n has a terminating representation in the binary number system. Another construction of an explicit ∞-distributed sequence, somewhat more complicated than the sequence just cited, follows from Theorem W below. See also N. M. Korobov, *Izv. Akad. Nauk SSSR* **20** (1956), 649–660.

C. Does ∞-distributed = random? In view of all the above theory about ∞-distributed sequences, we can be sure of one thing: the concept of an ∞-distributed sequence is an important one in mathematics. There is also a good deal of evidence that the following statement is a valid formulation of the intuitive idea of randomness:

Definition R1. *A* $[0,1)$ *sequence is defined to be "random" if it is an* ∞*-distributed sequence.*

We have seen that sequences meeting this definition will satisfy all the statistical tests of Section 3.3.2 and many more.

Let us attempt to criticize this definition objectively. First of all, is every "truly random" sequence ∞-distributed? There are uncountably many sequences $U_0, U_1, \ldots$ of real numbers between zero and one. If a truly random number generator is sampled to give values $U_0, U_1, \ldots$, any of the possible sequences may be considered equally likely, and some of the sequences (indeed, uncountably many of them) are not even equidistributed. On the other hand, using any reasonable definition of probability on this space of all possible sequences leads us to conclude that a random sequence is ∞-distributed *with probability one.* We are therefore led to formalize Franklin's definition of randomness (as given at the beginning of this section) in the following way:

Definition R2. *A $[0,1)$ sequence $\langle U_n \rangle$ is defined to be "random" if, whenever P is a property such that $P(\langle V_n \rangle)$ holds with probability one for a sequence $\langle V_n \rangle$ of independent samples of random variables from the uniform distribution, then $P(\langle U_n \rangle)$ is true.*

Is it perhaps possible that Definition R1 is equivalent to Definition R2? Let us try out some possible objections to Definition R1, and see whether these criticisms are valid.

In the first place, Definition R1 deals only with limiting properties of the sequence as $n \to \infty$. There are ∞-distributed sequences in which the first million elements are all zero; should such a sequence be considered random?

This objection is not very valid. If ϵ is any positive number, there is no reason why the first million elements of a sequence should not all be less than ϵ. With probability one, a truly random sequence contains infinitely many runs of a million consecutive elements less than ϵ, so why can't this happen at the beginning of the sequence?

On the other hand, consider Definition R2 and let P be the property that all elements of the sequence are distinct; P is true with probability one, so any sequence with a million zeros is not random by *this* criterion.

Now let P be the property that *no* element of the sequence is equal to zero; again, P is true with probability one, so by Definition R2 any sequence with a zero element is nonrandom. More generally, however, let x_0 be any fixed number between zero and one, and let P be the property that no element of the sequence is equal to x_0; Definition R2 now says that no random sequence may contain the element x_0! We can now prove that *no sequence satisfies the condition of Definition R2.* (For if $U_0, U_1, \ldots$ is such a sequence, take $x_0 = U_0$.)

Therefore if R1 is too weak a definition, R2 is certainly too strong. The "right" definition must be less strict than R2. We have not really shown that R1 is too weak, however, so let us continue to attack it some more. As mentioned above, an ∞-distributed sequence of *rational* numbers has been constructed. (Indeed, this is not so surprising; see exercise 18.) Almost all real numbers are irrational; perhaps we should insist that

$$\Pr(U_n \text{ is rational}) = 0$$

for a random sequence.

Note that the definition of equidistribution says that $\Pr(u \le U_n < v) = v - u$. There is an obvious way to generalize this definition, using measure theory: "If $S \subseteq [0,1)$ is a set of measure μ, then

$$\Pr(U_n \in S) = \mu, \tag{27}$$

for all random sequences $\langle U_n \rangle$." In particular, if S is the set of rationals, it has measure zero, so no sequence of rational numbers is equidistributed in this generalized sense. It is reasonable to expect that Theorem B could be extended to Lebesgue integration instead of Riemann integration, if property (27) is stipulated. However, once again we find that definition (27) is too strict, for *no* sequence satisfies that property. If $U_0, U_1, \ldots$ is any sequence, the set $S = \{U_0, U_1, \ldots\}$ is of measure zero, yet $\Pr(U_n \in S) = 1$. Thus, by the force of the same argument we used to exclude rationals from random sequences, we can exclude all random sequences.

So far Definition R1 has proved to be defensible. There are, however, some quite valid objections to it. For example, if we have a random sequence in the intuitive sense, the infinite subsequence

$$U_0, U_1, U_4, U_9, \ldots, U_{n^2}, \ldots \tag{28}$$

should also be a random sequence. This is not always true for an ∞-distributed sequence. In fact, if we take any ∞-distributed sequence and set $U_{n^2} \leftarrow 0$ for all n, the counts $\nu_k(n)$ that appear in the test of k-distributivity are changed by at most $\sqrt{n}$, so the limits of the ratios $\nu_k(n)/n$ remain unchanged. Definition R1 unfortunately fails to satisfy this randomness criterion.

Perhaps we should strengthen R1 as follows:

Definition R3. *A $[0,1)$ sequence is said to be "random" if each of its infinite subsequences is ∞-distributed.*

Once again, however, the definition turns out to be too strict; any equidistributed sequence $\langle U_n \rangle$ has a monotonic subsequence with $U_{s_0} < U_{s_1} < U_{s_2} < \cdots$.

The secret is to restrict the subsequences so that they could be defined by somebody who does not look at U_n before deciding whether or not it is to be in the subsequence. The following definition now suggests itself:

Definition R4. *A $[0,1)$ sequence $\langle U_n \rangle$ is said to be "random" if, for every effective algorithm that specifies an infinite sequence of distinct nonnegative integers s_n for $n \ge 0$, the subsequence $U_{s_0}, U_{s_1}, U_{s_2}, \ldots$ corresponding to this algorithm is ∞-distributed.*

The algorithms referred to in Definition R4 are effective procedures that compute s_n, given n. (See Section 1.1.) Thus, for example, the sequence $\langle \pi^n \bmod 1 \rangle$ will *not* satisfy R4, since it is either not equidistributed or there is an effective algorithm that determines an infinite subsequence s_n with $(\pi^{s_0} \bmod 1) < (\pi^{s_1} \bmod 1) < (\pi^{s_2} \bmod 1) < \cdots$. Similarly, *no explicitly defined sequence can satisfy Definition R4*; this is appropriate, if we agree that no explicitly defined sequence can really be random. It is quite likely, however, that the sequence $\langle \theta^n \bmod 1 \rangle$ will satisfy Definition R4, for almost all real numbers $\theta > 1$; this is no

contradiction, since almost all θ are uncomputable by algorithms. The following facts are known, for example: (i) The sequence $\langle \theta^n \bmod 1 \rangle$ satisfies Definition R4 for almost all real $\theta > 1$, if "∞-distributed" is replaced by "1-distributed." This theorem was proved by J. F. Koksma, *Compositio Mathematica* **2** (1935), 250–258. (ii) The particular sequence $\langle \theta^{s(n)} \bmod 1 \rangle$ is ∞-distributed for almost all real $\theta > 1$, if $\langle s(n) \rangle$ is a sequence of integers for which $s(n+1) - s(n) \to \infty$ as $n \to \infty$. For example, we could have $s(n) = n^2$, or $s(n) = \lfloor n \lg n \rfloor$.

Definition R4 is much stronger than Definition R1; but it is still reasonable to claim that Definition R4 is too weak. For example, let $\langle U_n \rangle$ be a truly random sequence, and define the subsequence $\langle U_{s_n} \rangle$ by the following rules: $s_0 = 0$, and (for $n > 0$) s_n is the smallest integer $\geq n$ for which U_{s_n-1}, U_{s_n-2}, $\ldots$, U_{s_n-n} are all less than $\frac{1}{2}$. Thus we are considering the subsequence of values following the first consecutive run of n values less than $\frac{1}{2}$. Suppose that "$U_n < \frac{1}{2}$" corresponds to the value "heads" in the flipping of a coin. Gamblers tend to feel that a long run of "heads" makes the opposite condition, "tails," more probable, assuming that a true coin is being used; and the subsequence $\langle U_{s_n} \rangle$ just defined corresponds to a gambling system for a man who places his nth bet on the coin toss following the first run of n consecutive "heads." The gambler may think that $\Pr(U_{s_n} \geq \frac{1}{2})$ is more than $\frac{1}{2}$, but of course in a truly random sequence $\langle U_{s_n} \rangle$ will be completely random. No gambling system will ever be able to beat the odds! Definition R4 says nothing about subsequences formed according to such a gambling system, so apparently we need something more.

Let us define a "subsequence rule" $\mathcal{R}$ as an infinite sequence of functions $\langle f_n(x_1, \ldots, x_n) \rangle$ where, for $n \geq 0$, f_n is a function of n variables, and the value of $f_n(x_1, \ldots, x_n)$ is either 0 or 1. Here x_1, $\ldots$, x_n are elements of some set S. (Thus, in particular, f_0 is a constant function, either 0 or 1.) A subsequence rule $\mathcal{R}$ defines a subsequence of any infinite sequence $\langle X_n \rangle$ of elements of S as follows: *The nth term X_n is in the subsequence $\langle X_n \rangle \mathcal{R}$ if and only if* $f_n(X_0, X_1, \ldots, X_{n-1}) = 1$. Note that the subsequence $\langle X_n \rangle \mathcal{R}$ thus defined is not necessarily infinite, and it may in fact contain no elements at all.

For example, the gambler's subsequence just described corresponds to the following subsequence rule: "$f_0 = 1$; and for $n > 0$, $f_n(x_1, \ldots, x_n) = 1$ if and only if there is some k in the range $0 < k \leq n$ such that the k consecutive parameters x_m, x_{m-1}, $\ldots$, x_{m-k+1} are all $< \frac{1}{2}$ when $m = n$ but not when $k \leq m < n$."

A subsequence rule $\mathcal{R}$ is said to be *computable* if there is an effective algorithm that determines the value of $f_n(x_1, \ldots, x_n)$, when n and x_1, $\ldots$, x_n are given as input. We had better restrict ourselves to computable subsequence rules when trying to define randomness, lest we obtain an overly restrictive definition like R3 above. But effective algorithms cannot deal nicely with arbitrary real numbers as inputs; for example, if a real number x is specified by an infinite radix-10 expansion, there is no algorithm to determine if x is $< \frac{1}{3}$ or not, since all digits of the number $0.333\ldots$ have to be examined. Therefore computable subsequence rules do not apply to all $[0, 1)$ sequences, and it is convenient to base our next definition on b-ary sequences.

Definition R5. *A b-ary sequence is said to be "random" if every infinite subsequence defined by a computable subsequence rule is 1-distributed.*

A $[0,1)$ sequence $\langle U_n \rangle$ is said to be "random" if the b-ary sequence $\langle \lfloor bU_n \rfloor \rangle$ is "random" for all integers $b \geq 2$.

Note that Definition R5 says only "1-distributed," not "∞-distributed." It is interesting to verify that this may be done without loss of generality. For we may define an obviously computable subsequence rule $\mathcal{R}(a_1 \ldots a_k)$ as follows, given any b-ary number $a_1 \ldots a_k$: Let $f_n(x_1, \ldots, x_n) = 1$ if and only if $n \geq k-1$ and $x_{n-k+1} = a_1, \ldots, x_{n-1} = a_{k-1}, x_n = a_k$. Now if $\langle X_n \rangle$ is a k-distributed b-ary sequence, this rule $\mathcal{R}(a_1 \ldots a_k)$—which selects the subsequence consisting of those terms just following an occurrence of $a_1 \ldots a_k$—defines an infinite subsequence; and if this subsequence is 1-distributed, each of the $(k+1)$-tuples $a_1 \ldots a_k a_{k+1}$ for $0 \leq a_{k+1} < b$ occurs with probability $1/b^{k+1}$ in $\langle X_n \rangle$. Thus we can prove that a sequence satisfying Definition R5 is k-distributed for all k, by induction on k. Similarly, by considering the "composition" of subsequence rules—if $\mathcal{R}_1$ defines an infinite subsequence $\langle X_n \rangle \mathcal{R}_1$, then we can define $\mathcal{R}_1 \mathcal{R}_2$ to be the subsequence rule for which $\langle X_n \rangle \mathcal{R}_1 \mathcal{R}_2 = (\langle X_n \rangle \mathcal{R}_1) \mathcal{R}_2$—we find that all subsequences considered in Definition R5 are ∞-distributed. (See exercise 32.)

The fact that ∞-distribution comes out of Definition R5 as a very special case is encouraging, and it is a good indication that we may at last have found the definition of randomness we have been seeking. But alas, there still is a problem. It is not clear that sequences satisfying Definition R5 must satisfy Definition R4. The "computable subsequence rules" we have just specified always enumerate subsequences $\langle X_{s_n} \rangle$ for which $s_0 < s_1 < \cdots$, but $\langle s_n \rangle$ does not have to be monotone in R4; it must only satisfy the condition $s_n \neq s_m$ for $n \neq m$.

To meet this objection, we may combine Definitions R4 and R5 as follows:

Definition R6. *A b-ary sequence $\langle X_n \rangle$ is said to be "random" if, for every effective algorithm that specifies an infinite sequence of distinct nonnegative integers $\langle s_n \rangle$ as a function of n and the values of $X_{s_0}, \ldots, X_{s_{n-1}}$, the subsequence $\langle X_{s_n} \rangle$ corresponding to this algorithm is "random" in the sense of Definition R5.*

A $[0,1)$ sequence $\langle U_n \rangle$ is said to be "random" if the b-ary sequence $\langle \lfloor bU_n \rfloor \rangle$ is "random" for all integers $b \geq 2$.

The author contends* that this definition surely meets all reasonable philosophical requirements for randomness, so it provides an answer to the principal question posed in this section.

D. Existence of random sequences. We have seen that Definition R3 is too strong, in the sense that no sequence can satisfy that definition; and the formulation of Definitions R4, R5, and R6 above was carried out in an attempt to recapture the essential characteristics of Definition R3. In order to show that Definition R6 is not overly restrictive, it is still necessary for us to prove that sequences satisfying all these conditions exist. Intuitively, we feel quite sure that there is no problem,

*At least, he made such a contention when originally preparing the material for this section in 1966.

because we believe that a truly random sequence exists and satisfies R6; but a proof is really necessary to show that the definition is consistent.

An interesting method for constructing sequences satisfying Definition R5 has been found by A. Wald, starting with a very simple 1-distributed sequence.

Lemma T. *Let the sequence of real numbers $\langle V_n \rangle$ be defined in terms of the binary system as follows:*

$$V_0 = 0, \quad V_1 = .1, \quad V_2 = .01, \quad V_3 = .11, \quad V_4 = .001, \quad \ldots$$
$$V_n = .c_r \ldots c_1 1 \quad \text{if } n = 2^r + c_1 2^{r-1} + \cdots + c_r. \tag{29}$$

Let $I_{b_1 \ldots b_r}$ denote the set of all real numbers in $[0, 1)$ whose binary representation begins with $0.b_1 \ldots b_r$; thus

$$I_{b_1 \ldots b_r} = \big[(0.b_1 \ldots b_r)_2, (0.b_1 \ldots b_r)_2 + 2^{-r}\big). \tag{30}$$

Then if $\nu(n)$ denotes the number of V_k in $I_{b_1 \ldots b_r}$ for $0 \le k < n$, we have

$$|\nu(n)/n - 2^{-r}| \le 1/n. \tag{31}$$

Proof. Since $\nu(n)$ is the number of k for which $k \bmod 2^r = (b_r \ldots b_1)_2$, we have $\nu(n) = t$ or $t + 1$ when $\lfloor n/2^r \rfloor = t$. Hence $|\nu(n) - n/2^r| \le 1$. ∎

It follows from (31) that the sequence $\langle \lfloor 2^r V_n \rfloor \rangle$ is an equidistributed 2^r-ary sequence; hence by Theorem A, $\langle V_n \rangle$ is an equidistributed $[0, 1)$ sequence. Indeed, it is pretty clear that $\langle V_n \rangle$ is about as equidistributed as a $[0, 1)$ sequence can be. (For further discussion of this and related sequences, see J. G. van der Corput, *Proc. Koninklijke Nederl. Akad. Wetenschappen* **38** (1935), 813–821, 1058–1066; J. H. Halton, *Numerische Math.* **2** (1960), 84–90, 196; L. H. Ramshaw, *J. Number Theory*, to appear.)

Now let $\mathcal{R}_1, \mathcal{R}_2, \ldots$ be infinitely many subsequence rules; we seek a sequence $\langle U_n \rangle$ for which all the infinite subsequences $\langle U_n \rangle \mathcal{R}_j$ are equidistributed.

Algorithm W (*Wald sequence*). Given an infinite sequence of subsequence rules $\mathcal{R}_1, \mathcal{R}_2, \ldots$ that define subsequences of $[0, 1)$ sequences of rational numbers, this procedure defines a $[0, 1)$ sequence $\langle U_n \rangle$. The computation involves infinitely many auxiliary variables $C[a_1, \ldots, a_r]$, where $r \ge 1$ and where $a_j = 0$ or 1 for $1 \le j \le r$. These variables are initially all zero.

W1. [Initialize n.] Set $n \leftarrow 0$.

W2. [Initialize r.] Set $r \leftarrow 1$.

W3. [Test $\mathcal{R}_r$.] If the element U_n is to be in the subsequence defined by $\mathcal{R}_r$, based on the values of U_k for $0 \le k < n$, set $a_r \leftarrow 1$; otherwise set $a_r \leftarrow 0$.

W4. [$B[a_1, \ldots, a_r]$ full?] If $C[a_1, \ldots, a_r] < 3 \cdot 4^{r-1}$, go to W6.

W5. [Increase r.] Set $r \leftarrow r + 1$ and return to W3.

W6. [Set U_n.] Increase the value of $C[a_1, \ldots, a_r]$ by 1 and let k be its new value. Set $U_n \leftarrow V_k$, where V_k is defined in Lemma T above.

W7. [Advance n.] Increase n by 1 and return to W2. ∎

Strictly speaking, this is not an algorithm, since it doesn't terminate; it would of course be easy to modify the procedure to stop when n reaches a given value. The reader will find it easier to grasp the idea of the construction by trying it out manually, replacing the number $3 \cdot 4^{r-1}$ of step W4 by 2^r during this experiment.

Algorithm W is not meant to be a practical source of random numbers. It is intended to serve only a theoretical purpose:

Theorem W. *Let $\langle U_n \rangle$ be the sequence of rational numbers defined by Algorithm W, and let k be a positive integer. If the subsequence $\langle U_n \rangle \mathcal{R}_k$ is infinite, it is 1-distributed.*

Proof. Let $A[a_1, \ldots, a_r]$ denote the (possibly empty) subsequence of $\langle U_n \rangle$ containing precisely those elements U_n that, for all $j \le r$, belong to subsequence $\langle U_n \rangle \mathcal{R}_j$ if $a_j = 1$ and do not belong to subsequence $\langle U_n \rangle \mathcal{R}_j$ if $a_j = 0$.

It suffices to prove, for all $r \ge 1$ and all pairs of binary numbers $a_1 \ldots a_r$ and $b_1 \ldots b_r$, that $\Pr(U_n \in I_{b_1 \ldots b_r}) = 2^{-r}$ with respect to the subsequence $A[a_1, \ldots, a_r]$, whenever the latter is infinite. (See Eq. (30).) For if $r \ge k$, the infinite sequence $\langle U_n \rangle \mathcal{R}_k$ is the finite union of the disjoint subsequences $A[a_1, \ldots, a_r]$ for $a_k = 1$ and $a_j = 0$ or 1 for $1 \le j \le r$, $j \ne k$; and it follows that $\Pr(U_n \in I_{b_1 \ldots b_r}) = 2^{-r}$ with respect to $\langle U_n \rangle \mathcal{R}_k$. (See exercise 33.) This is enough to show that the sequence is 1-distributed, by Theorem A.

Let $B[a_1, \ldots, a_r]$ denote the subsequence of $\langle U_n \rangle$ that consists of the values for those n in which $C[a_1, \ldots, a_r]$ is increased by one in step W6 of the algorithm. By the algorithm, $B[a_1, \ldots, a_r]$ is a finite sequence with at most $3 \cdot 4^{r-1}$ elements. All but a finite number of the members of $A[a_1, \ldots, a_r]$ come from the subsequences $B[a_1, \ldots, a_r, \ldots, a_t]$, where $a_j = 0$ or 1 for $r < j \le t$.

Now assume that $A[a_1, \ldots, a_r]$ is infinite, and let $A[a_1, \ldots, a_r] = \langle U_{s_n} \rangle$, where $s_0 < s_1 < s_2 \le \cdots$. If N is a large integer, with $4^r \le 4^q < N \le 4^{q+1}$, it follows that the number of values of $k < N$ for which U_{s_k} is in $I_{b_1 \ldots b_r}$ is (except for finitely many elements at the beginning of the subsequence)

$$\nu(N) = \nu(N_1) + \cdots + \nu(N_m).$$

Here m is the number of subsequences $B[a_1, \ldots, a_t]$ listed above in which U_{s_k} appears for some $k < N$; N_j is the number of values of k with U_{s_k} in the corresponding subsequence; and $\nu(N_j)$ is the number of such values that are also in $I_{b_1 \ldots b_r}$. Therefore by Lemma T,

$$\begin{aligned} |\nu(N) - 2^{-r}N| &= |\nu(N_1) - 2^{-r}N_1 + \cdots + \nu(N_m) - 2^{-r}N_m| \\ &\le |\nu(N_1) - 2^{-r}N_1| + \cdots + |\nu(N_m) - 2^{-r}N_m| \\ &\le m \le 1 + 2 + 4 + \cdots + 2^{q-r+1} < 2^{q+1}. \end{aligned}$$

The inequality on m follows here from the fact that, by our choice of N, U_{s_N} is in $B[a_1, \ldots, a_t]$ for some $t \le q + 1$.

We have proved that

$$|\nu(N)/N - 2^{-r}| \le 2^{q+1}/N < 2/\sqrt{N}. \quad \blacksquare$$

To show finally that sequences satisfying Definition R5 exist, we note first that if $\langle U_n \rangle$ is a $[0,1)$ sequence of rational numbers and if $\mathcal{R}$ is a computable subsequence rule for a b-ary sequence, we can make $\mathcal{R}$ into a computable subsequence rule $\mathcal{R}'$ for $\langle U_n \rangle$ by letting $f'_n(x_1, \ldots, x_n)$ in $\mathcal{R}'$ equal $f_n(\lfloor bx_1 \rfloor, \ldots, \lfloor bx_n \rfloor)$ in $\mathcal{R}$. If the $[0,1)$ sequence $\langle U_n \rangle \mathcal{R}'$ is equidistributed, so is the b-ary sequence $\langle \lfloor bU_n \rfloor \rangle \mathcal{R}$. Now the set of all computable subsequence rules for b-ary sequences, for all values of b, is countable (since only countably many effective algorithms are possible), so they may be listed in some sequence $\mathcal{R}_1$, $\mathcal{R}_2$, ...; therefore Algorithm W defines a $[0,1)$ sequence that is random in the sense of Definition R5.

This brings us to a somewhat paradoxical situation. As we mentioned earlier, no effective algorithm can define a sequence that satisfies Definition R4, and for the same reason there is no effective algorithm that defines a sequence satisfying Definition R5. A proof of the existence of such random sequences is necessarily nonconstructive; how then can Algorithm W construct such a sequence?

There is no contradiction here; we have merely stumbled on the fact that the set of all effective algorithms cannot be enumerated by an effective algorithm. In other words, there is no effective algorithm to select the jth computable subsequence rule $\mathcal{R}_j$; this happens because there is no effective algorithm to determine if a computational method ever terminates. (We shall return to this topic in Chapter 11.) Important large classes of algorithms *can* be systematically enumerated; thus, for example, Algorithm W shows that it is possible to construct, with an effective algorithm, a sequence that satisfies Definition R5 if we restrict consideration to subsequence rules that are "primitive recursive."

By modifying step W6 of Algorithm W, so that it sets $U_n \leftarrow V_{k+t}$ instead of V_k, where t is any nonnegative integer depending on $a_1, \ldots, a_r$, we can show that there are *uncountably* many $[0,1)$ sequences satisfying Definition R5.

The following theorem shows still another way to prove the existence of uncountably many random sequences, using a less direct argument based on measure theory, even if the strong definition R6 is used:

Theorem M. *Let the real number x, $0 \le x < 1$, correspond to the binary sequence $\langle X_n \rangle$ if the binary representation of x is $(0.X_0X_1\ldots)_2$. Under this correspondence, almost all x correspond to binary sequences that are random in the sense of Definition R6.* (In other words, the set of all real x that correspond to a binary sequence that is nonrandom by Definition R6 has measure zero.)

Proof. Let $\mathcal{S}$ be an effective algorithm that determines an infinite sequence of distinct nonnegative integers $\langle s_n \rangle$, where the choice of s_n depends only on n and X_{s_k} for $0 \le k < n$; and let $\mathcal{R}$ be a computable subsequence rule. Then any binary sequence $\langle X_n \rangle$ leads to a subsequence $\langle X_{s_n} \rangle \mathcal{R}$, and Definition R6 says this subsequence must either be finite or 1-distributed. It suffices to prove that *for fixed $\mathcal{R}$ and $\mathcal{S}$ the set $N(\mathcal{R}, \mathcal{S})$ of all real x corresponding to $\langle X_n \rangle$, such that $\langle X_{s_n} \rangle \mathcal{R}$ is infinite and not 1-distributed, has measure zero.* For x has a nonrandom binary representation if and only if x is in $\bigcup N(\mathcal{R}, \mathcal{S})$, taken over the countably many choices of $\mathcal{R}$ and $\mathcal{S}$.

Therefore let $\mathcal{R}$ and $\mathcal{S}$ be fixed. Consider the set $T(a_1a_2\ldots a_r)$ defined for all binary numbers $a_1a_2\ldots a_r$ as the set of all x corresponding to $\langle X_n\rangle$, such that $\langle X_{s_n}\rangle\mathcal{R}$ has $\geq r$ elements whose first r elements are respectively equal to a_1, a_2, $\ldots$, a_r. Our first result is that

$$T(a_1a_2\ldots a_r) \text{ has measure } \leq 2^{-r}. \tag{32}$$

To prove this, we start by observing that $T(a_1a_2\ldots a_r)$ is a measurable set: Each element of $T(a_1a_2\ldots a_r)$ is a real number $x = (0.X_0X_1\ldots)_2$ for which there exists an integer m such that algorithm $\mathcal{S}$ determines distinct values $s_0, s_1, \ldots, s_m$, and rule $\mathcal{R}$ determines a subsequence of $X_{s_0}, X_{s_1}, \ldots, X_{s_m}$ such that X_{s_m} is the rth element of this subsequence. The set of all real $y = (0.Y_0Y_1\ldots)_2$ such that $Y_{s_k} = X_{s_k}$ for $0 \leq k \leq m$ also belongs to $T(a_1a_2\ldots a_r)$, and this is a measurable set consisting of the finite union of dyadic subintervals $I_{b_1\ldots b_t}$. Since there are only countably many such dyadic intervals, we see that $T(a_1a_2\ldots a_r)$ is a countable union of dyadic intervals, and it is therefore measurable. Furthermore, this argument can be extended to show that the measure of $T(a_1\ldots a_{r-1}\,0)$ equals the measure of $T(a_1\ldots a_{r-1}\,1)$, since the latter is a union of dyadic intervals obtained from the former by requiring that $Y_{s_k} = X_{s_k}$ for $0 \leq k < m$ and $Y_{s_m} \neq X_{s_m}$. Now since

$$T(a_1\ldots a_{r-1}\,0) \cup T(a_1\ldots a_{r-1}\,1) \subseteq T(a_1\ldots a_{r-1}),$$

the measure of $T(a_1a_2\ldots a_r)$ is at most one-half the measure of $T(a_1\ldots a_{r-1})$. The inequality (32) follows by induction on r.

Now that (32) has been established, the remainder of the proof is essentially to show that the binary representations of almost all real numbers are equidistributed. The next few paragraphs constitute a rather long but not difficult proof of this fact, and they serve to provide probability estimates that are useful in many other problems.

For $0 < \epsilon < 1$, let $B(r,\epsilon)$ be $\bigcup T(a_1\ldots a_r)$, where the union is taken over all binary numbers $a_1\ldots a_r$ for which the number $\nu(r)$ of zeros among $a_1\ldots a_r$ satisfies

$$|\nu(r) - \tfrac{1}{2}r| \geq 1 + \epsilon r.$$

The number of such binary numbers is $C(r,\epsilon) = \sum\binom{r}{k}$ summed over the values of k with $|k - \frac{1}{2}r| \geq 1 + \epsilon r$. A suitable estimate for the tail of the binomial distribution can be obtained by the following standard trick: Let x and p be any positive numbers less than 1, let $q = 1 - p$, and let $s = (p + \epsilon)r$. Then

$$\sum_{k\geq s}\binom{r}{k}p^kq^{r-k} \leq \sum_{k\geq s}\binom{r}{k}p^kq^{r-k}x^{s-k} \leq \sum_{k\geq 0}\binom{r}{k}p^kq^{r-k}x^{s-k} = x^s\Big(q + \frac{p}{x}\Big)^r.$$

By elementary calculus, the minimum value of $x^s(q + p/x)^r$ occurs when $x = (p/(p+\epsilon))/(q/(q-\epsilon))$, and this value of x yields

$$\sum_{k\geq(p+\epsilon)r}\binom{r}{k}p^kq^{r-k} \leq \left(\left(\frac{p}{p+\epsilon}\right)^{p+\epsilon}\left(\frac{q}{q-\epsilon}\right)^{q-\epsilon}\right)^r.$$

Now when $\epsilon \le \min(p,q)$ we have

$$\ln\bigl(p/(p+\epsilon)\bigr)^{p+\epsilon} = -\epsilon - \frac{\epsilon^2}{2p} + \frac{\epsilon^3}{6p^2} - \frac{\epsilon^4}{12p^3} + \cdots < -\epsilon,$$

$$\ln\bigl(q/(q-\epsilon)\bigr)^{q-\epsilon} = +\epsilon - \frac{\epsilon^2}{2q} - \frac{\epsilon^3}{6q^2} - \frac{\epsilon^4}{12q^3} - \cdots < \epsilon - \frac{\epsilon^2}{2q},$$

so we have the following bound for all $r > 0$ and $0 \le \epsilon \le \min(p,q)$:

$$\sum_{k \ge (p+\epsilon)r} \binom{r}{k} p^k q^{r-k} < e^{-\epsilon^2 r/(2q)}. \tag{33}$$

But $C(r,\epsilon)$ is 2^{r+1} times this left-hand quantity, in the special case $p = q = \frac{1}{2}$, hence by (32)

$$B(r,\epsilon) \text{ has measure } \le 2^{-r} C(r,\epsilon) < 2e^{-\epsilon^2 r}.$$

The next step is to define

$$B^*(r,\epsilon) = B(r,\epsilon) \cup B(r+1,\epsilon) \cup B(r+2,\epsilon) \cup \cdots.$$

The measure of $B^*(r,\epsilon)$ is at most $\sum_{k \ge r} 2e^{-\epsilon^2 k}$, and this is the remainder of a convergent series, so

$$\lim_{r\to\infty} \bigl(\text{measure of } B^*(r,\epsilon)\bigr) = 0. \tag{34}$$

Now if x is a real number whose binary expansion $(0.X_0X_1\ldots)_2$ leads to an infinite sequence $\langle X_{s_n}\rangle \mathcal{R}$ that is not 1-distributed, and if $\nu(r)$ denotes the number of zeros in the first r elements of the latter sequence, then

$$|\nu(r)/r - \tfrac{1}{2}| \ge 2\epsilon,$$

for some $\epsilon > 0$ and infinitely many r. This means x is in $B^*(r,\epsilon)$ for all r. So finally we find that

$$N(\mathcal{R},S) = \bigcup_{t\ge 2} \bigcap_{r\ge 1} B^*(r,1/t);$$

and, by (34), $\bigcap_{r\ge 1} B^*(r,1/t)$ has measure zero for all t. Hence $N(\mathcal{R},S)$ has measure zero. ∎

From the existence of *binary* sequences satisfying Definition R6, we can show the existence of $[0,1)$ sequences that are random in this sense. For details, see exercise 36. The consistency of Definition R6 is thereby established.

E. Random finite sequences. An argument was given above to indicate that it is impossible to define the concept of randomness for finite sequences; any given finite sequence is as likely as any other. Still, nearly everyone would agree that the sequence 011101001 is "more random" than 101010101, and even the latter

sequence is "more random" than 000000000. Although it is true that truly random sequences will exhibit locally nonrandom behavior, we would expect such behavior only in a long finite sequence, not in a short one.

Several ways for defining the randomness of a finite sequence have been proposed, and only a few of the ideas will be sketched here. Let us consider only the case of b-ary sequences.

Given a b-ary sequence $X_1, X_2, \ldots, X_N$, we can say that

$$\Pr\big(S(n)\big) \approx p, \qquad \text{if } |\nu(N)/N - p| \le 1/\sqrt{N},$$

where $\nu(n)$ is the quantity appearing in Definition A at the beginning of this section. The above sequence can be called "k-distributed" if

$$\Pr(X_n X_{n+1} \ldots X_{n+k-1} = x_1 x_2 \ldots x_k) \approx 1/b^k$$

for all b-ary numbers $x_1 x_2 \ldots x_k$. (Cf. Definition D; unfortunately a sequence may be k-distributed by this new definition when it is not $(k-1)$-distributed.)

A definition of randomness may now be given analogous to Definition R1, as follows:

Definition Q1. *A b-ary sequence of length N is "random" if it is k-distributed (in the above sense) for all positive integers $k \le \log_b N$.*

According to this definition, for example, there are 170 nonrandom binary sequences of length 11:

00000001111	10000000111	11000000011	11100000001
00000001110	10000000110	11000000010	11100000000
00000001101	10000000101	11000000001	10100000001
00000001011	10000000011	01000000011	01100000001
00000000111			

plus 01010101010 and all sequences with nine or more zeros, plus all sequences obtained from the preceding sequences by interchanging ones and zeros.

Similarly, we can formulate a definition for finite sequences analogous to Definition R6. Let **A** be a set of algorithms, each of which is a combination selection and choice procedure that gives a subsequence $\langle X_{s_n} \rangle \mathcal{R}$, as in the proof of Theorem M.

Definition Q2. *The b-ary sequence $X_1, X_2, \ldots, X_N$ is (n, ϵ)-random with respect to a set of algorithms* **A**, *if for every subsequence $X_{t_1}, X_{t_2}, \ldots, X_{t_m}$ determined by an algorithm of* **A** *we have either $m < n$ or*

$$\left| \frac{1}{m} \nu_a(X_{t_1}, \ldots, X_{t_m}) - \frac{1}{b} \right| \le \epsilon \qquad \text{for } 0 \le a < b.$$

Here $\nu_a(x_1, \ldots, x_m)$ is the number of a's in the sequence $x_1, \ldots, x_m$.

(In other words, every sufficiently long subsequence determined by an algorithm of **A** must be approximately equidistributed.) The basic idea in this case is to let **A** be a set of "simple" algorithms; the number (and the complexity) of the algorithms in **A** can grow as N grows.

As an example of Definition Q2, let us consider binary sequences, and let **A** be just the following four algorithms:

a) Take the whole sequence.
b) Take alternate terms of the sequence, starting with the first.
c) Take the terms of the sequence following a zero.
d) Take the terms of the sequence following a one.

Now a sequence $X_1, \ldots, X_8$ is $(4, \frac{1}{8})$-random if:

by (a), $|\frac{1}{8}(X_1 + \cdots + X_8) - \frac{1}{2}| \le \frac{1}{8}$, i.e., if there are 3, 4, or 5 ones;

by (b), $|\frac{1}{4}(X_1 + X_3 + X_5 + X_7) - \frac{1}{2}| \le \frac{1}{8}$, i.e., if there are two ones in odd-numbered positions;

by (c), there are three possibilities depending on how many zeros occupy positions $X_1, \ldots, X_7$: if there are 2 or 3 zeros here, there is no condition to test (since $n = 4$); if there are 4 zeros, they must respectively be followed by two zeros and two ones; and if there are 5 zeros, they must respectively be followed by two or three zeros;

by (d), we get conditions similar to those implied by (c).

It turns out that only the following binary sequences of length 8 are $(4, \frac{1}{8})$-random with respect to these rules:

00001011	00101001	01001110	01101000
00011010	00101100	01011011	01101100
00011011	00110010	01011110	01101101
00100011	00110011	01100010	01110010
00100110	00110110	01100011	01110110
00100111	00111001	01100110	

plus those obtained by interchanging 0 and 1 consistently.

It is clear that we could make the set of algorithms so large that no sequences satisfy the definition, when n and ϵ are reasonably small. A. N. Kolomogorov has proved that an (n, ϵ)-random binary sequence *will* always exist, for any given N, if the number of algorithms in **A** does not exceed

$$\frac{1}{2}e^{2n\epsilon^2(1-\epsilon)}. \tag{35}$$

This result is not nearly strong enough to show that sequences satisfying Definition Q1 will exist, but the latter can be constructed efficiently using the procedure of Rees in exercise 3.2.2–21.

Still another interesting approach to a definition of randomness has been taken by Per Martin-Löf [*Information and Control* **9** (1966), 602–619]. Given a

finite b-ary sequence $X_1, \ldots, X_N$, let $l(X_1, \ldots, X_N)$ be the length of the shortest Turing machine program that generates this sequence. (For a definition of Turing machines, see Chapter 11; alternatively, we could use certain classes of effective algorithms, such as those defined in exercise 1.1–8.) Then $l(X_1, \ldots, X_N)$ is a measure of the "patternlessness" of the sequence, and we may equate this idea with randomness. The sequences of length N that maximize $l(X_1, \ldots, X_N)$ may be called random. (From the standpoint of practical random number generation by computer, this is, of course, the worst definition of "randomness" that can be imagined!)

Essentially the same definition of randomness was independently given by G. Chaitin at about the same time; see *JACM* **16** (1969), 145–159. It is interesting to note that even though this definition makes no reference to equidistribution properties as our other definitions have, Martin-Löf and Chaitin have proved that random sequences of this type also have the expected equidistribution properties. In fact, Martin-Löf has demonstrated that such sequences satisfy *all* computable statistical tests for randomness, in an appropriate sense.

For further developments in the definition of random finite sequences, see A. K. Zvonkin and L. A. Levin, *Uspekhi Mat. Nauk* **25**,6 (Nov. 1970), 85–127 [English translation in *Russian Math. Surveys* **25**,6 (Nov. 1970), 83–124]; L. A. Levin, *Doklady Akad. Nauk SSSR* **212** (1973), 548–550.

F. Summary, history, and bibliography. We have defined several degrees of randomness that a sequence might possess.

An infinite sequence that is ∞-distributed satisfies a great many useful properties that are expected of random sequences, and there is a rich theory concerning ∞-distributed sequences. (The exercises that follow develop several important properties of ∞-distributed sequences that have not been mentioned in the text.) Definition R1 is therefore an appropriate basis for theoretical studies of randomness.

The concept of an ∞-distributed b-ary sequence was introduced in 1909 by Emile Borel. He essentially defined the concept of an (m, k)-distributed sequence, and showed that the b-ary representations of almost all real numbers are (m, k)-distributed for all m and k. He called such numbers *normal* to base b. An excellent discussion of this topic appears in his well-known book, *Leçons sur la théorie des fonctions* (2nd ed., 1914), 182–216.

The notion of an ∞-distributed sequence of *real* numbers, also called a *completely equidistributed sequence*, first appeared in a note by N. M. Korobov in *Doklady Akad. Nauk SSSR* **62** (1948), 21–22. Korobov and several of his colleagues developed the theory of such sequences quite extensively in a series of papers during the 1950s. Completely equidistributed sequences were independently studied by Joel N. Franklin, *Math. Comp.* **17** (1963), 28–59, in a paper that is particularly noteworthy because it was inspired by the problem of random number generation. The book *Uniform Distribution of Sequences* by L. Kuipers and H. Niederreiter (New York: Wiley, 1974) is an extraordinarily complete source of information about the rich mathematical literature concerning k-distributed sequences of all kinds.

We have seen, however, that ∞-distributed sequences need not be sufficiently haphazard to qualify completely as "random." Three definitions, R4, R5, and R6, were formulated above to provide the additional conditions; and Definition R6, in particular, seems to be an appropriate way to define the concept of an infinite random sequence. It is a precise, quantitative statement that may well coincide with the intuitive idea of true randomness.

Historically, the development of these definitions was primarily influenced by R. von Mises' quest for a good definition of "probability." In *Math. Zeitschrift* **5** (1919), 52–99, von Mises proposed a definition similar in spirit to Definition R5, although stated too strongly (like our Definition R3) so that no sequences satisfying the conditions could possibly exist. Many people noticed this discrepancy, and A. H. Copeland [*Amer. J. Math.* **50** (1928), 535–552] suggested weakening von Mises' definition by substituting what he called "admissible numbers" (or Bernoulli sequences). These are equivalent to ∞-distributed $[0,1)$ sequences in which all entries U_n have been replaced by 1 if $U_n < p$ or by 0 if $U_n \geq p$, for a given probability p. Thus Copeland was essentially suggesting a return to Definition R1. Then Abraham Wald showed that it is not necessary to weaken von Mises' definition so drastically, and he proposed substituting a countable set of subsequence rules. In an important paper [*Ergebnisse eines math. Kolloquiums* **8** (Vienna, 1937), 38–72], Wald essentially proved Theorem W, although he made the erroneous assertion that the sequence constructed by Algorithm W also satisfies the stronger condition that $\Pr(U_n \in A) =$ measure of A, for all Lebesgue measurable $A \subseteq [0,1)$. We have observed that no sequence can satisfy this property.

The concept of "computability" was still very much in its infancy when Wald wrote his paper, and A. Church [*Bull. Amer. Math. Soc.* **47** (1940), 130–135] showed how the precise notion of "effective algorithm" could be added to Wald's theory to make his definitions completely rigorous. The extension to Definition R6 was due essentially to A. N. Kolmogorov [*Sankhyā* (A) **25** (1963), 369–376], who proposed Definition Q2 for finite sequences in that same paper. Another definition of randomness for finite sequences, somewhere "between" Definitions Q1 and Q2, had been formulated many years earlier by A. S. Besicovitch [*Math. Zeitschrift* **39** (1934), 146–156].

The publications of Church and Kolmogorov considered only binary sequences for which $\Pr(X_n = 1) = p$ for a given probability p. Our discussion in this section has been slightly more general, since a $[0,1)$ sequence essentially represents all p at once. The von Mises–Wald–Church definition has been refined in yet another interesting way by J. V. Howard, *Zeitschr. f. math. Logik und Grundlagen d. Math.* **21** (1975), 215–224.

Another important contribution was made by Donald W. Loveland [*Zeitschr. f. math. Logik und Grundlagen d. Math.* **12** (1966), 279–294], who discussed Definitions R4, R5, R6, and several intermediate concepts. Loveland proved that there are R5-random sequences that do not satisfy R4, thereby establishing the need for a stronger definition such as R6. In fact, he defined a rather simple permutation $\langle f(n) \rangle$ of the nonnegative integers, and an Algorithm W′ analogous

to Algorithm W, such that $\overline{\Pr}(U_{f(n)} \geq \frac{1}{2}) - \underline{\Pr}(U_{f(n)} \geq \frac{1}{2}) \geq \frac{1}{2}$ for every R5-random sequence $\langle U_n \rangle$ produced by Algorithm W′ when it is given an infinite set of subsequence rules $\mathcal{R}_k$.

Although Definition R6 is intuitively much stronger than R4, it is apparently not a simple matter to prove this rigorously, and for several years it was an open question whether or not R4 implies R6. Finally Thomas Herzog and James C. Owings, Jr., discovered how to construct a large family of sequences that satisfy R4 but not R6. [See *Zeitschr. f. math. Logik und Grundlagen d. Math.* **22** (1976), 385–389.]

Kolmogorov wrote another significant paper [*Problemy Peredači Informatsii* **1** (1965), 3–11] in which he considered the problem of defining the "information content" of a sequence, and this work led to Chaitin and Martin-Löf's interesting definition of finite random sequences via "patternlessness." [See *IEEE Trans.* **IT-14** (1968), 662–664.]

For a philosophical discussion of random sequences, see K. R. Popper, *The Logic of Scientific Discovery* (London, 1959), especially the interesting construction on pp. 162–163, which he first published in 1934.

Further connections between random sequences and recursive function theory have been explored by D. W. Loveland, *Trans. Amer. Math. Soc.* **125** (1966), 497–510. See also C.-P. Schnorr [*Zeitschr. Wahr. verw. Geb.* **14** (1969), 27–35], who found strong relations between random sequences and the "species of measure zero" defined by L. E. J. Brouwer in 1919. Schnorr's subsequent book *Zufälligkeit und Wahrscheinlichkeit* [*Lecture Notes in Math.* **218** (Berlin: Springer, 1971)] gives a detailed treatment of the entire subject of randomness and makes an excellent introduction to the ever-growing advanced literature on the topic.

EXERCISES

1. [*10*] Can a periodic sequence be equidistributed?

2. [*10*] Consider the periodic binary sequence 0, 0, 1, 1, 0, 0, 1, 1, ... Is it 1-distributed? Is it 2-distributed? Is it 3-distributed?

3. [*M22*] Construct a periodic ternary sequence that is 3-distributed.

▶ **4.** [*HM22*] Let $U_n = (2^{\lfloor \lg(n+1) \rfloor}/3) \bmod 1$. What is $\Pr(U_n < \frac{1}{2})$?

5. [*HM14*] Prove that $\Pr(S(n) \text{ and } T(n)) + \Pr(S(n) \text{ or } T(n)) = \Pr(S(n)) + \Pr(T(n))$, for any two statements $S(n)$, $T(n)$, provided that at least three of the limits exist. For example, if a sequence is 2-distributed, we would find that

$$\Pr(u_1 \leq U_n < v_1 \text{ or } u_2 \leq U_{n+1} < v_2) = v_1 - u_1 + v_2 - u_2 - (v_1 - u_1)(v_2 - u_2).$$

6. [*HM23*] Let $S_1(n)$, $S_2(n)$, ... be an infinite sequence of statements about mutually disjoint events; i.e., $S_i(n)$ and $S_j(n)$ cannot simultaneously be true if $i \neq j$. Assume that $\Pr(S_j(n))$ exists for each $j \geq 1$. Show that $\underline{\Pr}(S_j(n) \text{ is true for some } j \geq 1) \geq \sum_{j \geq 1} \Pr(S_j(n))$, and give an example to show that equality need not hold.

7. [*HM27*] Let $\{S_{ij}(n)\}$ be a family of statements such that $\Pr(S_{ij}(n))$ exists for all $i, j \geq 1$. Assume that for all $n > 0$, $S_{ij}(n)$ is true for exactly one pair of integers i, j. If $\sum_{i,j\geq 1} \Pr(S_{ij}(n)) = 1$, does it follow that "$\Pr(S_{ij}(n)$ is true for some $j \geq 1$)" exists for all $i \geq 1$, and that it equals $\sum_{j\geq 1} \Pr(S_{ij}(n))$?

8. [*M15*] Prove (13).

9. [*HM20*] Prove Lemma E. [*Hint:* Consider $\sum_{1\leq j\leq m}(y_{jn} - \alpha)^2$.]

▶ **10.** [*HM22*] Where was the fact that m divides q used in the proof of Theorem C?

11. [*M10*] Use Theorem C to prove that if $\langle U_n\rangle$ is ∞-distributed, so is the subsequence $\langle U_{2n}\rangle$.

12. [*HM20*] Show that a k-distributed sequence passes the "maximum-of-k test," in the following sense: $\Pr(u \leq \max(U_n, U_{n+1}, \ldots, U_{n+k-1}) < v) = v^k - u^k$.

▶ **13.** [*HM27*] Show that an ∞-distributed $[0, 1)$ sequence passes the "gap test" in the following sense: If $0 \leq \alpha < \beta \leq 1$ and $p = \beta - \alpha$, let $f(0) = 0$, and for $n \geq 1$ let $f(n)$ be the smallest integer $m > f(n-1)$ such that $\alpha \leq U_m < \beta$; then

$$\Pr(f(n) - f(n-1) = k) = p(1-p)^{k-1}.$$

14. [*HM25*] Show that an ∞-distributed sequence passes the "run test" in the following sense: If $f(0) = 1$ and if, for $n \geq 1$, $f(n)$ is the smallest integer $m > f(n-1)$ such that $U_{m-1} > U_m$, then

$$\Pr(f(n) - f(n-1) = k) = 2k/(k+1)! - 2(k+1)/(k+2)!.$$

▶ **15.** [*HM30*] Show that an ∞-distributed sequence passes the "coupon-collector's test" when there are only two kinds of coupons, in the following sense: Let $X_1, X_2, \ldots$ be an ∞-distributed binary sequence. Let $f(0) = 0$, and for $n \geq 1$ let $f(n)$ be the smallest integer $m > f(n-1)$ such that $\{X_{f(n-1)+1}, \ldots, X_m\}$ is the set $\{0, 1\}$. Prove that $\Pr(f(n) - f(n-1) = k) = 2^{1-k}$, for $k \geq 2$. (Cf. exercise 7.)

16. [*HM38*] Does the coupon-collector's test hold for ∞-distributed sequences when there are more than two kinds of coupons? (Cf. the previous exercise.)

17. [*HM50*] If r is any given rational number, Franklin has proved that the sequence $\langle r^n \bmod 1\rangle$ is not 2-distributed. But is there any rational number r for which this sequence is equidistributed? In particular, is the sequence equidistributed when $r = \frac{3}{2}$? [Cf. K. Mahler, *Mathematika* **4** (1957), 122–124.]

▶ **18.** [*HM22*] Prove that if $U_0, U_1, \ldots$ is k-distributed, so is the sequence $V_0, V_1, \ldots$, where $V_n = \lfloor nU_n\rfloor/n$.

19. [*HM35*] Consider a modification of Definition R4 that requires the subsequences to be only 1-distributed instead of ∞-distributed. Is there a sequence that satisfies this weaker definition, but that is not ∞-distributed? (Is the weaker definition really weaker?)

20. [*HM47*] Does the sequence $\langle \theta^n \bmod 1\rangle$ satisfy Definition R4 for almost all real numbers $\theta > 1$?

21. [*HM20*] Let S be a set and let $\mathcal{M}$ be a collection of subsets of S. Suppose that p is a real-valued function of the sets in $\mathcal{M}$, such that $p(M)$ denotes the probability that a "randomly" chosen element of S lies in M. Generalize Definitions B and D to obtain a good definition of the concept of a k-distributed sequence $\langle Z_n\rangle$ of elements of S with respect to the probability distribution p.

▸ **22.** [*HM30*] (Hermann Weyl.) Show that the $[0,1)$ sequence $\langle U_n \rangle$ is k-distributed if and only if

$$\lim_{N\to\infty} \frac{1}{N} \sum_{0\le n<N} \exp(2\pi i(c_1U_n + \cdots + c_kU_{n+k-1})) = 0$$

for every set of integers $c_1, c_2, \ldots, c_k$ not all zero.

23. [*M34*] Show that a b-ary sequence $\langle X_n \rangle$ is k-distributed if and only if all of the sequences $\langle c_1X_n + c_2X_{n+1} + \cdots + c_kX_{n+k-1} \rangle$ are *equidistributed*, whenever $c_1, c_2, \ldots, c_k$ are integers with $\gcd(c_1, \ldots, c_k) = 1$.

24. [*M25*] Show that a $[0,1)$ sequence $\langle U_n \rangle$ is k-distributed if and only if all of the sequences $\langle c_1U_n + c_2U_{n+1} + \cdots + c_kU_{n+k-1} \rangle$ are *equidistributed*, whenever $c_1, c_2, \ldots, c_k$ are integers not all zero.

25. [*HM20*] A sequence is called a "white sequence" if all serial correlations are zero, i.e., if the equation in Corollary S is true for *all* $k \ge 1$. (By Corollary S, an ∞-distributed sequence is white.) Show that if a $[0,1)$ sequence is equidistributed, it is white if and only if

$$\lim_{n\to\infty} \frac{1}{n} \sum_{0\le j<n} (U_j - \tfrac{1}{2})(U_{j+k} - \tfrac{1}{2}) = 0, \qquad \text{for all } k \ge 1.$$

26. [*HM34*] (J. Franklin.) A white sequence, as defined in the previous exercise, can definitely fail to be random. Let $U_0, U_1, \ldots$ be an ∞-distributed sequence, and define the sequence $V_0, V_1, \ldots$ as follows:

$$\begin{aligned} (V_{2n-1}, V_{2n}) &= (U_{2n-1}, U_{2n}) \qquad \text{if } (U_{2n-1}, U_{2n}) \in G, \\ (V_{2n-1}, V_{2n}) &= (U_{2n}, U_{2n-1}) \qquad \text{if } (U_{2n-1}, U_{2n}) \notin G, \end{aligned}$$

where G is the set $\{(x,y) \mid x - \frac{1}{2} \le y \le x \text{ or } x + \frac{1}{2} \le y\}$. Show that (a) $V_0, V_1, \ldots$ is equidistributed and white; (b) $\Pr(V_n > V_{n+1}) = \frac{5}{8}$. (This points out the weakness of the serial correlation test.)

27. [*HM48*] What is the highest possible value for $\Pr(V_n > V_{n+1})$ in an equidistributed, white sequence? (D. Coppersmith has constructed such a sequence achieving the value $\frac{7}{8}$.)

▸ **28.** [*HM21*] Use the sequence (11) to construct a $[0,1)$ sequence that is 3-distributed, for which $\Pr(U_{2n} \ge \frac{1}{2}) = \frac{3}{4}$.

29. [*HM34*] Let $X_0, X_1, \ldots$ be a $(2k)$-distributed binary sequence. Show that

$$\overline{\Pr}(X_{2n} = 0) \le \frac{1}{2} + \binom{2k-1}{k} \Big/ 2^{2k}.$$

▸ **30.** [*M39*] Construct a binary sequence that is $(2k)$-distributed, and for which

$$\Pr(X_{2n} = 0) = \frac{1}{2} + \binom{2k-1}{k} \Big/ 2^{2k}.$$

(Therefore the inequality in the previous exercise is the best possible.)

31. [*M30*] Show that $[0,1)$ sequences exist that satisfy Definition R5, yet $\nu_n/n \geq \frac{1}{2}$ for all $n > 0$, where ν_n is the number of $j < n$ for which $U_n < \frac{1}{2}$. (This might be considered a nonrandom property of the sequence.)

32. [*M24*] Given that $\langle X_n \rangle$ is a "random" b-ary sequence according to Definition R5, and that $\mathcal{R}$ is a computable subsequence rule that specifies an infinite subsequence $\langle X_n \rangle \mathcal{R}$, show that the latter subsequence is not only 1-distributed, it is "random" by Definition R5.

33. [*HM22*] Let $\langle U_{r_n} \rangle$ and $\langle U_{s_n} \rangle$ be infinite disjoint subsequences of a sequence $\langle U_n \rangle$. (Thus, $r_0 < r_1 < r_2 < \cdots$ and $s_0 < s_1 < s_2 < \cdots$ are increasing sequences of integers and $r_m \neq s_n$ for any m, n.) Let $\langle U_{t_n} \rangle$ be the combined subsequence, so that $t_0 < t_1 < t_2 < \cdots$ and the set $\{t_n\} = \{r_n\} \cup \{s_n\}$. Show that if $\Pr(U_{r_n} \in A) = \Pr(U_{s_n} \in A) = p$, then $\Pr(U_{t_n} \in A) = p$.

▶ **34.** [*M25*] Define subsequence rules $\mathcal{R}_1$, $\mathcal{R}_2$, $\mathcal{R}_3$, ... such that Algorithm W can be used with these rules to give an effective algorithm to construct a $[0,1)$ sequence satisfying Definition R1.

▶ **35.** [*HM35*] (D. W. Loveland.) Show that if a binary sequence $\langle X_n \rangle$ is R5-random, and if $\langle s_n \rangle$ is any computable sequence as in Definition R4, then $\overline{\Pr}(X_{s_n} = 1) \geq \frac{1}{2}$ and $\underline{\Pr}(X_{s_n} = 1) \leq \frac{1}{2}$.

36. [*HM30*] Let $\langle X_n \rangle$ be a binary sequence that is "random" according to Definition R6. Show that the $[0,1)$ sequence $\langle U_n \rangle$ defined in binary notation by the scheme

$$\begin{aligned} U_0 &= (0.X_0)_2 \\ U_1 &= (0.X_1X_2)_2 \\ U_2 &= (0.X_3X_4X_5)_2 \\ U_3 &= (0.X_6X_7X_8X_9)_2 \\ &\ldots \end{aligned}$$

is random in the sense of Definition R6.

37. [*M37*] (D. Coppersmith.) Define a sequence that satisfies Definition R4 but not Definition R5. [*Hint:* Consider changing U_0, U_1, U_4, U_9, ... in a truly random sequence.]

38. [*M49*] (A. N. Kolmogorov.) Given N, n and ϵ, what is the smallest number of algorithms in a set $\mathbf{A}$ such that no (n,ϵ)-random binary sequences of length N exist with respect to $\mathbf{A}$? (If exact formulas cannot be given, can asymptotic formulas be found? The point of this problem is to discover how close the bound (35) comes to being "best possible.")

39. [*HM45*] (W. M. Schmidt.) Let U_n be a $[0,1)$ sequence, and let $\nu_n(u)$ be the number of nonnegative integers $j \leq n$ such that $0 \leq U_j < u$. Prove that there is a positive constant c such that, for any N and for any $[0,1)$ sequence $\langle U_n \rangle$, we have

$$|\nu_n(u) - un| > c \ln N$$

for some n and u with $0 \leq n < N$, $0 \leq u < 1$. (In other words, no $[0,1)$ sequence can be *too* equidistributed.)

▶ **40.** [*16*] (I. J. Good.) Can a valid table of random digits contain just one misprint?

3.6. SUMMARY

WE HAVE COVERED a fairly large number of topics in this chapter: how to generate random numbers, how to test them, how to modify them in applications, and how to derive theoretical facts about them. Perhaps the main question in many readers' minds will be, "What is the result of all this theory? What is a simple, virtuous generator I can use in my programs in order to have a reliable source of random numbers?"

The detailed investigations in this chapter suggest that the following procedure gives the "nicest" and "simplest" random number generator for the machine language of most computers: At the beginning of the program, set an integer variable X to some value X_0. This variable X is to be used only for the purpose of random number generation. Whenever a new random number is required by the program, set

$$X \leftarrow (aX + c) \bmod m \tag{1}$$

and use the new value of X as the random value. It is necessary to choose X_0, a, c, and m properly, and to use the random numbers wisely, according to the following principles:

i) The "seed" number X_0 may be chosen arbitrarily. If the program is run several times and a different source of random numbers is desired each time, set X_0 to the last value attained by X on the preceding run; or (if more convenient) set X_0 to the current date and time. If the program may need to be rerun later with the *same* random numbers (e.g., when debugging), be sure to print out X_0 if it isn't otherwise known.

ii) The number m should be large, say at least 2^{30}. It may conveniently be taken as the computer's word size, since this makes the computation of $(aX + c) \bmod m$ quite efficient. Section 3.2.1.1 discusses the choice of m in more detail. The computation of $(aX + c) \bmod m$ must be done *exactly*, with no roundoff error.

iii) If m is a power of 2 (i.e., if a binary computer is being used), pick a so that $a \bmod 8 = 5$. If m is a power of 10 (i.e., if a decimal computer is being used), choose a so that $a \bmod 200 = 21$. This choice of a together with the choice of c given below ensures that the random number generator will produce all m different possible values of X before it starts to repeat (see Section 3.2.1.2) and ensures high "potency" (see Section 3.2.1.3).

iv) The multiplier a should preferably be chosen between $.01m$ and $.99m$, and its binary or decimal digits should *not* have a simple, regular pattern. By choosing some haphazard constant like $a = 3141592621$ (which satisfies both of the conditions in (iii)), one almost always obtains a reasonably good multiplier. Further testing should of course be done if the random number generator is to be used extensively; for example, there should be no large quotients when Euclid's algorithm is used to find the gcd of a and m (see Section 3.3.3). The multiplier should pass the spectral test (Section 3.3.4)

and several tests of Section 3.3.2, before it is considered to have a truly clean bill of health.

v) The value of c is immaterial when a is a good multiplier, except that c must have no factor in common with m. Thus we may choose $c = 1$ or $c = a$.

vi) The least significant (right-hand) digits of X are not very random, so decisions based on the number X should always be influenced primarily by the most significant digits. It is generally best to think of X as a random fraction X/m between 0 and 1, that is, to visualize X with a decimal point at its left, rather than to regard X as a random integer between 0 and $m - 1$. To compute a random integer between 0 and $k - 1$, one should multiply by k and truncate the result (see the beginning of Section 3.4.2).

vii) An important limitation on the randomness of sequence (1) is discussed in Section 3.3.4, where it is shown that the "accuracy" in t dimensions will be only about one part in $\sqrt[t]{m}$. Monte Carlo applications requiring higher resolution can improve the randomness by employing techniques discussed in Section 3.2.2.

The above comments apply primarily to machine-language coding. In higher-level programming languages, we are often unable to use such machine-dependent features as integer arithmetic modulo the word size, and careful compilers will not allow us to compute the product of two large integers. Another technique that we might call the *subtractive method* (exercise 3.2.2–23) can be used to provide a "portable" random number generator that is efficiently describable in any higher-level programming language, since it makes use only of integer arithmetic between -10^9 and $+10^9$. Here is how the subtractive method might be coded in FORTRAN, as a subroutine that delivers an array of 55 random integers at once:

```
      FUNCTION IRN55(IA)
      DIMENSION IA(1)
C     ASSUMING THAT IA(1), ..., IA(55) HAVE BEEN SET UP PROPERLY,
C     THIS SUBROUTINE RESETS THE IA ARRAY TO THE NEXT 55 NUMBERS
C     OF A PSEUDO-RANDOM SEQUENCE, AND RETURNS THE VALUE 1.
      DO 1 I = 1, 24
        J = IA(I) - IA(I+31)
        IF (J .LT. 0)  J = J + 1000000000
        IA(I) = J
  1   CONTINUE
      DO 2 I = 25, 55
        J = IA(I) - IA(I-24)
        IF (J .LT. 0)  J = J + 1000000000
        IA(I) = J
  2   CONTINUE
      IRN55=1
      RETURN
      END
```

To use these numbers in a FORTRAN program, let JRAND be an auxiliary integer variable; we may obtain the next random number U (as a fraction between 0 and 1) by writing the following three statements:

```
      JRAND = JRAND + 1
      IF (JRAND .GT. 55)  JRAND = IRN55(IA)
      U = FLOAT(IA(JRAND)) * 1.0E-9
```

At the beginning of our program we need to write "DIMENSION IA(55)" and "JRAND=55" and we must also initialize the IA array. Appropriate initialization can be done by calling the following subroutine with IX set to any integer value (selected like X_0 in rule (i) above, preferably large):

```
      SUBROUTINE IN55(IA,IX)
      DIMENSION IA(1)
C     THIS SUBROUTINE SETS IA(1), ..., IA(55) TO STARTING
C     VALUES SUITABLE FOR LATER CALLS ON IRN55(IA).
C     IX IS AN INTEGER "SEED" VALUE BETWEEN 0 AND 999999999.
      IA(55) = IX

      END
```

(This subroutine computes a Fibonacci-like sequence; multiplication of indices by 21 spreads the values around so as to alleviate initial nonrandomness problems such as those in exercise 3.2.2–2. Note that $2^{29} < 10^9 < 2^{30}$; any large even number may actually be substituted for 10^9 in these routines, if a corresponding change is made in the computation of the random fraction U. Furthermore it would be possible to work directly with floating point numbers instead of integers by making appropriate changes to these programs, *provided* that the computer's floating point arithmetic is sufficiently accurate to give *exact* results in all the computations required here. Most binary computers will be able to meet this requirement when all of the numbers to be dealt with have the form $a/2^p$, where a is an integer, $0 \le a < 2^p$, and there are p bits of precision in floating point fractions. The numbers $(24, 55)$ in these routines may be replaced by any pair

of values (j, k) in Table 3.2.2–1, for $k \geq 50$; the constants 31, 25, 54, 21 should then be replaced by $k - j$, $j + 1$, $k - 1$, and d respectively, where d is relatively prime to k and $d \approx 0.382k$.)

Although a great deal is known about linear congruential sequences like (1), very little has yet been proved about the randomness properties of the subtractive method. Both approaches seem to be reliable in practice.

Unfortunately, quite a bit of published material in existence at the time this chapter was written recommends the use of generators that violate the suggestions above; and the most common generator in actual use, RANDU, is really horrible (cf. Section 3.3.4). The authors of many contributions to the science of random number generation were unaware that particular methods they were advocating would prove to be inadequate. Perhaps further research will show that even the random number generators recommended here are unsatisfactory; we hope this is not the case, but the history of the subject warns us to be cautious. The most prudent policy for a person to follow is to run each Monte Carlo program at least twice using quite different sources of random numbers, before taking the answers of the program seriously; this not only will give an indication of the stability of the results, it also will guard against the danger of trusting in a generator with hidden deficiencies. (Every random number generator will fail in at least one application.)

Excellent bibliographies of the pre-1972 literature on random number generation have been compiled by Richard E. Nance and Claude Overstreet, Jr., *Computing Reviews* **13** (1972), 495–508, and by E. R. Sowey, *International Stat. Review* **40** (1972), 355–371. The period 1972–1976 is covered by Sowey in *International Stat. Review* **46** (1978), 89–102.

For a detailed study of the use of random numbers in numerical analysis, see J. M. Hammersley and D. C. Handscomb, *Monte Carlo Methods* (London: Methuen, 1964). This book shows that some numerical methods are enhanced by using numbers that are "quasi-random," designed specifically for a certain purpose (not necessarily satisfying the statistical tests we have discussed).

Every reader is urged to work exercise 6 in the following set of problems.

EXERCISES

1. [*21*] Write a MIX subroutine with the following characteristics, using method (1):

Calling sequence:	JMP RANDI
Entry conditions:	rA $= k$, a positive integer < 5000.
Exit conditions:	rA $\leftarrow$ a random integer Y, $1 \leq Y \leq k$, with each integer about equally probable; rX =?; overflow off.

▸ **2.** [*15*] Some people have been afraid that computers will someday take over the world; but they are reassured by the statement that a machine cannot do anything really new, since it is only obeying the commands of its master, the programmer. Lady Lovelace wrote in 1844, "The Analytical Engine has no pretensions to *originate*

anything. It can do *whatever we know how to order it* to perform." Her statement has been further elaborated by many philosophers. Discuss this topic, with random number generators in mind.

3. [*32*] (*A dice game.*) Write a program that simulates a roll of two dice, each of which takes on the values 1, 2, ..., 6 with equal probability. If the total is 7 or 11 on the first roll, the game is won; a total of 2, 3, or 12 loses; and on any other total, call that total the "point" and continue rolling dice until either a 7 occurs (a loss) or the point occurs again (a win).

Play ten games. The result of each roll of the dice should be printed in the form $m\,n$, where m and n are the contents of the two dice, followed by some appropriate comment (like "snake eyes" or "little Joe" or "the hard way", etc.).

4. [*40*] (*Solitaire or patience.*) Some people spend a lot of valuable time playing card games of solitaire, and perhaps automation will make an important inroad in this area. Write a program that (a) shuffles a simulated deck of cards; (b) plays some common game of solitaire based on the order of the cards in the deck; (c) prints out the result of the game, i.e., how close the program came to winning. Several games should be played. The program might be set up to "cheat" upon request.

5. [*46*] (*Creative writing by computer.*) A television program entitled "The Thinking Machine," broadcast by the CBS television network on October 26, 1960, featured (among other things) two Western-style playlets that were written by a computer program. Here are the two scripts as they were printed out by the computer:

Saga #1. (The gun is in the right hand; the money is in the left hand; the glass is on the table; the bottle is on the table; the holster is on the robber; the sheriff's gun is in the sheriff's right hand; the sheriff's holster is on the sheriff.)

ROBBER: (The robber is at the window.) Go to door; open door; go thru door; close door; go to corner; put money down at corner; go to table; put gun on table; sit and fidgit; sit at table; pick up glass with right hand (empty); put glass on table; pick up bottle with right hand; pour; put bottle on table; pick up glass with right hand; take a drink from glass; put glass on table; pick up bottle with right hand; sit at table; sit at table; go to corner; go to window; go to table; put bottle on table; sit and fidgit; sit at table; sit and fidgit; go to window; go to table; pick up glass with right hand.

SHERIFF: (The sheriff is at the window.) See robber; (robber sees sheriff); go to door.

ROBBER: Put glass on table; pick up gun with right hand; check gun.

SHERIFF: Wait; open door; see robber; (robber sees sheriff); go thru door.

ROBBER: Go to window; aim; fire; SHERIFF NICKED.

SHERIFF: Go to window; aim; fire; MISSED; go to door; go to window.

ROBBER: Go to door; aim; aim.

SHERIFF: Aim; fire; MISSED.

ROBBER: Fire; SHERIFF NICKED.

SHERIFF: Go to door; aim; fire; MISSED; go thru door; aim.

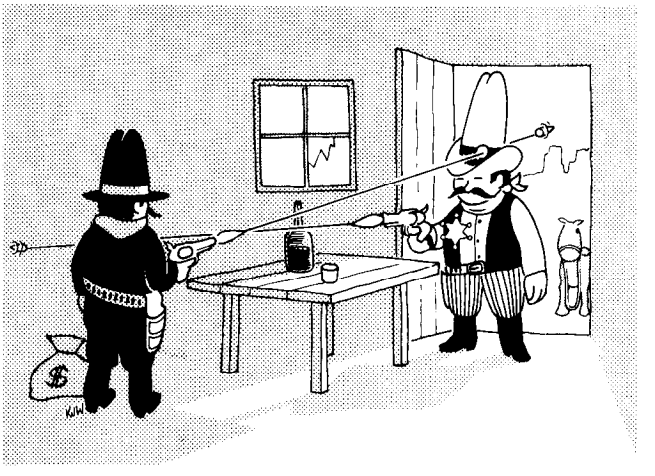
ROBBER: Aim; fire; MISSED; aim; fire; MISSED.

SHERIFF: Fire; MISSED; go to window; aim; fire; MISSED.

ROBBER: Aim; fire; MISSED; aim; fire; MISSED; aim; fire; SHERIFF NICKED.

SHERIFF: Aim; fire; ROBBER HIT.

ROBBER: Drop gun; robber dies.



SHERIFF: Put gun in holster; go to table; pick up glass with right hand (empty); take glass from right hand with left hand; pick up bottle with right hand; pour; put bottle on table; take glass from left hand with right hand; take a drink from glass; take glass from right hand with left hand; pick up bottle with right hand; pour; put bottle on table; take glass from left hand with right hand; take a drink from glass; put glass on table; go to corner; pick up money with right hand; go to door; go thru door; close door. CURTAIN.

Saga #2. (The gun is in the right hand; the money is in the left hand; the glass is on the table; the bottle is on the table; the holster is on the robber; the sheriff's gun is in the sheriff's right hand; the sheriff's holster is on the sheriff.)

ROBBER: (The robber is at the window.) Go to door; open door; go thru door; close door; go to corner; put money down at corner; go to window; put gun down at window; lean on window and look; lean on window and look; go to corner; count money; go to table; pick up glass with right hand (empty); take glass from right hand with left hand; pick up bottle with right hand; pour; put bottle on table; take glass from left hand with right hand; take a drink from glass; put glass on table; pick up bottle with right hand; pour; go to corner; put bottle down at corner; go to window; pick up gun with right hand; check gun; put gun in holster; go to table; pick up glass with right hand; take a drink from glass; go to window; put glass down at window.

SHERIFF: (The sheriff is at the window.) See robber; (robber sees sheriff); go to door.

ROBBER: Take gun from holster with right hand; check gun; go to door; check gun; put gun down at door.

SHERIFF: Open door; see robber; (robber sees sheriff); go thru door; go to window.

ROBBER: Pick up gun with right hand.

SHERIFF: Go to table.

ROBBER: Aim; fire; MISSED; aim; fire; SHERIFF HIT; blow out barrel; put gun in holster.

SHERIFF: Drop gun; sheriff dies.

ROBBER: Go to corner; pick up money with right hand; go to door; go thru door; close door. CURTAIN.

A careful reading of the above scripts reveals the highly intense drama present here. The computer program was careful to keep track of the locations of each player, the contents of his hands, etc. Actions taken by the players were random, governed by certain probabilities; the probability of a foolish action was increased depending on how much that player had had to drink and on how often he had been nicked in a shot. The reader will be able to deduce further properties of the program by studying the sample scripts.

Of course, even the best scripts are rewritten before they are produced, and this is especially true when an inexperienced writer has prepared the original draft. Here are the scripts just as they were actually used in the show:

Saga #1. Music up.
MS Robber peering thru window of shack.
CU Robber's face.
MS Robber entering shack.
CU Robber sees whiskey bottle on table.
CU Sheriff outside shack.
MS Robber sees sheriff.
LS Sheriff in doorway over shoulder of robber, both draw.
MS Sheriff drawing gun.
LS Shooting it out. Robber gets shot.
MS Sheriff picking up money bags.
MS Robber staggering.
MS Robber dying. Falls across table, after trying to take last shot at sheriff.
MS Sheriff walking thru doorway with money.
MS of robber's body, now still, lying across table top. Camera dollies back. (Laughter)

Saga #2. Music up.
CU of window. Robber appears.
MS Robber entering shack with two sacks of money.
MS Robber puts money bags on barrel.
CU Robber—sees whiskey on table.
MS Robber pouring himself a drink at table. Goes to count money. Laughs.
MS Sheriff outside shack.
MS thru window.
MS Robber sees sheriff thru window.
LS Sheriff entering shack. Draw. Shoot it out.
CU Sheriff. Writhing from shot.
M/2 shot Sheriff staggering to table for a drink . . . falls dead.
MS Robber leaves shack with money bags.*

[*Note:* CU = "close up", MS = "medium shot", etc. The above details were kindly furnished to the author by Thomas H. Wolf, producer of the television show, who suggested the idea of a computer-written playlet in the first place, and also by Douglas T. Ross and Harrison R. Morse who produced the computer program.]

The reader will undoubtedly have many ideas about how he could prepare his own computer program to do creative writing; and that is the point of this exercise.

▶ **6.** [*40*] Look at the subroutine library of each computer installation in your organization, and replace the random number generators by good ones. Try to avoid being too shocked at what you find.

▶ **7.** [*M40*] A programmer decided to encipher his files by using a linear congruential sequence $\langle X_n \rangle$ of period 2^{32} generated by (a, c, X_0) with $m = 2^{32}$. He took the most significant bits $\lfloor X_n/2^{16} \rfloor$ and exclusive-or'ed them onto his data, but kept the parameters a, c, and X_0 secret.

Show that this isn't a very secure scheme, by devising a method that deduces the multiplier a and the first difference $X_1 - X_0$ in a reasonable amount of time, given only the values of $\lfloor X_n/2^{16} \rfloor$ for $0 \leq n < 150$.

CHAPTER FOUR

ARITHMETIC

Seeing there is nothing (right well beloved Students in the Mathematickes) that is so troublesome to Mathematicall practise, nor that doth more molest and hinder Calculators, then the Multiplications, Divisions, square and cubical Extractions of great numbers, which besides the tedious expence of time are for the most part subject to many slippery errors. I began therefore to consider in my minde, by what certaine and ready Art I might remove those hindrances.

—JOHN NAPIER (1614)

I do hate sums. There is no greater mistake than to call arithmetic an exact science. There are . . . hidden laws of number which it requires a mind like mine to perceive. For instance, if you add a sum from the bottom up, and then again from the top down, the result is always different.

—MRS. LA TOUCHE (19th century)

I cannot conceive that anybody will require multiplications at the rate of 40,000, or even 4,000 per hour; such a revolutionary change as the octonary scale should not be imposed upon mankind in general for the sake of a few individuals.

—F. H. WALES (1936)

Most numerical analysts have no interest in arithmetic.

—B. PARLETT (1979)

THE CHIEF PURPOSE of this chapter is to make a careful study of the four basic processes of arithmetic: addition, subtraction, multiplication, and division. Many people regard arithmetic as a trivial thing that children learn and computers do, but we will see that arithmetic is a fascinating topic with many interesting facets. It is important to make a thorough study of efficient methods for calculating with numbers, since arithmetic underlies so many computer applications.

Arithmetic is, in fact, a lively subject that has played an important part in the history of the world, and it still is undergoing rapid development. In this chapter, we shall analyze algorithms for doing arithmetic operations on many types of quantities, such as "floating point" numbers, extremely large numbers, fractions (rational numbers), polynomials, and power series; and we will also discuss related topics such as radix conversion, factoring of numbers, and the evaluation of polynomials.

4.1. POSITIONAL NUMBER SYSTEMS

THE WAY WE DO ARITHMETIC is intimately related to the way we represent the numbers we deal with, so it is appropriate to begin our study of the subject with a discussion of the principal means for representing numbers.

Positional notation using base b (or *radix* b) is defined by the rule

$$(\ldots a_3a_2a_1a_0.a_{-1}a_{-2}\ldots)_b$$
$$= \cdots + a_3b^3 + a_2b^2 + a_1b^1 + a_0 + a_{-1}b^{-1} + a_{-2}b^{-2} + \cdots; \qquad (1)$$

for example, $(520.3)_6 = 5\cdot 6^2 + 2\cdot 6^1 + 0 + 3\cdot 6^{-1} = 192\frac{1}{2}$. Our conventional decimal number system is, of course, the special case when b is ten, and when the a's are chosen from the "decimal digits" 0, 1, 2, 3, 4, 5, 6, 7, 8, 9; in this case the subscript b in (1) may be omitted.

The simplest generalizations of the decimal number system are obtained when we take b to be an integer greater than 1 and when we require the a's to be integers in the range $0 \le a_k < b$. This gives us the standard binary ($b = 2$), ternary ($b = 3$), quaternary ($b = 4$), quinary ($b = 5$), ... number systems. In general, we could take b to be any nonzero number, and we could choose the a's from any specified set of numbers; this leads to some interesting situations, as we shall see.

The dot that appears between a_0 and a_{-1} in (1) is called the *radix point.* (When $b = 10$, it is also called the decimal point, and when $b = 2$, it is sometimes called the binary point, etc.) Continental Europeans often use a comma instead of a dot to denote the radix point; Englishmen often use a raised dot.

The a's in (1) are called the *digits* of the representation. A digit a_k for large k is often said to be "more significant" than the digits a_k for small k; accordingly, the leftmost or "leading" digit is referred to as the *most significant digit* and the rightmost or "trailing" digit is referred to as the *least significant digit.* In the standard binary system the binary digits are often called *bits*; in the standard hexadecimal system (radix sixteen) the hexadecimal digits zero through fifteen are usually denoted by

0, 1, 2, 3, 4, 5, 6, 7, 8, 9, A, B, C, D, E, F.

The historical development of number representations is a fascinating story, since it parallels the development of civilization itself. We would be going far afield if we were to examine this history in minute detail, but it will be instructive to look at its main features here.

The earliest forms of number representations, still found in primitive cultures, are generally based on groups of fingers, piles of stones, etc., usually with special conventions about replacing a larger pile or group of, say, five or ten objects by one object of a special kind or in a special place. Such systems lead naturally to the earliest ways of representing numbers in written form, as in the systems of Babylonian, Egyptian, Greek, Chinese, and Roman numerals; but such notations are comparatively inconvenient for performing arithmetic operations except in the simplest cases.

During the twentieth century, historians of mathematics have made extensive studies of early cuneiform tablets found by archeologists in the Middle East. These studies show that the Babylonian people actually had two distinct systems of number representation: Numbers used in everyday business transactions were written in a notation based on grouping by tens, hundreds, etc.; this notation was inherited from earlier Mesopotamian civilizations, and large numbers were seldom required. When more difficult mathematical problems were considered, however, Babylonian mathematicians made extensive use of a sexagesimal (radix sixty) positional notation that was highly developed at least as early as 1750 B.C. This notation was unique in that it was actually a *floating point* form of representation with exponents omitted; the proper scale factor or power of sixty was to be supplied by the context, so that, for example, the numbers 2, 120, 7200, and $\frac{1}{30}$ were all written in an identical manner. The notation was especially convenient for multiplication and division, using auxiliary tables, since radix-point alignment had no effect on the answer. As examples of this Babylonian notation, consider the following excerpts from early tables: The square of 30 is 15 (which may also be read, "The square of $\frac{1}{2}$ is $\frac{1}{4}$"); the reciprocal of $81 = (1\ 21)_{60}$ is $(44\ 26\ 40)_{60}$; and the square of the latter is $(32\ 55\ 18\ 31\ 6\ 40)_{60}$. The Babylonians had a symbol for zero, but because of their "floating point" philosophy, it was used only within numbers, not at the right end to denote a scale factor. For the interesting story of early Babylonian mathematics, see O. Neugebauer, *The Exact Sciences in Antiquity* (Princeton, N. J.: Princeton University Press, 1952), and B. L. van der Waerden, *Science Awakening*, tr. by A. Dresden (Groningen: P. Noordhoff, 1954); see also D. E. Knuth, *CACM* **15** (1972), 671–677; **19** (1976), 108.

Fixed point positional notation was apparently first conceived by the Maya Indians in central America 2000 years ago; their radix-20 system was highly developed, especially in connection with astronomical records and calendar dates. But the Spanish conquerors destroyed nearly all of the Maya books on history and science, so we have comparatively little knowledge about how sophisticated the native Americans had become at arithmetic; special-purpose multiplication tables have been found, but no examples of division are known [cf. J. Eric S. Thompson, *Contributions to Amer. Anthropology and History* **7** (Carnegie Inst. of Washington, 1942), 37–62].

Several centuries before Christ, the Greek people employed an early form of the abacus to do their arithmetical calculations, using sand and/or pebbles on a board that had rows or columns corresponding in a natural way to our decimal system. It is perhaps surprising to us that the same positional notation was never adapted to written forms of numbers, since we are so accustomed to reckoning with the decimal system using pencil and paper; but the greater ease of calculating by abacus (since handwriting was not a common skill, and since abacus calculation makes it unnecessary to memorize addition and multiplication tables) probably made the Greeks feel it would be silly even to suggest that computing could be done better on "scratch paper." At the same time Greek astronomers did make use of a sexagesimal positional notation for fractions, which they had learned from the Babylonians.

Our decimal notation, which differs from the more ancient forms primarily because of its fixed radix point, together with its symbol for zero to mark an empty position, was developed first in India within the Hindu culture. The exact date when this notation first appeared is quite uncertain; about 600 A.D. seems to be a good guess. Hindu science was rather highly developed at that time, particularly in astronomy. The earliest known Hindu manuscripts that show this notation have numbers written backwards (with the most significant digit at the right), but soon it became standard to put the most significant digit at the left.

About 750 A.D., the Hindu principles of decimal arithmetic were brought to Persia, as several important works were translated into Arabic; a picturesque account of this development is given in a Hebrew document, which has been translated into English in *AMM* **15** (1918), 99–108. Not long after this, al-Khwârizmî wrote his Arabic textbook on the subject. (As noted in Chapter 1, our word "algorithm" comes from al-Khwârizmî's name.) His work was translated into Latin and was a strong influence on Leonardo Pisano (Fibonacci), whose book on arithmetic (1202 A.D.) played a major role in the spreading of Hindu-Arabic numerals into Europe. It is interesting to note that the left-to-right order of writing numbers was unchanged during these two transitions, although Arabic is written from right to left while Hindu and Latin scholars generally wrote from left to right. A detailed account of the subsequent propagation of decimal numeration and arithmetic into all parts of Europe during the period from 1200 to 1600 A.D. has been given by David Eugene Smith in his *History of Mathematics* **1** (Boston: Ginn and Co., 1923), Chapters 6 and 8.

Decimal notation was applied at first only to integer numbers, not to fractions. Arabic astronomers, who required fractions in their star charts and other tables, continued to use the notation of Ptolemy (the famous Greek astronomer), a notation based on sexagesimal fractions. This system still survives today, in our trigonometric units of "degrees, minutes, and seconds," and also in our units of time, as a remnant of the original Babylonian sexagesimal notation. Early European mathematicians also used sexagesimal fractions when dealing with noninteger numbers; for example, Fibonacci gave the value

$$1^\circ\ 22'\ 7''\ 42'''\ 33^{IV}\ 4^{V}\ 40^{VI}$$

as an approximation to the root of the equation $x^3 + 2x^2 + 10x = 20$. (The correct answer is $1^\circ\ 22'\ 7''\ 42'''\ 33^{IV}\ 4^{V}\ 38^{VI}\ 30^{VII}\ 50^{VIII}\ 15^{IX}\ 43^{X}\ \ldots$.)

The use of decimal notation also for tenths, hundredths, etc., in a similar way seems to be a comparatively minor change; but, of course, it is hard to break with tradition, and sexagesimal fractions have an advantage over decimal fractions in that numbers such as $\frac{1}{3}$ can be expressed exactly, in a simple way.

Chinese mathematicians—who never used sexagesimals—were apparently the first people to work with the equivalent of decimal fractions, although their numeral system (lacking zero) was not originally a positional number system in the strict sense. Chinese units of weights and measures were decimal, so that Tsu Chhung-Chih (who died c. 500 A.D.) was able to express an approximation

to π in the following form:

3 chang, 1 chhih, 4 tshun, 1 fên, 5 li, 9 hao, 2 miao, 7 hu.

Here chang, ..., hu are units of length; 1 hu (the diameter of a silk thread) equals 1/10 miao, etc. The use of such decimal-like fractions was fairly widespread in China after about 1250 A.D.

The first known appearance of decimal fractions in a true positional system occurs in a 10th-century arithmetic text written in Damascus by an obscure mathematician named al-Uqlîdisî ("the Euclidean"). He used the symbol $'$ for a decimal point, for example in connection with a problem about compound interest, the computation of 135 times $(1.1)^n$ for $1 \leq n \leq 5$. [See A. S. Saidan, *The Arithmetic of al-Uqlîdisî* (Dordrecht: D. Reidel, 1975), 110, 114, 343, 355, 481–485.] But he did not develop the idea very fully, and his trick was soon forgotten; five centuries passed before decimal fractions were reinvented by a Persian mathematician, al-Kashî, who died c. 1436. Al-Kashî was a highly skillful calculator, who gave the value of 2π as follows, correct to 16 decimal places:

integer		fractions															
0	6	2	8	3	1	8	5	3	0	7	1	7	9	5	8	6	5

This was by far the best approximation to π known until Ludolph van Ceulen laboriously calculated 35 decimal places during the period 1596–1610.

The earliest known example of decimal fractions in Europe occurs in a 15th-century text where, for example, 153.5 is multiplied by 16.25 to get 2494.375; this was referred to as a "Turkish method." In 1525, Christof Rudolff of Germany discovered decimal fractions for himself; but like al-Uqlîdisî, his work seems to have had little influence. François Viète suggested the idea again in 1579. Finally, an arithmetic text by Simon Stevin of Belgium, who independently hit on the idea of decimal fractions in 1585, became popular. Stevin's work, and the discovery of logarithms soon afterwards, made decimal fractions commonplace in Europe during the 17th century. [See D. E. Smith, *History of Mathematics* **2** (Boston: Ginn and Co., 1925), 228–247, and C. B. Boyer, *History of Mathematics* (New York: Wiley, 1968), for further remarks and references.]

The binary system of notation has its own interesting history. Many primitive tribes in existence today are known to use a binary or "pair" system of counting (making groups of two instead of five or ten), but they do not count in a true radix-2 system, since they do not treat powers of 2 in a special manner. See *The Diffusion of Counting Practices* by Abraham Seidenberg, *Univ. Calif. Publ. in Math.* **3** (1960), 215–300, for interesting details about primitive number systems. Another "primitive" example of an essentially binary system is the conventional musical notation for expressing rhythms and durations of time.

Nondecimal number systems were discussed in Europe during the seventeenth century. For many years astronomers had occasionally used sexagesimal arithmetic both for the integer and the fractional parts of numbers, primarily when performing multiplication [see John Wallis, *Treatise of Algebra* (Oxford,

1685), 18–22, 30]. The fact that *any* integer greater than 1 could serve as radix was apparently first stated in print by Blaise Pascal in *De numeris multiplicibus*, which was written about 1658 [see Pascal's *Œuvres Complètes* (Paris: Éditions de Seuil, 1963), 84–89]. Pascal wrote, "Denaria enim ex institute hominum, non ex necessitate naturæ ut vulgus arbitratur, et sane satis inepte, posita est"; i.e., "The decimal system has been established, somewhat foolishly to be sure, according to man's custom, not from a natural necessity as most people would think." He stated that the duodecimal (radix twelve) system would be a welcome change, and he gave a rule for testing a duodecimal number for divisibility by nine. Erhard Weigel tried to drum up enthusiasm for the quaternary (radix four) system in a series of publications beginning in 1673. A detailed discussion of radix-twelve arithmetic was given by Joshua Jordaine, *Duodecimal Arithmetick* (London, 1687).

Although decimal notation was almost exclusively used for arithmetic during that era, other systems of weights and measures were rarely if ever based on multiples of 10, and many business transactions required a good deal of skill in adding quantities such as pounds, shillings, and pence. For centuries merchants had therefore learned to compute sums and differences of quantities expressed in peculiar units of currency, weights, and measures; and this was actually arithmetic in a nondecimal number system. The common units of liquid measure in England, dating from the 13th century or earlier, are particularly noteworthy:

2 gills = 1 chopin	2 demibushels = 1 bushel or firkin
2 chopins = 1 pint	2 firkins = 1 kilderkin
2 pints = 1 quart	2 kilderkins = 1 barrel
2 quarts = 1 pottle	2 barrels = 1 hogshead
2 pottles = 1 gallon	2 hogsheads = 1 pipe
2 gallons = 1 peck	2 pipes = 1 tun
2 pecks = 1 demibushel	

Quantities of liquid expressed in gallons, pottles, quarts, pints, etc. were essentially written in binary notation. Perhaps the true inventors of binary arithmetic were English wine merchants!

The first known appearance of pure binary notation was about 1605 in some unpublished manuscripts of Thomas Harriot (1560–1621). Harriot was a creative man, who first became famous by coming to America as a representative of Sir Walter Raleigh. He invented (among other things) a notation like that now used for "less than" and "greater than" relations; but for some reason he chose not to publish many of his discoveries. Excerpts from his notes on binary arithmetic have been reproduced by John W. Shirley, *Amer. J. Physics* **19** (1951), 452–454. The first published discussion of the binary system was given in a comparatively little-known work by a Spanish bishop, Juan Caramuel Lobkowitz, *Mathesis biceps* **1** (Campaniæ, 1670), 45–48; Caramuel discussed the representation of numbers in radices 2, 3, 4, 5, 6, 7, 8, 9, 10, 12, and 60 at some length, but gave no examples of arithmetic operations in nondecimal systems (except for the trivial operation of adding unity).

Ultimately, an article by G. W. Leibniz [*Memoires de l'Academie Royale des Sciences* (Paris: 1703), 110–116], which illustrated binary addition, subtraction, multiplication, and division, really brought binary notation into the limelight, and this article is usually referred to as the birth of radix-2 arithmetic. Leibniz later referred to the binary system quite frequently. He did not recommend it for practical calculations, but he stressed its importance in number-theoretical investigations, since patterns in number sequences are often more apparent in binary notation than they are in decimal; he also saw a mystical significance in the fact that everything is expressible in terms of zero and one. Leibniz's unpublished manuscripts show that he had been interested in binary notation as early as 1679, when he referred to it as a "bimal" system (analogous to "decimal").

A careful study of Leibniz's early work with binary numbers has been made by Hans J. Zacher, *Die Hauptschriften zur Dyadik von G. W. Leibniz* (Frankfurt am Main: Klostermann, 1973). Zacher points out that Leibniz was familiar with John Napier's so-called "local arithmetic," a way for calculating with stones that amounts to using a radix-2 abacus. [Napier had published the idea of local arithmetic as an appendix to his little book *Rhabdologia* in 1617; it may be called the world's first "binary computer," and it is surely the world's cheapest, although Napier felt that it was more amusing than practical. See Martin Gardner's discussion in *Scientific American* **228** (April 1973), 106–111.]

It is interesting to note that the important concept of negative powers to the right of the radix point was not yet well understood at that time. Leibniz asked James Bernoulli to calculate π in the binary system, and Bernoulli "solved" the problem by taking a 35-digit approximation to π, multiplying it by 10^{35}, and then expressing this integer in the binary system as his answer. On a smaller scale this would be like saying that $\pi \approx 3.14$, and $(314)_{10} = (100111010)_2$; hence π in binary is 100111010! [See Leibniz, *Math. Schriften*, ed. by K. Gehrhardt, **3** (Halle: 1855), 97; two of the 118 bits in the answer are incorrect, due to computational errors.] The motive for Bernoulli's calculation was apparently to see whether any simple pattern could be observed in this representation of π.

Charles XII of Sweden, whose talent for mathematics perhaps exceeded that of all other kings in the history of the world, hit on the idea of radix-8 arithmetic about 1717. This was probably his own invention, although he had met Leibniz briefly in 1707. Charles felt that radix 8 or 64 would be more convenient for calculation than the decimal system, and he considered introducing octal arithmetic into Sweden; but he died in battle before decreeing such a change. [See *The Works of Voltaire* **21** (Paris: E. R. DuMont, 1901), 49; E. Swedenborg, *Gentleman's Magazine* **24** (1754), 423–424.]

Octal notation was proposed also in colonial America before 1750, by the Rev. Hugh Jones, rector of a parish in Maryland [cf. *Gentleman's Magazine* **15** (1745), 377–379; H. R. Phalen, *AMM* **56** (1949), 461–465].

More than a century later, a prominent Swedish-American civil engineer named John W. Nystrom decided to carry Charles XII's plans a step further, by devising a complete system of numeration, weights, and measures based on radix-16 arithmetic. He wrote, "I am not afraid, or do not hesitate, to advocate a

binary system of arithmetic and metrology. I know I have nature on my side; if I do not succeed to impress upon you its utility and great importance to mankind, it will reflect that much less credit upon our generation, upon our scientific men and philosophers." Nystrom devised special means for pronouncing hexadecimal numbers; e.g., $(\texttt{B0160})_{16}$ was to be read "vybong, bysanton." His entire system was called the Tonal System, and it is described in *J. Franklin Inst.* **46** (1863), 263–275, 337–348, 402–407. A similar system, but using radix 8, was worked out by Alfred B. Taylor [*Proc. Amer. Pharmaceutical Assoc.* **8** (1859), 115–216; *Proc. Amer. Philosophical Soc.* **24** (1887), 296–366]. Increased use of the French (metric) system of weights and measures prompted extensive debate about the merits of decimal arithmetic during that era; indeed, octal arithmetic was even being proposed in France [J. D. Colenne, *Le système octaval* (Paris: 1845); Aimé Mariage, *Numération par huit* (Paris: Le Nonnant, 1857)].

The binary system was well known as a curiosity ever since Leibniz's time, and about 20 early references to it have been compiled by R. C. Archibald [*AMM* **25** (1918), 139–142]. It was applied chiefly to the calculation of powers, as explained in Section 4.6.3, and to the analysis of certain games and puzzles. Giuseppe Peano [*Atti della R. Accademia delle Scienze di Torino* **34** (1898), 47–55] used binary notation as the basis of a "logical" character set of 256 symbols. Joseph Bowden [*Special Topics in Theoretical Arithmetic* (Garden City: 1936), 49] gave his own system of nomenclature for hexadecimal numbers.

The book *History of Binary and Other Nondecimal Numeration* by Anton Glaser (privately printed, 1971) contains an informative and nearly complete discussion of the development of binary notation, including English translations of many of the works cited above.

Much of the recent history of number systems is connected with the development of calculating machines. Charles Babbage's notebooks for 1838 show that he considered using nondecimal numbers in his Analytical Engine [cf. M. V. Wilkes, *Historia Math.* **4** (1977), 421]. Increased interest in mechanical devices for arithmetic, especially for multiplication, led several people in the 1930s to consider the binary system for this purpose. A particularly delightful account of such activity appears in the article "Binary Calculation" by E. William Phillips [*Journal of the Institute of Actuaries* **67** (1936), 187–221] together with a record of the discussion that followed a lecture he gave on the subject. Phillips began by saying, "The ultimate aim [of this paper] is to persuade the whole civilized world to abandon decimal numeration and to use octonal [i.e., radix 8] numeration in its place."

Modern readers of Phillips's article will perhaps be surprised to discover that a radix-8 number system was properly referred to as "octonary" or "octonal," according to all dictionaries of the English language at that time, just as the radix-10 number system is properly called either "denary" or "decimal"; the word "octal" did not appear in English language dictionaries until 1961, and it apparently originated as a term for the "base" of a certain class of vacuum tubes. The word "hexadecimal," which has crept into our language even more recently, is a mixture of Greek and Latin stems; more proper terms would be

"senidenary" or "sedecimal" or even "sexadecimal," but the latter is perhaps too risqué for computer programmers.

The comment by Mr. Wales that is quoted at the beginning of this chapter has been taken from the discussion printed with Phillips's paper. Another man who attended the same lecture objected to the octal system for business purposes: "5% becomes $3.\dot{1}46\dot{3}$ per 64, which sounds rather horrible."

Phillips got the inspiration for his proposals from an electronic circuit that was capable of counting in binary [C. E. Wynn-Williams, Proc. Roy. Soc. London **A136** (1932), 312–324]. Electromechanical and electronic circuitry for general arithmetic operations was developed during the late 1930s, notably by John V. Atanasoff and George R. Stibitz in the U.S.A., L. Couffignal and R. Valtat in France, Helmut Schreyer and Konrad Zuse in Germany. All of these inventors used the binary system, although Stibitz later developed excess-3 binary-coded-decimal notation. A fascinating account of these early developments, including reprints and translations of important contemporary documents, appears in Brian Randell's book *The Origins of Digital Computers* (Berlin: Springer, 1973).

The first American high-speed computers, built in the early 1940s, used decimal arithmetic. But in 1946, an important memorandum by A. W. Burks, H. H. Goldstine, and J. von Neumann, in connection with the design of the first stored-program computers, gave detailed reasons for the decision to make a radical departure from tradition and to use base-two notation [see John von Neumann, *Collected Works* **5**, 41–65]. Since then binary computers have multiplied. After a dozen years of experience with binary machines, a discussion of the relative advantages and disadvantages of radix-2 notation was given by W. Buchholz in his paper "Fingers or Fists?" [*CACM* **2** (December 1959), 3–11].

The MIX computer used in this book has been defined so that it can be either binary or decimal. It is interesting to note that nearly all MIX programs can be expressed without knowing whether binary or decimal notation is being used—even when we are doing calculations involving multiple-precision arithmetic. Thus we find that the choice of radix does not significantly influence computer programming. (Noteworthy exceptions to this statement, however, are the "Boolean" algorithms discussed in Section 7.1; see also Algorithm 4.5.2B.)

There are several different methods for representing *negative* numbers in a computer, and this sometimes influences the way arithmetic is done. In order to understand these other notations, let us first consider MIX as if it were a decimal computer; then each word contains 10 digits and a sign, for example

$$-12345\ 67890. \tag{2}$$

This is called the *signed-magnitude* representation. Such a representation agrees with common notational conventions, so it is preferred by many programmers. A potential disadvantage is that minus zero and plus zero can both be represented, while they usually should mean the same number; this possibility requires some care in practice, although it turns out to be useful at times.

Most mechanical calculators that do decimal arithmetic use another system called *ten's complement* notation. If we subtract 1 from 00000 00000, we get

99999 99999 in this notation; in other words, no explicit sign is attached to the number, and calculation is done *modulo* 10^{10}. The number —12345 67890 would appear as

$$87654\ 32110 \tag{3}$$

in ten's complement notation. It is conventional to regard any number whose leading digit is 5, 6, 7, 8, or 9 as a negative value in this notation, although with respect to addition and subtraction there is no harm in regarding (3) as the number +87654 32110 if it is convenient to do so. Note that there is no problem of "minus zero" in such a system.

The major difference between signed magnitude and ten's complement notations in practice is that shifting right does not divide the magnitude by ten; for example, the number $-11 = \ldots 99989$, shifted right one, gives $\ldots 99998 = -2$ (assuming that a shift to the right inserts "9" as the leading digit when the number shifted is negative). In general, x shifted right one digit in ten's complement notation will give $\lfloor x/10 \rfloor$, whether x is positive or negative.

A possible disadvantage of the ten's complement system is the fact that it is not symmetric about zero; the largest negative number representable in p digits is $500\ldots0$, and it is not the negative of any p-digit positive number. Thus it is possible that changing x to $-x$ will cause overflow. (See exercises 7 and 31 for a discussion of radix-complement notation with *infinite* precision.)

Another notation that has been used since the earliest days of high-speed computers is called *nines' complement* representation. In this case the number —12345 67890 would appear as

$$87654\ 32109. \tag{4}$$

Each digit of a negative number $(-x)$ is equal to 9 minus the corresponding digit of x. It is not difficult to see that the nines' complement notation for a negative number is always one less than the corresponding ten's complement notation. Addition and subtraction are done modulo $10^{10} - 1$, which means that a carry off the left end is to be added at the right end. (Cf. Section 3.2.1.1.) Again there is a potential problem with minus zero, since 99999 99999 and 00000 00000 denote the same value.

The ideas just explained for radix 10 arithmetic apply in a similar way to radix 2 arithmetic, where we have *signed magnitude*, *two's complement*, and *ones' complement* notations. The MIX computer, as used in the examples of this chapter, deals only with signed-magnitude arithmetic; however, alternative procedures for complement notations are discussed in the accompanying text when it is important to do so.

Most computer manuals tell us that the machine's circuitry assumes that the radix point is situated in a particular place within each computer word. This advice should usually be disregarded. It is better to learn the rules concerning where the radix point will appear in the result of an instruction if we assume that it lies in a certain place beforehand. For example, in the case of MIX we could regard our operands either as integers with the radix point at the extreme

right, or as fractions with the radix point at the extreme left, or as some mixture of these two extremes; the rules for the appearance of the radix point in each result are straightforward.

It is easy to see that there is a simple relation between radix b and radix b^k:

$$(\ldots a_3a_2a_1a_0.a_{-1}a_{-2}\ldots)_b = (\ldots A_3A_2A_1A_0.A_{-1}A_{-2}\ldots)_{b^k}, \tag{5}$$

where

$$A_j = (a_{kj+k-1}\ldots a_{kj+1}a_{kj})_b;$$

see exercise 8. Thus we have simple techniques for converting at sight between, say, binary and octal notation.

Many interesting variations on positional number systems are possible besides the standard b-ary systems discussed so far. For example, we might have numbers in base (-10), so that

$$\begin{aligned}(\ldots a_3a_2a_1a_0.a_{-1}a_{-2}\ldots)_{-10}&\\ &= \cdots + a_3(-10)^3 + a_2(-10)^2 + a_1(-10)^1 + a_0 + \cdots\\ &= \cdots - 1000a_3 + 100a_2 - 10a_1 + a_0 - \tfrac{1}{10}a_{-1} + \tfrac{1}{100}a_{-2} - \cdots.\end{aligned}$$

Here the individual digits satisfy $0 \le a_k \le 9$ just as in the decimal system. The number 12345 67890 appears in the "negadecimal" system as

$$(1\,93755\,73910)_{-10}, \tag{6}$$

since the latter represents 10305070900 — 9070503010. It is interesting to note that the negative of this number, $-12345\,67890$, would be written

$$(28466\,48290)_{-10}, \tag{7}$$

and, in fact, *every real number whether positive or negative can be represented without a sign* in the -10 system.

Negative-base systems were first considered by Vittorio Grünwald [*Giornale di matematiche di Battaglini* **23** (1885), 203–221, 367], who explained how to perform the four arithmetic operations in such systems; Grünwald also discussed root extraction, divisibility tests, and radix conversion. However, since his work was published in a rather obscure journal, it seems to have had no effect on other research, and it was soon forgotten. The next publication about negative-base systems was apparently by A. J. Kempner [*AMM* **43** (1936), 610–617], who discussed the properties of non-integer radices and remarked in a footnote that negative radices would be feasible too. After twenty more years the idea was rediscovered again, this time by Z. Pawlak and A. Wakulicz [*Bulletin de l'Academie Polonaise des Sciences*, Classe III, **5** (1957), 233–236; Série des sciences techniques **7** (1959), 713–721], and also by L. Wadel [*IRE Transactions* **EC-6**

(1957), 123]. For further references see *IEEE Transactions* **EC-12** (1963), 274–276; *Computer Design* **6** (May 1967), 52–63. There is evidence that the idea of negative bases occurred independently to quite a few people. For example, D. E. Knuth had discussed negative-base systems in 1955, together with a further generalization to complex-valued bases, in a short paper submitted to a "science talent search" contest for high-school seniors.

The base $2i$ gives rise to a system called the "quater-imaginary" number system (by analogy with "quaternary"), which has the unusual feature that *every complex number can be represented with the digits* 0, 1, 2, *and* 3 *without a sign.* [See D. E. Knuth, *CACM* **3** (1960), 245–247.] For example,

$$\begin{aligned}(11210.31)_{2i} &= 1\cdot 16 + 1\cdot(-8i) + 2\cdot(-4) + 1\cdot(2i) + 3\cdot(-\tfrac{1}{2}i) + 1(-\tfrac{1}{4})\\ &= 7\tfrac{3}{4} - 7\tfrac{1}{2}i.\end{aligned}$$

Here the number $(a_{2n}\ldots a_1a_0.a_{-1}\ldots a_{-2k})_{2i}$ is equal to

$$(a_{2n}\ldots a_2a_0.a_{-2}\ldots a_{-2k})_{-4} + 2i(a_{2n-1}\ldots a_3a_1.a_{-1}\ldots a_{-2k+1})_{-4},$$

so conversion to and from quater-imaginary notation reduces to conversion to and from negative quaternary representation of the real and imaginary parts. The interesting property of this system is that it allows multiplication and division of complex numbers to be done in a fairly unified manner without treating real and imaginary parts separately. For example, we can multiply two numbers in this system much as we do with any base, merely using a different "carry" rule: whenever a digit exceeds 3 we subtract 4 and "carry" -1 two columns to the left; when a digit is negative, we add 4 to it and "carry" $+1$ two columns to the left. A study of the following example shows this peculiar carry rule at work:

				1	2	2	3	1	$[9-10i]$
				1	2	2	3	1	$[9-10i]$
				1	2	2	3	1	
1	0	3	2	0	2	1	3		
		1	3	0	2	2			
	1	3	0	2	2				
1	2	2	3	1					
0	2	1	3	3	3	1	2	1	$[-19-180i]$

A similar system that uses just the digits 0 and 1 may be based on $\sqrt{2}\,i$, but this requires an infinite nonrepeating expansion for the simple number "i" itself. Vittorio Grünwald proposed using the digits 0 and $1/\sqrt{2}$ in odd-numbered positions, to avoid such a problem, but this actually spoils the whole system [cf. *Commentari dell' Ateneo di Brescia* (1886), 43–54].

Another "binary" complex number system may be obtained by using the base $i-1$, as suggested by W. Penney [*JACM* **12** (1965), 247–248]:

$$\begin{aligned}&(\ldots a_4a_3a_2a_1a_0.a_{-1}\ldots)_{i-1}\\ &\quad = \cdots - 4a_4 + (2{+}2i)a_3 - 2ia_2 + (i{-}1)a_1 + a_0 - \tfrac{1}{2}(i{+}1)a_{-1} + \cdots.\end{aligned}$$

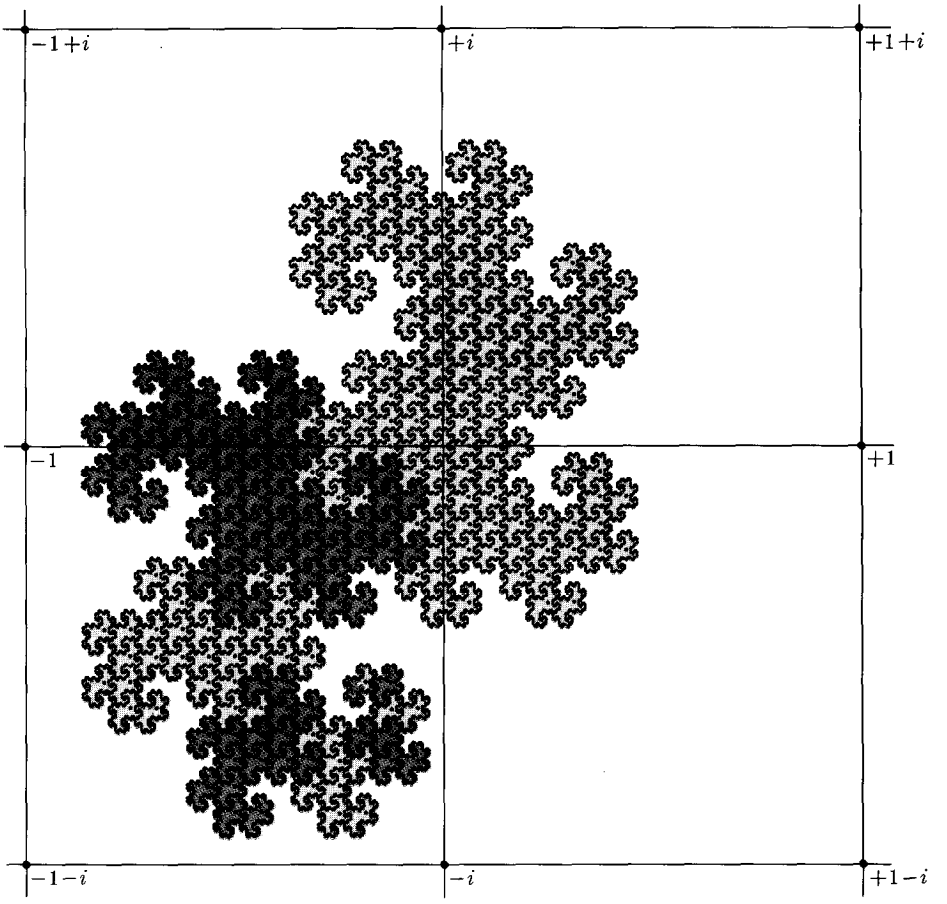


Fig. 1. The set S. (Illustration by P. M. Farmwald, R. W. Gosper, and R. E. Maas.)

In this system, only the digits 0 and 1 are needed. One way to demonstrate that every complex number has such a representation is to consider the interesting set S shown in Fig. 1; this set is, by definition, all points that can be written as $\sum_{k\geq 1} a_k(i-1)^{-k}$, for an infinite sequence $a_1, a_2, a_3, \ldots$ of zeros and ones. Figure 1 shows that S can be decomposed into 256 pieces congruent to $\frac{1}{16}S$; note that if the diagram of S is rotated counterclockwise by 135°, we obtain two adjacent sets congruent to $(1/\sqrt{2})\,S$ (since $(i-1)S = S \cup (S+1)$). For details of a proof that S contains all complex numbers that are of sufficiently small magnitude, see exercise 18.

Perhaps the prettiest number system of all is the *balanced ternary* notation, which consists of base-3 representation using -1, 0, and $+1$ as "trits" (ternary digits) instead of 0, 1, and 2. If we use the symbol $\bar{1}$ to stand for -1, we have the following examples of balanced ternary numbers:

Balanced ternary	Decimal
$1\,0\,\bar{1}$	8
$1\,1\,\bar{1}\,0.\bar{1}\,\bar{1}$	$32\frac{5}{9}$
$\bar{1}\,\bar{1}\,1\,0.1\,1$	$-32\frac{5}{9}$
$\bar{1}\,\bar{1}\,1\,0$	-33
$0.1\,1\,1\,1\,1\ldots$	$\frac{1}{2}$

One way to find the representation of a number in the balanced ternary system is to start by representing it in ternary notation; for example,

$$208.3 = (21201.022002200220\ldots)_3.$$

(A very simple pencil-and-paper method for converting to ternary notation is given in exercise 4.4–12.) Now add the infinite number $\ldots 11111.11111\ldots$ in ternary notation; we obtain, in the above example, the infinite number

$$(\ldots 11111210012.210121012101\ldots)_3.$$

Finally, subtract $\ldots 11111.11111\ldots$ by decrementing each digit; we get

$$208.3 = (10\bar{1}\bar{1}01.10\bar{1}010\bar{1}010\bar{1}0\ldots)_3. \tag{8}$$

This process may clearly be made rigorous if we replace the artificial infinite number $\ldots 11111.11111\ldots$ by a number with suitably many ones.

The balanced ternary number system has many pleasant properties:

a) The negative of a number is obtained by interchanging 1 and $\bar{1}$.

b) The sign of a number is given by its most significant nonzero "trit," and in general we can compare any two numbers by reading them from left to right and using lexicographic order, as in the decimal system.

c) The operation of rounding to the nearest integer is identical to truncation (i.e., deleting everything to the right of the radix point).

Addition in the balanced ternary system is quite simple, using the table

$\bar{1}$	$\bar{1}$	$\bar{1}$	$\bar{1}$	$\bar{1}$	$\bar{1}$	$\bar{1}$	$\bar{1}$	$\bar{1}$	0	0	0	0	0	0	0	0	0	1	1	1	1	1	1	1	1	1
$\bar{1}$	$\bar{1}$	$\bar{1}$	0	0	0	1	1	1	$\bar{1}$	$\bar{1}$	$\bar{1}$	0	0	0	1	1	1	$\bar{1}$	$\bar{1}$	$\bar{1}$	0	0	0	1	1	1
$\bar{1}$	0	1	$\bar{1}$	0	1	$\bar{1}$	0	1	$\bar{1}$	0	1	$\bar{1}$	0	1	$\bar{1}$	0	1	$\bar{1}$	0	1	$\bar{1}$	0	1	$\bar{1}$	0	1
$\bar{1}0$	$\bar{1}1$	$1\,\bar{1}$	$\bar{1}\,\bar{1}$	1	0	$\bar{1}$	0	1	$\bar{1}\,\bar{1}$	$\bar{1}$	0	$\bar{1}$	0	1	0	1	$1\bar{1}$	$\bar{1}$	0	1	0	$1\,\bar{1}$	$1\,\bar{1}$	1	$1\bar{1}$	10

(The three inputs to the addition are the digits of the numbers to be added and the carry digits.) Subtraction is negation followed by addition; and multiplication also reduces to negation and addition, as in the following example:

$$\begin{array}{rl}
 & 1\,\bar{1}\,0\,\bar{1} \quad [17] \\
 & 1\,\bar{1}\,0\,\bar{1} \quad [17] \\
 & \overline{\bar{1}\,1\,0\,1} \\
 \bar{1}\,1\,0\,1\,0 & \\
1\,\bar{1}\,0\,\bar{1} & \\
\overline{0\,1\,1\,\bar{1}\,\bar{1}\,0\,1} & \quad [289]
\end{array}$$

Representation of numbers in the balanced ternary system is implicitly present in a famous mathematical puzzle, which is commonly called "Bachet's problem of weights" although it was already stated by Fibonacci four centuries before Bachet wrote his book. [See W. Ahrens, *Mathematische Unterhaltungen und Spiele* **1** (Leipzig: Teubner, 1910), Section 3.4.] Positional number systems with negative digits have apparently been known for more than 1000 years in India; see J. Bharati, *Vedic Mathematics* (Delhi: Motilal Banarsidass, 1965). They were independently rediscovered by J. Colson [*Philos. Trans.* **34** (1726), 161–173], and by Sir John Leslie [*The Philosophy of Arithmetic* (Edinburgh, 1817); see pp. 33–34, 54, 64–65, 117, 150]; and also by A. Cauchy [*Comptes Rendus* **11** (Paris: 1840), 789–798], who pointed out that negative digits make it unnecessary for a person to memorize the multiplication table past 5×5. The first true appearance of "pure" balanced ternary notation was in an article by Léon Lalanne [*Comptes Rendus* **11** (Paris: 1840), 903–905], who was a designer of mechanical devices for arithmetic. The system was mentioned only rarely for 100 years after Lalanne's paper, until the development of the first electronic computers at the Moore School of Electrical Engineering in 1945–1946; at that time it was given serious consideration along with the binary system as a possible replacement for the decimal system. The complexity of arithmetic circuitry for balanced ternary arithmetic is not much greater than it is for the binary system, and a given number requires only $\ln 2 / \ln 3 \approx 63\%$ as many digit positions for its representation. Discussions of the balanced ternary number system appear in *AMM* **57** (1950), 90–93, and in *High-speed Computing Devices*, Engineering Research Associates (McGraw-Hill, 1950), 287–289. The experimental Russian computer SETUN was based on balanced ternary notation [see *CACM* **3** (1960), 149–150], and perhaps the symmetric properties and simple arithmetic of this number system will prove to be quite important some day—when the "flip-flop" is replaced by a "flip-flap-flop".

Positional notation generalizes in another important way to a *mixed-radix* system. Given a sequence of numbers $\langle b_n \rangle$ (where n may be negative), we define

$$\begin{bmatrix} \cdots, a_3, a_2, a_1, a_0; a_{-1}, a_{-2}, \cdots \\ \cdots, b_3, b_2, b_1, b_0; b_{-1}, b_{-2}, \cdots \end{bmatrix} \tag{9}$$
$$= \cdots + a_3 b_2 b_1 b_0 + a_2 b_1 b_0 + a_1 b_0 + a_0 + a_{-1}/b_{-1} + a_{-2}/b_{-1} b_{-2} + \cdots .$$

In the simplest mixed-radix systems, we work only with integers; we let b_0, b_1, b_2, ... be integers greater than one, and deal only with numbers that have no radix point, where a_n is required to lie in the range $0 \le a_n < b_n$.

One of the most important mixed-radix systems is the *factorial number system*, where $b_n = n + 2$. Using this system, we can represent every positive integer uniquely in the form

$$c_n\, n! + c_{n-1}\, (n-1)! + \cdots + c_2\, 2! + c_1, \tag{10}$$

where $0 \le c_k \le k$ for $1 \le k \le n$, and $c_n \ne 0$. (See Algorithm 3.3.2P.)

Mixed-radix systems are familiar in everyday life, when we deal with units of measure. For example, the quantity "3 weeks, 2 days, 9 hours, 22 minutes, 57 seconds, and 492 milliseconds" is equal to

$$\begin{bmatrix} 3, & 2, & 9, & 22, & 57; & 492 \\ & 7, & 24, & 60, & 60; & 1000 \end{bmatrix} \text{ seconds.}$$

The quantity "10 pounds, 6 shillings, and thruppence ha'penny" was once equal to $\begin{bmatrix} 10, & 6, & 3; & 1 \\ & 20, & 12; & 2 \end{bmatrix}$ pence in British currency, before Great Britain changed to a purely decimal monetary system.

It is possible to add and subtract mixed-radix numbers by using a straightforward generalization of the usual addition and subtraction algorithms, provided of course that the same mixed-radix system is being used for both operands (see exercise 4.3.1–9). Similarly, we can easily multiply or divide a mixed-radix number by small integer constants, using simple extensions of the familiar pencil-and-paper methods.

Mixed-radix systems were first discussed in full generality by Georg Cantor [*Zeitschrift für Math. und Physik* **14** (1869), 121–128]. Exercises 26 and 29 give further information about them.

Some questions concerning *irrational* radices have been investigated by W. Parry, *Acta Mathematica*, Acad. Sci. Hung., **11** (1960), 401–416.

Besides the systems described in this section, several other ways to represent numbers are mentioned elsewhere in this series of books: the binomial number system (exercise 1.2.6–56); the Fibonacci number system (exercises 1.2.8–34, 5.4.2–10); the phi number system (exercise 1.2.8–35); modular representations (Section 4.3.2); Gray code (Section 7.2.1); and roman numerals (Section 9.1).

EXERCISES

1. [*15*] Express $-10, -9, \ldots, 9, 10$ in the number system whose base is -2.

▶ **2.** [*24*] Consider the following four number systems: (a) binary (signed magnitude); (b) negabinary (radix -2); (c) balanced ternary; and (d) radix $b = \frac{1}{10}$. Use each of these four number systems to express each of the following three numbers: (i) -49; (ii) $-3\frac{1}{7}$ (show the repeating cycle); (iii) π (to a few significant figures).

3. [*20*] Express $-49 + i$ in the quater-imaginary system.

4. [*15*] Assume that we have a MIX program in which location A contains a number for which the radix point lies between bytes 3 and 4, while location B contains a number whose radix point lies between bytes 2 and 3. (The leftmost byte is number 1). Where will the radix point be, in registers A and X, after the following instructions?

a)
```
LDA  A
MUL  B
```

b)
```
LDA  A
SRAX 5
DIV  B
```

5. [*00*] Explain why a negative integer in nines' complement notation has a representation in ten's complement notation that is always one greater, if the representations are regarded as positive.

6. [*16*] What are the largest and smallest p-bit integers that can be represented in (a) signed-magnitude binary notation (including one bit for the sign), (b) two's complement notation, (c) ones' complement notation?

7. [*M20*] The text defines ten's complement notation only for integers represented in a single computer word. Is there a way to define a ten's complement notation *for all real numbers*, having "infinite precision," analogous to the text's definition? Is there a similar way to define a nines' complement notation for all real numbers?

8. [*M10*] Prove Eq. (5).

▶ **9.** [*15*] Change the following *octal* numbers to *hexadecimal* notation, using the hexadecimal digits 0, 1, ..., F: *12*; *5655*; *2550276*; *76545336*; *3726755*.

10. [*M22*] Generalize Eq. (5) to mixed-radix notation.

11. [*22*] Design an algorithm that uses the -2 number system to compute the sum of $(a_n \ldots a_1 a_0)_{-2}$ and $(b_n \ldots b_1 b_0)_{-2}$, obtaining the answer $(c_{n+2} \ldots c_1 c_0)_{-2}$.

12. [*23*] Specify algorithms that convert (a) the binary signed magnitude number $\pm(a_n \ldots a_0)_2$ to its negabinary form $(b_{n+1} \ldots b_0)_{-2}$; and (b) the negabinary number $(b_{n+1} \ldots b_0)_{-2}$ to its signed magnitude form $\pm(a_{n+1} \ldots a_0)_2$.

▶ **13.** [*M21*] In the decimal system there are some numbers with two infinite decimal expansions; e.g., $2.3599999\ldots = 2.3600000\ldots$. Does the *negadecimal* (base -10) system have unique expansions, or are there real numbers with two different infinite expansions in this base also?

14. [*14*] Multiply $(11321)_{2i}$ by itself in the quater-imaginary system using the method illustrated in the text.

15. [*M24*] What are the sets

$$S = \left\{ \sum_{k \geq 1} a_k b^{-k} \;\middle|\; a_k \text{ an allowable digit} \right\},$$

analogous to Fig. 1, for the negative decimal and for the quater-imaginary number systems?

16. [*M24*] Design an algorithm to add 1 to $(a_n \ldots a_1 a_0)_{i-1}$ in the $i-1$ number system.

17. [*M30*] It may seem peculiar that $i - 1$ has been suggested as a number-system base, instead of the similar but intuitively simpler number $i + 1$. Can every complex number $a+bi$, where a and b are integers, be represented in a positional number system to base $i + 1$, using only the digits 0 and 1?

18. [*HM32*] Show that the set S of Fig. 1 is a closed set that contains a neighborhood of the origin. (Consequently, every complex number has a "binary" representation to base $i - 1$.)

▶ **19.** [*23*] (David W. Matula.) Let D be a set of b integers, containing exactly one solution to the congruence $x \equiv j$ (modulo b) for $0 \leq j < b$. Prove that all integers m (positive, negative, or zero) can be represented in the form $m = (a_n \ldots a_0)_b$, where all the a_j are in D, if and only if all integers in the range $l \leq m \leq u$ can be so represented, where $l = -\max\{\, a \mid a \in D \,\}/(b-1)$, $u = -\min\{\, a \mid a \in D \,\}/(b-1)$. For example, $D = \{-1, 0, \ldots, b-2\}$ satisfies the conditions for all $b \geq 3$. [*Hint:* Design an algorithm that constructs a suitable representation.]

20. [*HM28*] (David W. Matula.) Consider a decimal number system that uses the digits $D = \{-1, 0, 8, 17, 26, 35, 44, 53, 62, 71\}$ instead of $\{0, 1, \ldots, 9\}$. The result of exercise 19 implies (as in exercise 18) that all real numbers have an infinite decimal expansion using digits from D.

In the usual decimal system, exercise 13 points out that some numbers have two representations. (a) Find a real number that has *more* than two D-decimal representations. (b) Show that no real number has infinitely many D-decimal representations. (c) Show that uncountably many numbers have two or more D-decimal representations.

▶ **21.** [*M22*] (C. E. Shannon.) Can every real number (positive, negative, or zero) be expressed in a "balanced decimal" system, i.e., in the form $\sum_{k\le n} a_k 10^k$, for some integer n and some sequence a_n, a_{n-1}, a_{n-2}, ..., where each a_k is one of the ten numbers $\{-4\frac{1}{2}, -3\frac{1}{2}, -2\frac{1}{2}, -1\frac{1}{2}, -\frac{1}{2}, \frac{1}{2}, 1\frac{1}{2}, 2\frac{1}{2}, 3\frac{1}{2}, 4\frac{1}{2}\}$? (Note that zero is not one of the allowed digits, but we implicitly assume that a_{n+1}, a_{n+2}, ... are zero.) Find all representations of zero in this number system, and find all representations of unity.

22. [*HM25*] Let $\alpha = -\sum_{m\ge 1} 10^{-m^2}$. Given $\epsilon > 0$ and any real number x, prove that there is a "decimal" representation such that $0 < \left|x - \sum_{0\le k\le n} a_k 10^k\right| < \epsilon$, where each a_k is allowed to be only one of the three values 0, 1, or α. (Note that no negative powers of 10 are used in this representation!)

23. [*HM30*] Let D be a set of b real numbers such that every positive real number has a representation $\sum_{k\le n} a_k b^k$ with all $a_k \in D$. Exercise 20 shows that there may be many numbers without *unique* representations; but prove that the set T of all such numbers has measure zero.

24. [*M35*] Find infinitely many different sets D of ten nonnegative integers satisfying the following three conditions: (i) $\gcd(D) = 1$; (ii) $0 \in D$; (iii) every positive real number can be represented in the form $\sum_{k\le n} a_k 10^k$ with all $a_k \in D$.

25. [*M25*] (S. A. Cook.) Let b, u, and v be positive integers, where $b \ge 2$ and $0 < v < b^m$. Show that the base b representation of u/v does not contain a run of m consecutive digits equal to $b - 1$, anywhere to the right of the radix point. (By convention, no runs of infinitely many $(b - 1)$'s are permitted in the standard base b representation.)

▶ **26.** [*HM30*] (N. S. Mendelsohn.) Let $\langle\beta_n\rangle$ be a sequence of real numbers defined for all integers n, $-\infty < n < \infty$, such that

$$\beta_n < \beta_{n+1}; \qquad \lim_{n\to\infty} \beta_n = \infty; \qquad \lim_{n\to-\infty} \beta_n = 0.$$

Let $\langle c_n\rangle$ be an arbitrary sequence of positive integers that is defined for all integers n, $-\infty < n < \infty$. Let us say that a number x has a "generalized representation" if there is an integer n and an infinite sequence of integers a_n, a_{n-1}, a_{n-2}, ... such that $x = \sum_{k\le n} a_k\beta_k$, where $a_n \neq 0$, $0 \le a_k \le c_k$, and $a_k < c_k$ for infinitely many k.

Show that every positive real number x has exactly one generalized representation if and only if $\beta_{n+1} = \sum_{k\le n} c_k\beta_k$ for all n. (Consequently, the mixed-radix systems with integer bases have this property; and mixed-radix systems with $\beta_1 = (c_0 + 1)\beta_0$, $\beta_2 = (c_1 + 1)(c_0 + 1)\beta_0$, ..., $\beta_{-1} = \beta_0/(c_{-1} + 1)$, ... are the most general number systems of this type.)

27. [*M21*] Show that every nonzero integer has a unique "reversing binary representation"

$$2^{e_0} - 2^{e_1} + \cdots + (-1)^t 2^{e_t},$$

where $e_0 < e_1 < \cdots < e_t$.

▸ **28.** [*M24*] Show that every nonzero complex number of the form $a + bi$ where a and b are integers has a unique "revolving binary representation"

$$(1+i)^{e_0} + i(1+i)^{e_1} - (1+i)^{e_2} - i(1+i)^{e_3} + \cdots + i^t(1+i)^{e_t},$$

where $e_0 < e_1 < \cdots < e_t$. (Cf. exercise 27.)

29. [*M35*] (N. G. de Bruijn.) Let S_0, S_1, S_2, ... be sets of nonnegative integers; we will say that the collection $\{S_0, S_1, S_2, \ldots\}$ has Property B if every nonnegative integer n can be written in the form

$$n = s_0 + s_1 + s_2 + \cdots, \qquad s_j \in S_j,$$

in exactly one way. (Property B implies that $0 \in S_j$ for all j, since $n = 0$ can only be represented as $0 + 0 + 0 + \cdots$.) Any mixed-radix number system with radices b_0, b_1, b_2, ... provides an example of a collection of sets satisfying Property B, if we let $S_j = \{0, B_j, \ldots, (b_j - 1)B_j\}$, where $B_j = b_0 b_1 \ldots b_{j-1}$; here the representation of $n = s_0 + s_1 + s_2 + \cdots$ corresponds in an obvious manner to its mixed-radix representation (9). Furthermore, if the collection $\{S_0, S_1, S_2, \ldots\}$ has Property B, and if A_0, A_1, A_2, ... is any partition of the nonnegative integers (so that we have $A_0 \cup A_1 \cup A_2 \cup \cdots = \{0, 1, 2, \ldots\}$ and $A_i \cap A_j = \emptyset$ for $i \neq j$; some A_j's may be empty), then the "collapsed" collection $\{T_0, T_1, T_2, \ldots\}$ also has Property B, where T_j is the set of all sums $\sum_{i \in A_j} s_i$ taken over all possible choices of $s_i \in S_i$.

Prove that *any* collection $\{T_0, T_1, T_2, \ldots\}$ that satisfies Property B may be obtained by collapsing some collection $\{S_0, S_1, S_2, \ldots\}$ that corresponds to a mixed-radix number system.

30. [*M39*] (N. G. de Bruijn.) The radix-(−2) number system shows us that every integer (positive, negative, or zero) has a unique representation of the form

$$(-2)^{e_1} + (-2)^{e_2} + \cdots + (-2)^{e_t}, \qquad e_1 > e_2 > \cdots > e_t \geq 0, \qquad t \geq 0.$$

The purpose of this exercise is to explore generalizations of this phenomenon.

a) Let b_0, b_1, b_2, ... be a sequence of integers such that every integer n has a unique representation of the form

$$n = b_{e_1} + b_{e_2} + \cdots + b_{e_t}, \qquad e_1 > e_2 > \cdots > e_t \geq 0, \qquad t \geq 0.$$

(Such a sequence $\langle b_n \rangle$ is called a "binary basis.") Show that there is an index j such that b_j is odd, but b_k is even for all $k \neq j$.

b) Prove that a binary basis $\langle b_n \rangle$ can always be rearranged into the form d_0, $2d_1$, $4d_2$, ... $= \langle 2^n d_n \rangle$, where each d_k is odd.

c) If each of d_0, d_1, d_2, ... in (b) is ± 1, prove that $\langle b_n \rangle$ is a binary basis if and only if there are infinitely many $+1$'s and infinitely many -1's.

d) Prove that 7, $-13 \cdot 2$, $7 \cdot 2^2$, $-13 \cdot 2^3$, ..., $7 \cdot 2^{2k}$, $-13 \cdot 2^{2k+1}$, ... is a binary basis, and find the representation of $n = 1$.

▶ **31.** [*M35*] A generalization of two's complement arithmetic, called "2-adic numbers," was invented about 1900 by K. Hensel. (In fact he treated *p-adic numbers*, for any prime p.) A 2-adic number may be regarded as a binary number

$$u = (\ldots u_3 u_2 u_1 u_0 . u_{-1} \ldots u_{-n})_2,$$

whose representation extends infinitely far to the left, but only finitely many places to the right, of the binary point. Addition, subtraction, and multiplication of 2-adic numbers are done according to the ordinary procedures of arithmetic, which can in principle be extended indefinitely to the left. For example,

$$\begin{aligned} 7 &= (\ldots 000000000000111)_2 & \tfrac{1}{7} &= (\ldots 110110110110111)_2 \\ -7 &= (\ldots 111111111111001)_2 & -\tfrac{1}{7} &= (\ldots 001001001001001)_2 \\ \tfrac{7}{4} &= (\ldots 000000000000001.11)_2 & \tfrac{1}{10} &= (\ldots 110011001100110.1)_2 \\ \sqrt{-7} &= (\ldots 100000010110101)_2 \quad \text{or} \quad (\ldots 011111101001011)_2. \end{aligned}$$

Here 7 appears as the ordinary binary integer seven, while -7 is its two's complement (extending infinitely to the left); it is easy to verify that the ordinary procedure for addition of binary numbers will give $-7 + 7 = (\ldots 00000)_2 = 0$, when the procedure is continued indefinitely. The values of $\frac{1}{7}$ and $-\frac{1}{7}$ are the unique 2-adic numbers that, when formally multiplied by 7, give 1 and -1, respectively. The values of $\frac{7}{4}$ and $\frac{1}{10}$ are examples of 2-adic numbers that are not 2-adic "integers," since they have nonzero bits to the right of the binary point. The two values of $\sqrt{-7}$, which are negatives of each other, are the only 2-adic numbers that, when formally squared, yield the value $(\ldots 111111111111001)_2$.

a) Prove that any 2-adic number u can be divided by any nonzero 2-adic number v to obtain a unique 2-adic number w satisfying $u = vw$. (Hence the set of 2-adic numbers forms a "field"; cf. Section 4.6.1.)

b) Prove that the 2-adic representation of the rational number $-1/(2n+1)$ may be obtained as follows, when n is a positive integer: First find the ordinary binary expansion of $+1/(2n+1)$, which has the periodic form $(0.\alpha\alpha\alpha\ldots)_2$ for some string α of 0's and 1's. Then $-1/(2n+1)$ is the 2-adic number $(\ldots\alpha\alpha\alpha)_2$.

c) Prove that the representation of a 2-adic number u is ultimately periodic (that is, $u_{N+\lambda} = u_N$ for all large N, for some $\lambda \geq 1$) if and only if u is rational (that is, $u = m/n$, for some integers m and n).

d) Prove that, when n is an integer, $\sqrt{n}$ is a 2-adic number if and only if it satisfies $n \bmod 2^{2k+3} = 2^{2k}$ for some nonnegative integer k. (Thus, the possibilities are either $n \bmod 8 = 1$, or $n \bmod 32 = 4$, etc.)

32. [*M40*] (I. Z. Ruzsa.) Prove that there are infinitely many integers whose ternary representation uses only 0's and 1's and whose quinary representation uses only 0's, 1's, and 2's.

33. [*M40*] (D. A. Klarner.) Let D be any set of integers, let b be any positive integer, and let k_n be the number of distinct integers that can be written as n-digit numbers $(a_{n-1}\ldots a_1 a_0)_b$ to base b with digits a_i in D. Prove that the sequence $\langle k_n \rangle$ satisfies a linear recurrence relation, and explain how to compute the generating function $\sum_n k_n z^n$. Illustrate your algorithm in the case $b = 3$ and $D = \{-1, 0, 3\}$.

4.2. FLOATING POINT ARITHMETIC

IN THIS SECTION, we shall study the basic principles of doing arithmetic on "floating point" numbers, by analyzing the internal mechanisms underlying such calculations. Perhaps many readers will have little interest in this subject, since their computers either have built-in floating point instructions or their computer manufacturer has supplied suitable subroutines. But, in fact, the material of this section should not merely be the concern of computer-design engineers or of a small clique of people who write library subroutines for new machines; every well-rounded programmer ought to have a knowledge of what goes on during the elementary steps of floating point arithmetic. This subject is not at all as trivial as most people think; it involves a surprising amount of interesting information.

4.2.1. Single-Precision Calculations

A. Floating point notation. We have discussed "fixed point" notation for numbers in Section 4.1; in such a case the programmer knows where the radix point is assumed to lie in the numbers he manipulates. For many purposes it is considerably more convenient to let the position of the radix point be dynamically variable or "floating" as a program is running, and to carry with each number an indication of its current radix point position. This idea has been used for many years in scientific calculations, especially for expressing very large numbers like Avogadro's number $N = 6.02252 \times 10^{23}$, or very small numbers like Planck's constant $\hbar = 1.0545 \times 10^{-27}$ erg sec.

In this section we shall work with *base b, excess q, floating point numbers with p digits*: Such numbers will be represented by pairs of values (e, f), denoting

$$(e, f) = f \times b^{e-q}. \tag{1}$$

Here e is an integer having a specified range, and f is a signed fraction. We will adopt the convention that

$$|f| < 1;$$

in other words, the radix point appears at the left of the positional representation of f. More precisely, the stipulation that we have p-digit numbers means that $b^p f$ is an integer, and that

$$-b^p < b^p f < b^p. \tag{2}$$

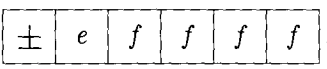
The term "floating binary" implies that $b = 2$, "floating decimal" implies $b = 10$, etc. Using excess-50 floating decimal numbers with 8 digits, we can write, for example,

$$\begin{aligned} &\text{Avogadro's number} \quad N = (74, +.60225200); \\ &\text{Planck's constant} \quad \hbar = (24, +.10545000). \end{aligned} \tag{3}$$

The two components e and f of a floating point number are called the exponent and the *fraction* parts, respectively. (Other names are occasionally

used for this purpose, notably "characteristic" and "mantissa"; but it is an abuse of terminology to call the fraction part a mantissa, since this concept has quite a different meaning in connection with logarithms. Furthermore the English word mantissa means "a worthless addition.")

The MIX computer assumes that its floating point numbers have the form



(4)

Here we have base b, excess q, floating point notation with four bytes of precision, where b is the byte size (e.g., $b = 64$ or $b = 100$), and q is equal to $\lfloor \frac{1}{2}b \rfloor$. The fraction part is $\pm f\,f\,f\,f$, and e is the exponent, which lies in the range $0 \le e < b$. This internal representation is typical of the conventions in most existing computers, although b is a much larger base than usual.

B. Normalized calculations. A floating point number (e, f) is *normalized* if the most significant digit of the representation of f is nonzero, so that

$$1/b \le |f| < 1; \tag{5}$$

or if $f = 0$ and e has its smallest possible value. It is possible to tell which of two normalized floating point numbers has a greater magnitude by comparing the exponent parts first, and then testing the fraction parts only if the exponents are equal.

Most floating point routines now in use deal almost entirely with normalized numbers: inputs to the routines are assumed to be normalized, and the outputs are always normalized. Under these conventions we lose the ability to represent a few numbers of very small magnitude—for example, the value $(0, .00000001)$ can't be normalized without producing a negative exponent—but we gain in speed, uniformity, and the ability to give relatively simple bounds on the relative error in our computations. (Unnormalized floating point arithmetic is discussed in Section 4.2.2.)

Let us now study the normalized floating point operations in detail. At the same time we can consider the construction of subroutines for these operations, assuming that we have a computer without built-in floating point hardware.

Machine-language subroutines for floating point arithmetic are usually written in a very machine-dependent manner, using many of the wildest idiosyncrasies of the computer at hand; so floating point addition subroutines for two different machines usually bear little superficial resemblance to each other. Yet a careful study of numerous subroutines for both binary and decimal computers reveals that these programs actually have quite a lot in common, and it is possible to discuss the topics in a machine-independent way.

The first (and by far the most difficult!) algorithm we shall discuss in this section is a procedure for floating point addition,

$$(e_u, f_u) \oplus (e_v, f_v) = (e_w, f_w). \tag{6}$$

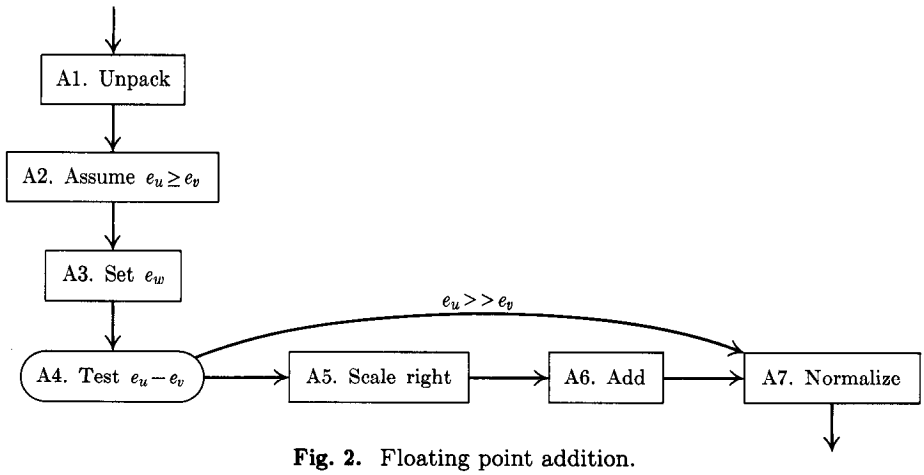


Fig. 2. Floating point addition.

Note: Since floating point arithmetic is inherently approximate, not exact, we will use "round" symbols

$$\oplus, \quad \ominus, \quad \otimes, \quad \oslash$$

to stand for floating point addition, subtraction, multiplication, and division, respectively, in order to distinguish approximate operations from the true ones.

The basic idea involved in floating point addition is fairly simple: Assuming that $e_u \geq e_v$, we take $e_w = e_u$, $f_w = f_u + f_v/b^{e_u - e_v}$ (thereby aligning the radix points for a meaningful addition), and normalize the result. Several situations can arise that make this process nontrivial, and the following algorithm explains the method more precisely.

Algorithm A (*Floating point addition*). Given base b, excess q, p-digit, normalized floating point numbers $u = (e_u, f_u)$ and $v = (e_v, f_v)$, this algorithm forms the sum $w = u \oplus v$. The same procedure may be used for floating point subtraction, if $-v$ is substituted for v.

A1. [Unpack.] Separate the exponent and fraction parts of the representations of u and v.

A2. [Assume $e_u \geq e_v$.] If $e_u < e_v$, interchange u and v. (In many cases, it is best to combine step A2 with step A1 or with some of the later steps.)

A3. [Set e_w.] Set $e_w \leftarrow e_u$.

A4. [Test $e_u - e_v$.] If $e_u - e_v \geq p + 2$ (large difference in exponents), set $f_w \leftarrow f_u$ and go to step A7. (Actually, since we are assuming that u is normalized, we could terminate the algorithm; but it is occasionally useful to be able to normalize a possibly unnormalized number by adding zero to it.)

A5. [Scale right.] Shift f_v to the right $e_u - e_v$ places; i.e., divide it by $b^{e_u - e_v}$. [*Note:* This will be a shift of up to $p + 1$ places, and the next step (which adds f_u to f_v) thereby requires an accumulator capable of holding $2p + 1$

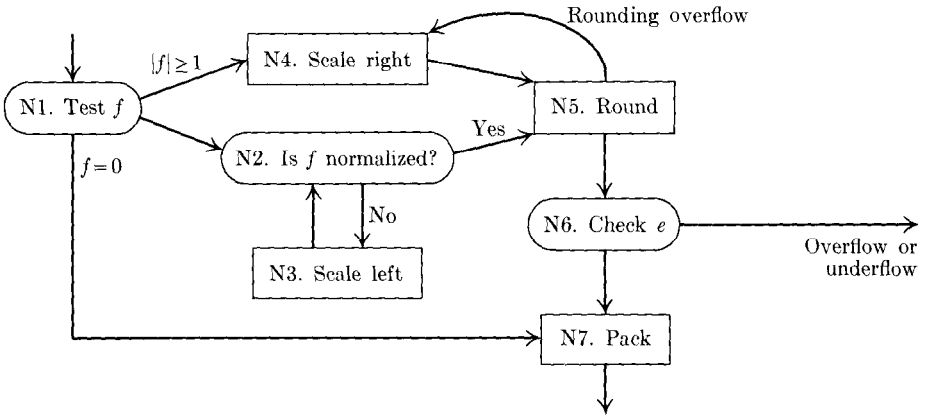

Fig. 3. Normalization of (e, f).

base-b digits to the right of the radix point. If such a large accumulator is not available, it is possible to shorten the requirement to $p + 2$ or $p + 3$ places if proper precautions are taken; the details are given in exercise 5.]

A6. [Add.] Set $f_w \leftarrow f_u + f_v$.

A7. [Normalize.] (At this point (e_w, f_w) represents the sum of u and v, but $|f_w|$ may have more than p digits, and it may be greater than unity or less than $1/b$.) Perform Algorithm N below, to normalize and round (e_w, f_w) into the final answer. ∎

Algorithm N (*Normalization*). A "raw exponent" e and a "raw fraction" f are converted to normalized form, rounding if necessary to p digits. This algorithm assumes that $|f| < b$.

N1. [Test f.] If $|f| \geq 1$ ("fraction overflow"), go to step N4. If $f = 0$, set e to its lowest possible value and go to step N7.

N2. [Is f normalized?] If $|f| \geq 1/b$, go to step N5.

N3. [Scale left.] Shift f to the left by one digit position (i.e., multiply it by b), and decrease e by 1. Return to step N2.

N4. [Scale right.] Shift f to the right by one digit position (i.e., divide it by b), and increase e by 1.

N5. [Round.] Round f to p places. (We take this to mean that f is changed to the nearest multiple of b^{-p}. It is possible that $(b^p f) \bmod 1 = \frac{1}{2}$ so that there are *two* nearest multiples; if b is even, we choose the one that makes $b^p f + \frac{1}{2}b$ odd. Further discussion of rounding appears in Section 4.2.2.) It is important to note that this rounding operation can make $|f| = 1$ ("rounding overflow"); in such a case, return to step N4.

N6. [Check e.] If e is too large, i.e., larger than its allowed range, an *exponent overflow* condition is sensed. If e is too small, an *exponent underflow* condition is sensed. (See the discussion below; since the result cannot

be expressed as a normalized floating point number in the required range, special action is necessary.)

N7. [Pack.] Put e and f together into the desired output representation. ∎

Some simple examples of floating point addition are given in exercise 4.

The following MIX subroutines, for addition and subtraction of numbers having the form (4), show how Algorithms A and N can be expressed as computer programs. The subroutines below are designed to take one input u from symbolic location ACC, and the other input v comes from register A upon entrance to the subroutine. The output w appears both in register A and location ACC. Thus, a fixed point coding sequence

```
LDA A; ADD B; SUB C; STA D                    (7)
```

would correspond to the floating point coding sequence

```

Program A (*Addition, subtraction, and normalization*). The following program is a subroutine for Algorithm A, and it is also designed so that the normalization portion can be used by other subroutines that appear later in this section. In this program and in many others throughout this chapter, OFLO stands for a subroutine that prints out a message to the effect that MIX's overflow toggle was unexpectedly found to be "on." The byte size b is assumed to be a multiple of 4. The normalization routine NORM assumes that rI2 $= e$ and rAX $= f$, where rA $= 0$ implies rX $= 0$ and rI2 $< b$.

```
00  BYTE  EQU  1(4:4)        Byte size b
01  EXP   EQU  1:1           Definition of exponent field
02  FSUB  STA  TEMP          Floating point subtraction subroutine:
03        LDAN TEMP          Change sign of operand.
04  FADD  STJ  EXITF         Floating point addition subroutine:
05        JOV  OFLO          Ensure overflow is off.
06        STA  TEMP          TEMP ← v.
07        LDX  ACC           rX ← u.
08        CMPA ACC(EXP)      Steps A1, A2, A3 are combined here:
09        JGE  1F            Jump if e_v ≥ e_u.
10        STX  FU(0:4)       FU ← ±fffff0.
11        LD2  ACC(EXP)      rI2 ← e_w.
12        STA  FV(0:4)
13        LD1N TEMP(EXP)     rI1 ← −e_v.
14        JMP  4F
15  1H    STA  FU(0:4)       FU ← ±fffff0 (u, v interchanged).
16        LD2  TEMP(EXP)     rI2 ← e_w.
17        STX  FV(0:4)
18        LD1N ACC(EXP)      rI1 ← −e_v.
```

```
19  4H      INC1  0,2          rI1 ← e_u − e_v.  (Step A4 unnecessary.)
20  5H      LDA   FV           A5. Scale right.
21          ENTX  0            Clear rX.
22          SRAX  0,1          Shift right e_u − e_v places.
23  6H      ADD   FU           A6. Add.
24          JOV   N4           A7. Normalize. Jump if fraction overflow.
25          JXZ   NORM         Easy case?
26          CMPA  =0=(1:1)     Is f normalized?
27          JNE   N5           If so, round it.
28          SRC   5            |rX| ↔ |rA|.
29          DECX  1            (rX is positive.)

67  ACC     CON   0            Floating point accumulator ∎
```

The rather long section of code from lines 25 to 37 is needed because MIX has only a 5-byte accumulator for adding signed numbers while in general $2p+1 = 9$ places of accuracy are required by Algorithm A. The program could be shortened to about half its present length if we were willing to sacrifice a little bit of its accuracy, but we shall see in the next section that full accuracy is important. Line 55 uses a nonstandard MIX instruction defined in Section 4.5.2. The running time for floating point addition and subtraction depends on several factors that are analyzed in Section 4.2.4.

Now let us consider multiplication and division, which are simpler than addition, and which are somewhat similar to each other.

Algorithm M (*Floating point multiplication or division*). Given base b, excess q, p-digit, normalized floating point numbers $u = (e_u, f_u)$ and $v = (e_v, f_v)$, this algorithm forms the product $w = u \otimes v$ or the quotient $w = u \oslash v$.

M1. [Unpack.] Separate the exponent and fraction parts of the representations of u and v. (Sometimes it is convenient, but not necessary, to test the operands for zero during this step.)

M2. [Operate.] Set

$$\begin{aligned} e_w &\leftarrow e_u + e_v - q, \qquad f_w \leftarrow f_u f_v \qquad \text{for multiplication;} \\ e_w &\leftarrow e_u - e_v + q + 1, \quad f_w \leftarrow (b^{-1} f_u)/f_v \quad \text{for division.} \end{aligned} \tag{9}$$

(Since the input numbers are assumed to be normalized, it follows that either $f_w = 0$, or $1/b^2 \le |f_w| < 1$, or a division-by-zero error has occurred.) If necessary, the representation of f_w may be reduced to $p+2$ or $p+3$ digits at this point, as in exercise 5.

M3. [Normalize.] Perform Algorithm N on (e_w, f_w) to normalize, round, and pack the result. (*Note:* Normalization is simpler in this case, since scaling left occurs at most once, and since rounding overflow cannot occur after division.) ∎

The following MIX subroutines, which are intended to be used in connection with Program A, illustrate the machine considerations necessary in connection with Algorithm M.

Program M (*Floating point multiplication and division*).

```
01  Q      EQU  BYTE/2        q is half the byte size
02  FMUL   STJ  EXITF         Floating point multiplication subroutine:
03         JOV  OFLO          Ensure overflow is off.
04         STA  TEMP          TEMP ← v.
05         LDX  ACC           rX ← u.
06         STX  FU(0:4)       FU ← ±fffff0.
07         LD1  TEMP(EXP)
08         LD2  ACC(EXP)
09         INC2 -Q,1          rI2 ← e_u + e_v − q.
10         SLA  1
11         MUL  FU            Multiply f_u times f_v.
12         JMP  NORM          Normalize, round, and exit.
```

```
13  FDIV  STJ   EXITF      Floating point division subroutine:
14        JOV   OFLO       Ensure overflow is off.
15        STA   TEMP       TEMP ← v.
16        STA   FV(0:4)    FV ← ±fffff0.
17        LD1   TEMP(EXP)
18        LD2   ACC(EXP)
19        DEC2  -Q,1       rI2 ← e_u − e_v + q.
20        ENTX  0
21        LDA   ACC
22        SLA   1          rA ← f_u.
23        CMPA  FV(1:5)
24        JL    *+3        Jump if |f_u| < |f_v|.
25        SRA   1          Otherwise, scale f_u right
26        INC2  1              and increase rI2 by 1.
27        DIV   FV         Divide.
28        JNOV  NORM       Normalize, round, and exit.
29  DVZRO HLT   3          Unnormalized or zero divisor  ∎
```

The most noteworthy feature of this program is the provision for division in lines 23–26, which is made in order to ensure enough accuracy to round the answer. If $|f_u| < |f_v|$, straightforward application of Algorithm M would leave a result of the form "$\pm 0 f f f f$" in register A, and this would not allow a proper rounding without a careful analysis of the remainder (which appears in register X). So the program computes $f_w \leftarrow f_u/f_v$ in this case, ensuring that f_w is either zero or normalized in all cases; rounding can proceed with five significant bytes, possibly testing whether the remainder is zero.

We occasionally need to convert values between fixed and floating point representations. A "fix-to-float" routine is easily obtained with the help of the normalization algorithm above; for example, in MIX, the following subroutine converts an integer to floating point form:

```
01  FLOT  STJ   EXITF    Assume that rA = u, an integer.
02        JOV   OFLO     Ensure overflow is off.
03        ENT2  Q+5      Set raw exponent.                (10)
04        ENTX  0
05        JMP   NORM     Normalize, round, and exit.  ∎
```

A "float-to-fix" subroutine is the subject of exercise 14.

The debugging of floating point subroutines is usually a difficult job, since there are so many cases to consider. Here is a list of common pitfalls that often trap a programmer or machine designer who is preparing floating point routines:

1) *Losing the sign.* On many machines (not MIX), shift instructions between registers will affect the sign, and the shifting operations used in normalizing and scaling numbers must be carefully analyzed. The sign is also lost frequently when minus zero is present. (For example, Program A is careful to retain the sign of register A in lines 30–34. See also exercise 6.)

2) *Failure to treat exponent underflow or overflow properly.* The size of e_w should not be checked until *after* the rounding and normalization, because preliminary tests may give an erroneous indication. Exponent underflow and overflow can occur on floating point addition and subtraction, not only during multiplication and division; and even though this is a rather rare occurrence, it must be tested each time. Enough information should be retained so that meaningful corrective actions are possible after overflow or underflow has occurred.

It has unfortunately become customary in many instances to ignore exponent underflow and simply to set underflowed results to zero with no indication of error. This causes a serious loss of accuracy in most cases (indeed, it is the loss of *all* the significant digits), and the assumptions underlying floating point arithmetic have broken down, so the programmer really must be told when underflow has occurred. Setting the result to zero is appropriate only in certain cases when the result is later to be added to a significantly larger quantity. When exponent underflow is not detected, we find mysterious situations in which $(u \otimes v) \otimes w$ is zero, but $u \otimes (v \otimes w)$ is not, since $u \otimes v$ results in exponent underflow but $u \otimes (v \otimes w)$ can be calculated without any exponents falling out of range. Similarly, we can find positive numbers a, b, c, d, and y such that

$$\begin{aligned} (a \otimes y \oplus b) \oslash (c \otimes y \oplus d) &\approx \tfrac{2}{3}, \\ (a \oplus b \oslash y) \oslash (c \oplus d \oslash y) &= 1 \end{aligned} \tag{11}$$

if exponent underflow is not detected. (See exercise 9.) Even though floating point routines are not precisely accurate, such a disparity as (11) is certainly unexpected when a, b, c, d, and y are all *positive*! Exponent underflow is usually not anticipated by a programmer, so he needs to be told about it.*

3) *Inserted garbage.* When scaling to the left it is important to keep from introducing anything but zeros at the right. For example, note the "`ENTX 0`" instruction in line 21 of Program A, and the all-too-easily-forgotten "`ENTX 0`" instruction in line 04 of the `FLOT` subroutine (10). (But it would be a mistake to clear register X after line 27 in the division subroutine.)

*On the other hand, it must be admitted that today's high-level programming languages give the programmer little or no satisfactory way to make use of the information that a floating point routine wants to tell him; and the `MIX` programs in this section, which simply '`HLT`' when errors are detected, are even worse. There are numerous important applications in which exponent underflow is relatively harmless, and it is desirable to find a way for programmers to cope with such situations easily and safely. The practice of silently replacing underflows by zero has been thoroughly discredited, but there is another alternative that has recently been gaining much favor, namely to modify the definition we have given for floating point numbers, allowing an unnormalized fraction part when the exponent has its smallest possible value. This idea of "gradual underflow," which was first embodied in the hardware of the Electrologica X8 computer, adds only a small amount of complexity to the algorithms, and it makes exponent underflow impossible during addition or subtraction. The simple formulas for relative error in Section 4.2.2 no longer hold in the presence of gradual underflow, so the topic is beyond the scope of this book. However, by using formulas like $\text{round}(x) = x(1-\delta)+\epsilon$, where $|\delta| < \frac{1}{2}b^{1-p}$ and $|\epsilon| < \frac{1}{2}b^{-p-q}$, one can show that gradual underflow succeeds in many important cases. See W. M. Kahan and J. Palmer, *ACM SIGNUM Newsletter* (Oct. 1979), 13–21.

4) *Unforeseen rounding overflow.* When a number like .999999997 is rounded to 8 digits, a carry will occur to the left of the decimal point, and the result must be scaled to the right. Many people have mistakenly concluded that rounding overflow is impossible during multiplication, since they look at the maximum value of $|f_u f_v|$, which is $1 - 2b^{-p} + b^{-2p}$; and this cannot round up to 1. The fallacy in this reasoning is exhibited in exercise 11. Curiously, it turns out that the phenomenon of rounding overflow *is* impossible during floating point division (see exercise 12).

There is a school of thought that says it is harmless to "round" a value like .999999997 to .99999999 instead of to 1.0000000, since this does not increase the worst-case bounds on relative error. The floating point number 1.0000000 may be said to represent all real values in the interval $[1.0000000 - 5 \times 10^{-8}, 1.0000000 + 5 \times 10^{-8}]$, while .99999999 represents all values in the much smaller interval $(.99999999 - 5 \times 10^{-9}, .99999999 + 5 \times 10^{-9})$. Even though the latter interval does not contain the original value .999999997, each number of the second interval is contained in the first, so subsequent calculations with the second interval are no less accurate than with the first. This ingenious argument is, however, incompatible with the mathematical philosophy of floating point arithmetic expressed in Section 4.2.2.

5) *Rounding before normalizing.* Inaccuracies are caused by premature rounding in the wrong digit position. This error is obvious when rounding is being done to the left of the appropriate position; but it is also dangerous in the less obvious cases where rounding is first done too far to the right, followed by rounding in the true position. For this reason it is a mistake to round during the "scaling-right" operation in step A5, except as prescribed in exercise 5. (The special case of rounding in step N5, then rounding again after rounding overflow has occurred, is harmless, however, because rounding overflow always yields ± 1.0000000 and this is unaffected by the subsequent rounding process.)

6) *Failure to retain enough precision in intermediate calculations.* Detailed analyses of the accuracy of floating point arithmetic, made in the next section, suggest strongly that normalizing floating point routines should always deliver a properly rounded result to the maximum possible accuracy. There should be no exceptions to this dictum, even in cases that occur with extremely low probability; the appropriate number of significant digits should be retained throughout the computations, as stated in Algorithms A and M.

C. Floating point hardware. Nearly every large computer intended for scientific calculations includes floating point arithmetic as part of its repertoire of built-in operations. Unfortunately, the design of such hardware usually includes some anomalies that result in dismally poor behavior in certain circumstances, and we hope that future computer designers will pay more attention to providing the proper behavior than they have in the past. It costs only a little more to build the machine right, and considerations in the following section show that substantial benefits will be gained. Yesterday's compromises are no longer appropriate for modern machines, based on what we know now.

The MIX computer, which is being used as an example of a "typical" machine in this series of books, has an optional "floating point attachment" (available at extra cost) that includes the following seven operations:

• FADD, FSUB, FMUL, FDIV, FLOT, FCMP (C = 1, 2, 3, 4, 5, 56, respectively; F = 6). The contents of rA after the operation "FADD V" are precisely the same as the contents of rA after the operations

```
STA ACC
LDA V
JMP FADD
```

where FADD is the subroutine that appears earlier in this section, except that both operands are automatically normalized before entry to the subroutine if they are not already in normalized form. (If exponent underflow occurs during this pre-normalization, but not during the normalization of the answer, no underflow is signalled.) Similar remarks apply to FSUB, FMUL, and FDIV. The contents of rA after the operation "FLOT" are the contents after "JMP FLOT" in the subroutine (10) above.

The contents of rA are unchanged by the operation "FCMP V"; this instruction sets the comparison indicator to less, equal, or greater, depending on whether the contents of rA are "definitely less than," "approximately equal to," or "definitely greater than" V; this subject is discussed in the next section, and the precise action is defined by the subroutine FCMP of exercise 4.2.2–17 with EPSILON in location 0.

No register other than rA is affected by any of the floating point operations. If exponent overflow or underflow occurs, the overflow toggle is turned on and the exponent of the answer is given modulo the byte size. Division by zero leaves undefined garbage in rA. Execution times: $4u$, $4u$, $9u$, $11u$, $3u$, $4u$, respectively.

• FIX (C = 5; F = 7). The contents of rA are replaced by the integer "round(rA)", rounding to the nearest integer as in step N5 of Algorithm N. However, if this answer is too large to fit in the register, the overflow toggle is set on and the result is undefined. Execution time: $3u$.

Sometimes it is helpful to use floating point operators in a nonstandard way. For example, if the operation FLOT had not been included as part of MIX's floating point attachment, we could easily achieve its effect on 4-byte numbers by writing

```
FLOT STJ  9F
     SLA  1
     ENTX Q+4
     SRC  1                    (12)
     FADD =0=
9H   JMP  *          ∎
```

This routine is not strictly equivalent to the FLOT operator, since it assumes that the 1:1 byte of rA is zero, and it destroys rX. The handling of more general situations is a little tricky, because rounding overflow can occur even during a FLOT operation.

Similarly, suppose MIX had a FADD operation but not FIX. If we wanted to round a number u from floating point form to the nearest fixed point integer, and if we knew that the number was nonnegative and would fit in at most three bytes, we could write

```
FADD FUDGE
```

where location FUDGE contains the constant

+	Q+4	1	0	0	0	;

the result in rA would be

+	Q+4	1	round(u)	.	(13)

D. History and bibliography. The origins of floating point notation can be traced back to Babylonian mathematicians (1800 B.C. or earlier), who made extensive use of radix-60 floating point arithmetic but did not have a notation for the exponents. The appropriate exponent was always somehow "understood" by the man doing the calculations. At least one case has been found in which the wrong answer was given because addition was performed with improper alignment of the operands, but such examples are very rare; see O. Neugebauer, *The Exact Sciences in Antiquity* (Princeton, N. J.: Princeton University Press, 1952), 26–27. Another early contribution to floating point notation is due to the Greek mathematician Apollonius (3rd century B.C.), who apparently was the first to explain how to simplify multiplication by collecting powers of 10 separately from their coefficients, at least in simple cases. [For a discussion of Apollonius's method, see Pappus, *Mathematical Collections* (4th century A.D.).] After the Babylonian civilization died out, the first significant uses of floating point notation for products and quotients did not emerge until much later, about the time logarithms were invented (1600) and shortly afterwards when Oughtred invented the slide rule (1630). The modern notation "x^n" for exponents was being introduced at about the same time; separate symbols for x squared, x cubed, etc., had been in use before this.

Floating point arithmetic was incorporated into the design of some of the earliest computers. It was independently proposed by Leonardo Torres y Quevedo in Madrid, 1914; by Konrad Zuse in Berlin, 1936; and by George Stibitz in New Jersey, 1939. Zuse's machines used a floating binary representation that he called "semi-logarithmic notation"; he also incorporated conventions for dealing with special quantities like "∞" and "undefined." The first American computers to operate with floating point arithmetic hardware were the Bell Laboratories' Model V and the Harvard Mark II, both of which were relay calculators designed in 1944. [See B. Randell, *The Origins of Digital Computers* (Berlin: Springer, 1973), 100, 155, 163–164, 259–260; *Proc. Symp. Large-Scale Digital Calculating Machinery* (Harvard, 1947), 41–68, 69–79; *Datamation* **13** (April 1967), 35–44 (May 1967), 45–49; *Zeit. für angew. Math. und Physik* **1** (1950), 345–346.]

The use of floating binary arithmetic was seriously considered in 1944–1946 by researchers at the Moore School in their plans for the first *electronic* digital computers, but it turned out to be much harder to implement floating point circuitry with tubes than with relays. The group realized that scaling was a problem in programming; but at the time it was only a very small part of a total programming job, and it seemed to be worth the time and trouble it took, since it tended to keep a programmer aware of the numerical accuracy he was getting. Furthermore, they argued that floating point representation would take up valuable memory space, since the exponents must be stored, and that it would be difficult to adapt floating point arithmetic to multiple-precision calculations. [See von Neumann's *Collected Works* **5** (New York: Macmillan, 1963), 43, 73–74.] At this time, of course, they were designing the first stored-program computer and the second electronic computer, and their choice had to be either fixed point *or* floating point arithmetic, not both. They anticipated the coding of floating binary routines, and in fact "shift left" and "shift right" instructions were put into their machine primarily to make such routines more efficient. The first machine to have both kinds of arithmetic in its hardware was apparently a computer developed at General Electric Company [see *Proc. 2nd Symp. Large-Scale Digital Calculating Machinery* (Cambridge: Harvard University Press, 1951), 65–69].

Floating point subroutines and interpretive systems for early machines were coded by D. J. Wheeler and others, and the first publication of such routines was in *The Preparation of Programs for an Electronic Digital Computer* by Wilkes, Wheeler, and Gill (Reading, Mass.: Addison-Wesley, 1951), subroutines A1–A11, pp. 35–37, 105–117. It is interesting to note that floating *decimal* subroutines are described here, although a binary computer was being used; in other words, the numbers were represented as $10^e f$, not $2^e f$, and therefore the scaling operations required multiplication or division by 10. On this particular machine such decimal scaling was about as easy as shifting, and the decimal approach greatly simplified input/output conversions.

Most published references to the details of floating point arithmetic routines are scattered in "technical memorandums" distributed by various computer manufacturers, but there have been occasional appearances of these routines in the open literature. Besides the reference above, the following are of historical interest: R. H. Stark and D. B. MacMillan, *Math. Comp.* **5** (1951), 86–92, where a plugboard-wired program is described; D. McCracken, *Digital Computer Programming* (New York: Wiley, 1957), 121–131; J. W. Carr III, *CACM* **2**,5 (May 1959), 10–15; W. G. Wadey, *JACM* **7** (1960), 129–139; D. E. Knuth, *JACM* **8** (1961), 119–128; O. Kesner, *CACM* **5** (1962), 269–271; F. P. Brooks and K. E. Iverson, *Automatic Data Processing* (New York: Wiley, 1963), 184–199. For a discussion of floating point arithmetic from a computer designer's standpoint, see "Floating point operation" by S. G. Campbell, in *Planning a computer System*, ed. by W. Buchholz (New York: McGraw-Hill, 1962), 92–121. A set of algorithms by J. Coonen, W. M. Kahan, and H. S. Stone, submitted to the IEEE Microprocessor Floating-Point Standards Committee during 1978–1980, represented

the state of the floating point art as of 1980; these carefully considered procedures will probably be published some day. Additional references, which deal primarily with the accuracy of floating point methods, are given in Section 4.2.2.

EXERCISES

1. [*10*] How would Avogadro's number and Planck's constant be represented in base 100, excess 50, four-digit floating point notation? (This would be the representation used by MIX, as in (4), if the byte size is 100.)

2. [*12*] Assume that the exponent e is constrained to lie in the range $0 \le e \le E$; what are the largest and smallest positive values that can be written as base b, excess q, p-digit floating point numbers? What are the largest and smallest positive values that can be written as *normalized* floating point numbers with these specifications?

3. [*11*] (K. Zuse, 1936.) Show that if we are using normalized floating binary arithmetic, there is a way to increase the precision slightly without loss of memory space: A p-bit fraction part can be represented using only $p - 1$ bit positions of a computer word, if the range of exponent values is decreased very slightly.

▶ **4.** [*12*] Assume that $b = 10$, $p = 8$. What result does Algorithm A give for $(50, +.98765432) \oplus (49, +.33333333)$? For $(53, -.99987654) \oplus (54, +.10000000)$? For $(45, -.50000001) \oplus (54, +.10000000)$?

▶ **5.** [*24*] Let us say that $x \sim y$ (with respect to a given radix b) if x and y are real numbers satisfying the following conditions:

$$\lfloor x/b \rfloor = \lfloor y/b \rfloor;$$

$$\begin{aligned}
x \bmod b = 0 \quad &\text{iff} \quad y \bmod b = 0;\\
0 < x \bmod b < \tfrac{1}{2}b \quad &\text{iff} \quad 0 < y \bmod b < \tfrac{1}{2}b;\\
x \bmod b = \tfrac{1}{2}b \quad &\text{iff} \quad y \bmod b = \tfrac{1}{2}b;\\
\tfrac{1}{2}b < x \bmod b < b \quad &\text{iff} \quad \tfrac{1}{2}b < y \bmod b < b.
\end{aligned}$$

Prove that if f_v is replaced by $b^{-p-2}F_v$ between steps A5 and A6 of Algorithm A, where $F_v \sim b^{p+2}f_v$, the result of that algorithm will be unchanged. (If F_v is an integer and b is even, this operation essentially truncates f_v to $p + 2$ places while remembering whether any nonzero digits have been dropped, thereby minimizing the length of register that is needed for the addition in step A6.)

6. [*20*] If the result of a FADD instruction is zero, what will be the sign of rA, according to the definitions of MIX's floating point attachment given in this section?

7. [*27*] Discuss floating point arithmetic using balanced ternary notation.

8. [*20*] Give examples of normalized eight-digit floating decimal numbers u and v for which addition yields (a) exponent underflow, (b) exponent overflow, assuming that exponents must satisfy $0 \le e < 100$.

9. [*M24*] (W. M. Kahan.) Assume that the occurrence of exponent underflow causes the result to be replaced by zero, with no error indication given. Using excess zero, eight-digit floating decimal numbers with e in the range $-50 \le e < 50$, find positive values of a, b, c, d, and y such that (11) holds.

10. [*12*] Give an example of normalized eight-digit floating decimal numbers u and v for which rounding overflow occurs in addition.

▸ **11.** [*M20*] Give an example of normalized, excess 50, eight-digit floating decimal numbers u and v for which rounding overflow occurs in multiplication.

12. [*M25*] Prove that rounding overflow cannot occur during the normalization phase of floating point division.

13. [*30*] When doing "interval arithmetic" we don't want to round the results of a floating point computation; we want rather to implement operations such as $\triangledown$ and $\triangle$, which give the tightest possible representable bounds on the true sum:

$$u \mathbin{\triangledown} v \;\le\; u + v \;\le\; u \mathbin{\triangle} v.$$

How should the algorithms of this section be modified for such a purpose?

14. [*25*] Write a MIX subroutine that begins with an arbitrary floating point number in register A, not necessarily normalized, and converts it to the nearest fixed point integer (or determines that the number is too large in absolute value to make such a conversion possible).

▸ **15.** [*28*] Write a MIX subroutine, to be used in connection with the other subroutines of this section, that calculates $u \bmod 1$, that is, $u - \lfloor u \rfloor$ rounded to nearest floating point number, given a floating point number u. Note that when u is a very small negative number, $u \bmod 1$ will be rounded so that the result is unity (even though $u \bmod 1$ has been defined to be always *less* than unity, as a real number).

16. [*HM21*] (Robert L. Smith.) Design an algorithm to compute the real and imaginary parts of the complex number $(a+bi)/(c+di)$, given real floating point values a, b, c, and d. Avoid the computation of c^2+d^2, since it would cause floating point overflow even when $|c|$ or $|d|$ is approximately the square root of the maximum allowable floating point value.

17. [*40*] (John Cocke.) Explore the idea of extending the range of floating point numbers by defining a single-word representation in which the precision of the fraction decreases as the magnitude of the exponent increases.

18. [*25*] Consider a binary computer with 36-bit words, on which positive floating binary numbers are represented as $(0e_1e_2\ldots e_8f_1f_2\ldots f_{27})_2$; here $(e_1e_2\ldots e_8)_2$ is an excess $(10000000)_2$ exponent and $(f_1f_2\ldots f_{27})_2$ is a 27-bit fraction. Negative floating point numbers are represented by the *two's complement* of the corresponding positive representation (see Section 4.1). Thus, 1.5 is *201|600000000* in octal notation, while -1.5 is *576|200000000*; the octal representations of 1.0 and -1.0 are *201|400000000* and *576|400000000*, respectively. (A vertical line is used here to show the boundary between exponent and fraction.) Note that bit f_1 of a normalized positive number is always 1, while it is almost always zero for negative numbers; the exceptional cases are representations of -2^k.

Suppose that the exact result of a floating point operation has the octal code *572|740000000|01*; this (negative) 33-bit fraction must be normalized and rounded to 27 bits. If we shift left until the leading fraction bit is zero, we get *576|000000000|20*, but this rounds to the illegal value *576|000000000*; we have over-normalized, since the correct answer is *575|400000000*. On the other hand if we start (in some other problem) with the value *572|740000000|05* and stop before over-normalizing it, we get *575|400000000|50*, which rounds to the unnormalized number *575|400000001*; subsequent normalization yields *576|000000002* while the correct answer is *576|000000001*.

Give a simple, correct rounding rule that resolves this dilemma on such a machine (without abandoning two's complement notation).

Round numbers are always false.

—SAMUEL JOHNSON (1750)

I shall speak in round numbers, not absolutely accurate, yet not so wide from truth as to vary the result materially.

—THOMAS JEFFERSON (1824)

19. [24] What is the running time for the FADD subroutine in Program A, in terms of relevant characteristics of the data? What is the maximum running time, over all inputs that do not cause overflow or underflow?

4.2.2. Accuracy of Floating Point Arithmetic

Floating point computation is by nature inexact, and it is not difficult to misuse it so that the computed answers consist almost entirely of "noise." One of the principal problems of numerical analysis is to determine how accurate the results of certain numerical methods will be. A "credibility-gap" problem is involved here: we don't know how much of the computer's answers to believe. Novice computer users solve this problem by implicitly trusting in the computer as an infallible authority; they tend to believe that all digits of a printed answer are significant. Disillusioned computer users have just the opposite approach, they are constantly afraid that their answers are almost meaningless. Many a serious mathematician has attempted to give rigorous analyses of a sequence of floating point operations, but has found the task to be so formidable that he has tried to content himself with plausibility arguments instead.

A thorough examination of error analysis techniques is, of course, beyond the scope of this book, but in this section we shall study some of the characteristics of floating point arithmetic errors. Our goal is to discover how to perform floating point arithmetic in such a way that reasonable analyses of error propagation are facilitated as much as possible.

A rough (but reasonably useful) way to express the behavior of floating point arithmetic can be based on the concept of "significant figures" or *relative error.* If we are representing an exact real number x inside a computer by using the approximation $\hat{x} = x(1 + \epsilon)$, the quantity $\epsilon = (\hat{x} - x)/x$ is called the relative error of approximation. Roughly speaking, the operations of floating point multiplication and division do not magnify the relative error by very much; but floating point subtraction of nearly equal quantities (and floating point addition, $u \oplus v$, where u is nearly equal to $-v$) can very greatly increase the relative error. So we have a general rule of thumb, that a substantial loss of accuracy is expected from such additions and subtractions, but not from multiplications and divisions. On the other hand, the situation is somewhat paradoxical and needs to be understood properly, since "bad" additions and subtractions are performed with perfect accuracy! (See exercise 25.)

One of the consequences of the possible unreliability of floating point addition is that the associative law breaks down:

$$(u \oplus v) \oplus w \neq u \oplus (v \oplus w), \qquad \text{for many } u, v, w. \tag{1}$$

For example,

$$\begin{aligned}(11111113. \oplus -11111111.) \oplus 7.5111111 &= 2.0000000 \oplus 7.5111111\\ &= 9.5111111;\\ 11111113. \oplus (-11111111. \oplus 7.5111111) &= 11111113. \oplus -11111103.\\ &= 10.000000.\end{aligned}$$

(All examples in this section are given in eight-digit floating decimal arithmetic, with exponents indicated by an explicit decimal point. Recall that, as in Section 4.2.1, the symbols $\oplus$, $\ominus$, $\otimes$, $\oslash$ are used to stand for floating point operations corresponding to the exact operations $+$, $-$, $\times$, $/$.)

In view of the failure of the associative law, the comment of Mrs. La Touche that appears at the beginning of this chapter [taken from *Math. Gazette* **12** (1924), 95] makes a good deal of sense with respect to floating point arithmetic. Mathematical notations like "$a_1 + a_2 + a_3$" or "$\sum_{1 \le k \le n} a_k$" are inherently based upon the assumption of associativity, so a programmer must be especially careful that he does not implicitly assume the validity of the associative law.

A. An axiomatic approach. Although the associative law is not valid, the commutative law

$$u \oplus v = v \oplus u \tag{2}$$

does hold, and this law can be a valuable conceptual asset in programming and in the analysis of programs. This example suggests that we should look for important laws that *are* satified by $\oplus$, $\ominus$, $\otimes$, and $\oslash$; it is not unreasonable to say that *floating point routines should be designed to preserve as many of the ordinary mathematical laws as possible.* If more axioms are valid, it becomes easier to write good programs, and programs also become more portable from machine to machine.

Let us therefore consider some of the other basic laws that are valid for normalized floating point operations as described in the previous section. First we have

$$u \ominus v = u \oplus -v; \tag{3}$$

$$-(u \oplus v) = -u \oplus -v; \tag{4}$$

$$u \oplus v = 0 \quad \text{if and only if} \quad v = -u; \tag{5}$$

$$u \oplus 0 = u. \tag{6}$$

From these laws we can derive further identities; for example (exercise 1),

$$u \ominus v = -(v \ominus u). \tag{7}$$

Identities (2) to (6) are easily deduced from the algorithms in Section 4.2.1. The following rule is slightly less obvious:

$$\text{if} \quad u \le v \quad \text{then} \quad u \oplus w \le v \oplus w. \tag{8}$$

Instead of attempting to prove this rule by analyzing Algorithm 4.2.1A, let us go back to the principle underlying the design of that algorithm. (Algorithmic proofs aren't always easier than mathematical ones.) Our idea was that the floating point operations should satisfy

$$\begin{aligned} u \oplus v &= \text{round}(u + v), \qquad u \ominus v = \text{round}(u - v), \\ u \otimes v &= \text{round}(u \times v), \qquad u \oslash v = \text{round}(u \;/\; v), \end{aligned} \tag{9}$$

where round(x) denotes the best floating point approximation to x as defined in Algorithm 4.2.1N. We have

$$\text{round}(-x) = -\text{round}(x), \tag{10}$$

$$x \le y \quad \text{implies} \quad \text{round}(x) \le \text{round}(y), \tag{11}$$

and these fundamental relations prove properties (2) through (8) immediately. We can also write down several more identities:

$$u \otimes v = v \otimes u, \qquad (-u) \otimes v = -(u \otimes v), \qquad 1 \otimes v = v;$$

$$u \otimes v = 0 \quad \text{if and only if} \quad u = 0 \text{ or } v = 0;$$

$$(-u) \oslash v = u \oslash (-v) = -(u \oslash v);$$

$$0 \oslash v = 0, \qquad u \oslash 1 = u, \qquad u \oslash u = 1.$$

If $u \le v$ and $w > 0$, then $u \otimes w \le v \otimes w$ and $u \oslash w \le v \oslash w$ and $w \oslash u \ge w \oslash v$. If $u \oplus v = u + v$, then $(u \oplus v) \ominus v = u$; and if $u \otimes v = u \times v \neq 0$, then $(u \otimes v) \oslash v = u$. We see that a good deal of regularity is present in spite of the inexactness of the floating point operations, when things have been defined properly.

Several familiar rules of algebra are still, of course, conspicuously absent from the collection of identities above; the associative law for floating point multiplication is not strictly true, as shown in exercise 3, and the distributive law between $\otimes$ and $\oplus$ can fail rather badly: Let $u = 20000.000$, $v = -6.0000000$, and $w = 6.0000003$; then

$$(u \otimes v) \oplus (u \otimes w) = -120000.00 \oplus 120000.01 = .010000000$$

$$u \otimes (v \oplus w) = 20000.000 \otimes .00000030000000 = .0060000000$$

so

$$u \otimes (v \oplus w) \neq (u \otimes v) \oplus (u \otimes w). \tag{12}$$

On the other hand we do have $b \otimes (v \oplus w) = (b \otimes v) \oplus (b \otimes w)$, when b is the floating point radix, since

$$\text{round}(bx) = b\,\text{round}(x). \tag{13}$$

(Strictly speaking, the identities and inequalities we are considering in this section implicitly assume that exponent underflow and overflow do not occur. The function round(x) is undefined when $|x|$ is too small or too large, and equations such as (13) hold only when both sides are defined.)

The failure of Cauchy's fundamental inequality

$$(x_1^2 + \cdots + x_n^2)(y_1^2 + \cdots + y_n^2) \geq (x_1y_1 + \cdots + x_ny_n)^2$$

is another important example of the breakdown of traditional algebra in the presence of floating point arithmetic. Exercise 7 shows that Cauchy's inequality can fail even in the simple case $n = 2$, $x_1 = x_2 = 1$. Novice programmers who calculate the standard deviation of some observations by using the textbook formula

$$\sigma = \sqrt{\Bigg(n \sum_{1\leq k\leq n} x_k^2 - \Bigg(\sum_{1\leq k\leq n} x_k\Bigg)^2\Bigg) \Big/ n(n-1)} \tag{14}$$

often find themselves taking the square root of a negative number! A much better way to calculate means and standard deviations with floating point arithmetic is to use the recurrence formulas

$$M_1 = x_1, \qquad M_k = M_{k-1} \oplus (x_k \ominus M_{k-1}) \oslash k, \tag{15}$$

$$S_1 = 0, \qquad S_k = S_{k-1} \oplus (x_k \ominus M_{k-1}) \otimes (x_k \ominus M_k), \tag{16}$$

for $2 \leq k \leq n$, where $\sigma = \sqrt{S_n/(n-1)}$. [Cf. B. P. Welford, *Technometrics* **4** (1962), 419–420.] With this method S_n can never be negative, and we avoid other serious problems encountered by the naïve method of accumulating sums, as shown in exercise 16. (See exercise 19 for a summation technique that provides an even better guarantee on the accuracy.)

Although algebraic laws do not always hold exactly, we can often show that they aren't too far off base. When $b^{e-1} \leq x < b^e$ we have $\text{round}(x) = x + \rho(x)$, where $|\rho(x)| \leq \frac{1}{2}b^{e-p}$; hence

$$\text{round}(x) = x\big(1 + \delta(x)\big), \tag{17}$$

where the relative error is bounded independently of x:

$$|\delta(x)| \leq \tfrac{1}{2}/(b^{1-p} + \tfrac{1}{2}) < \tfrac{1}{2}b^{1-p}. \tag{18}$$

We can use this inequality to estimate the relative error of normalized floating point calculations in a simple way, since $u \oplus v = (u + v)(1 + \delta(u + v))$, etc.

As an example of typical error-estimation procedures, let us consider the associative law for multiplication. Exercise 3 shows that $(u \otimes v) \otimes w$ is not in general equal to $u \otimes (v \otimes w)$; but the situation in this case is much better than it was with respect to the associative law of addition (1) and the distributive law (12). In fact, we have

$$(u \otimes v) \otimes w = \big((uv)(1+\delta_1)\big) \otimes w = uvw(1+\delta_1)(1+\delta_2),$$
$$u \otimes (v \otimes w) = u \otimes \big((vw)(1+\delta_3)\big) = uvw(1+\delta_3)(1+\delta_4),$$

for some δ_1, δ_2, δ_3, δ_4, provided that no exponent underflow or overflow occurs, where $|\delta_j| < \frac{1}{2}b^{1-p}$ for each j. Hence

$$\frac{(u \otimes v) \otimes w}{u \otimes (v \otimes w)} = \frac{(1+\delta_1)(1+\delta_2)}{(1+\delta_3)(1+\delta_4)} = 1+\delta,$$

where

$$|\delta| < 2b^{1-p}/(1 - \tfrac{1}{2}b^{1-p})^2. \tag{19}$$

The number b^{1-p} occurs so often in such analyses, it has been given a special name, one *ulp*, meaning one "unit in the last place" of the fraction part. Floating point operations are correct to within half an ulp, and the calculation of uvw by two floating point multiplications will be correct within about one ulp (ignoring second-order terms). Hence the associative law for multiplication holds to within about two ulps of relative error.

We have shown that $(u \otimes v) \otimes w$ is approximately equal to $u \otimes (v \otimes w)$, except when exponent overflow or underflow is a problem. It is worthwhile to study this intuitive idea of being "approximately equal" in more detail; can we make such a statement more precise in a reasonable way?

A programmer using floating point arithmetic almost never wants to test if two computed values are exactly equal to each other (or at least he hardly ever should try to do so), because this is an extremely improbable occurrence. For example, if a recurrence relation

$$x_{n+1} = f(x_n)$$

is being used, where the theory in some textbook says that x_n approaches a limit as $n \to \infty$, it is usually a mistake to wait until $x_{n+1} = x_n$ for some n, since the sequence x_n might be periodic with a longer period due to the rounding of intermediate results. The proper procedure is to wait until $|x_{n+1} - x_n| < \delta$, for some suitably chosen number δ; but since we don't necessarily know the order of magnitude of x_n in advance, it is even better to wait until

$$|x_{n+1} - x_n| \le \epsilon |x_n|; \tag{20}$$

now ϵ is a number that is much easier to select. This relation (20) is another way of saying that x_{n+1} and x_n are approximately equal; and our discussion

indicates that a relation of "approximately equal" would be more useful than the traditional relation of equality, when floating point computations are involved, if we could only define a suitable approximation relation.

In other words, the fact that strict equality of floating point values is of little importance implies that we ought to have a new operation, *floating point comparison*, which is intended to help assess the relative values of two floating point quantities. The following definitions seem to be appropriate for base b, excess q, floating point numbers $u = (e_u, f_u)$ and $v = (e_v, f_v)$:

$$u \prec v \quad (\epsilon) \qquad \text{if and only if} \qquad v - u > \epsilon \max(b^{e_u - q}, b^{e_v - q}); \tag{21}$$

$$u \sim v \quad (\epsilon) \qquad \text{if and only if} \qquad |v - u| \leq \epsilon \max(b^{e_u - q}, b^{e_v - q}); \tag{22}$$

$$u \succ v \quad (\epsilon) \qquad \text{if and only if} \qquad u - v > \epsilon \max(b^{e_u - q}, b^{e_v - q}); \tag{23}$$

$$u \approx v \quad (\epsilon) \qquad \text{if and only if} \qquad |v - u| \leq \epsilon \min(b^{e_u - q}, b^{e_v - q}). \tag{24}$$

These definitions apply to unnormalized values as well as to normalized ones. Note that exactly one of the conditions $u \prec v$ (definitely less than), $u \sim v$ (approximately equal to), or $u \succ v$ (definitely greater than) must always hold for any given pair of values u and v. The relation $u \approx v$ is somewhat stronger than $u \sim v$, and it might be read "u is essentially equal to v." All of the relations are given in terms of a positive real number ϵ that measures the degree of approximation being considered.

One way to view the above definitions is to associate a "neighborhood" set $N(u) = \{ x \mid |x - u| \leq \epsilon b^{e_u - q} \}$ with each floating point number u; thus, $N(u)$ represents a set of values near u based on the exponent of u's floating point representation. In these terms, we have $u \prec v$ if and only if $N(u) < v$ and $u < N(v)$; $u \sim v$ if and only if $u \in N(v)$ or $v \in N(u)$; $u \succ v$ if and only if $u > N(v)$ and $N(u) > v$; $u \approx v$ if and only if $u \in N(v)$ and $v \in N(u)$. (Here we are assuming that the parameter ϵ, which measures the degree of approximation, is a constant; a more complete notation would indicate the dependence of $N(u)$ upon ϵ.)

Here are some simple consequences of the above definitions:

$$\text{if} \quad u \prec v \quad (\epsilon) \quad \text{then} \quad v \succ u \quad (\epsilon); \tag{25}$$

$$\text{if} \quad u \approx v \quad (\epsilon) \quad \text{then} \quad u \sim v \quad (\epsilon); \tag{26}$$

$$u \approx u \quad (\epsilon); \tag{27}$$

$$\text{if} \quad u \prec v \quad (\epsilon) \quad \text{then} \quad u < v; \tag{28}$$

$$\text{if} \quad u \prec v \quad (\epsilon_1) \quad \text{and} \quad \epsilon_1 \geq \epsilon_2 \quad \text{then} \quad u \prec v \quad (\epsilon_2); \tag{29}$$

$$\text{if} \quad u \sim v \quad (\epsilon_1) \quad \text{and} \quad \epsilon_1 \leq \epsilon_2 \quad \text{then} \quad u \sim v \quad (\epsilon_2); \tag{30}$$

$$\text{if} \quad u \approx v \quad (\epsilon_1) \quad \text{and} \quad \epsilon_1 \leq \epsilon_2 \quad \text{then} \quad u \approx v \quad (\epsilon_2); \tag{31}$$

$$\text{if} \quad u \prec v \quad (\epsilon_1) \quad \text{and} \quad v \prec w \quad (\epsilon_2) \quad \text{then} \quad u \prec w \quad (\epsilon_1 + \epsilon_2); \tag{32}$$

$$\text{if} \quad u \approx v \quad (\epsilon_1) \quad \text{and} \quad v \approx w \quad (\epsilon_2) \quad \text{then} \quad u \sim w \quad (\epsilon_1 + \epsilon_2). \tag{33}$$

Moreover, we can prove without difficulty that

$$|u - v| \le \epsilon|u| \quad \text{and} \quad |u - v| \le \epsilon|v| \quad \text{implies} \quad u \approx v \quad (\epsilon); \tag{34}$$
$$|u - v| \le \epsilon|u| \quad \text{or} \quad |u - v| \le \epsilon|v| \quad \text{implies} \quad u \sim v \quad (\epsilon); \tag{35}$$

and conversely, for *normalized* floating point numbers u and v, when $\epsilon < 1$,

$$u \approx v \quad (\epsilon) \quad \text{implies} \quad |u - v| \le b\epsilon|u| \quad \text{and} \quad |u - v| \le b\epsilon|v|; \tag{36}$$
$$u \sim v \quad (\epsilon) \quad \text{implies} \quad |u - v| \le b\epsilon|u| \quad \text{or} \quad |u - v| \le b\epsilon|v|. \tag{37}$$

Let $\epsilon_0 = b^{1-p}$ be one ulp. The derivation of (17) establishes the inequality $|x - \text{round}(x)| = |\rho(x)| < \frac{1}{2}\epsilon_0 \min\bigl(|x|, |\text{round}(x)|\bigr)$, hence

$$x \approx \text{round}(x) \quad (\tfrac{1}{2}\epsilon_0); \tag{38}$$

it follows that $u \oplus v \approx u + v \ (\frac{1}{2}\epsilon_0)$, etc. The approximate associative law for multiplication derived above can be recast as follows: We have

$$|(u \otimes v) \otimes w - u \otimes (v \otimes w)| < \frac{2\epsilon_0}{(1 - \frac{1}{2}\epsilon_0)^2}|u \otimes (v \otimes w)|$$

by (19), and the same inequality is valid with $(u \otimes v) \otimes w$ and $u \otimes (v \otimes w)$ interchanged. Hence by (34),

$$(u \otimes v) \otimes w \approx u \otimes (v \otimes w) \quad (\epsilon) \tag{39}$$

whenever $\epsilon \ge 2\epsilon_0/(1 - \frac{1}{2}\epsilon_0)^2$. For example, if $b = 10$ and $p = 8$ we may take $\epsilon = 0.00000021$.

The relations $\prec$, $\sim$, $\succ$, and $\approx$ are useful within numerical algorithms, and it is therefore a good idea to provide routines for comparing floating point numbers as well as for doing arithmetic on them.

Let us now shift our attention back to the question of finding *exact* relations that are satisfied by the floating point operations. It is interesting to note that floating point addition and subtraction are not completely intractable from an axiomatic standpoint, since they do satisfy the nontrivial identities stated in the following theorems.

Theorem A. *Let u and v be normalized floating point numbers. Then*

$$\bigl((u \oplus v) \ominus u\bigr) + \bigl((u \oplus v) \ominus \bigl((u \oplus v) \ominus u\bigr)\bigr) = u \oplus v, \tag{40}$$

provided that no exponent overflow or underflow occurs.

This rather cumbersome-looking identity can be rewritten in a simpler manner: Let

$$\begin{aligned} u' &= (u \oplus v) \ominus v, \qquad & v' &= (u \oplus v) \ominus u; \\ u'' &= (u \oplus v) \ominus v', \qquad & v'' &= (u \oplus v) \ominus u'. \end{aligned} \tag{41}$$

Intuitively, u' and u'' should be approximations to u, and v' and v'' should be approximations to v. Theorem A tells us that

$$u \oplus v = u' + v'' = u'' + v'. \tag{42}$$

This is a stronger statement than the identity

$$u \oplus v = u' \oplus v'' = u'' \oplus v', \tag{43}$$

which follows by rounding (42).

Proof. Let us say that t is a *tail* of x modulo b^e if

$$t \equiv x \text{ (modulo } b^e), \qquad |t| \le \tfrac{1}{2} b^e; \tag{44}$$

thus, $x - \text{round}(x)$ is always a tail of x. The proof of Theorem A rests largely on the following simple fact proved in exercise 11:

Lemma T. *If t is a tail of the floating point number x, then $x \ominus t = x - t$.* ∎

Let $w = u \oplus v$. Theorem A holds trivially when $w = 0$. By multiplying all variables by a suitable power of b, we may assume without loss of generality that $e_w = p$. Then $u + v = w + r$, where r is a tail of $u + v$ modulo 1. Furthermore $u' = \text{round}(w - v) = \text{round}(u - r) = u - r - t$, where t is a tail of $u - r$ modulo b^e and $e = e_{u'} - p$.

If $e \le 0$, then $t \equiv u - r \equiv -v$ (modulo b^e), hence t is a tail of $-v$ and $v'' = \text{round}(w - u') = \text{round}(v + t) = v + t$; this proves (40). If $e > 0$, then $|u - r| \ge b^p - \frac{1}{2}$; and since $|r| \le \frac{1}{2}$, we have $|u| \ge b^p - 1$. It follows that r is a tail of v modulo 1. If $u' = u$, we have $v'' = \text{round}(w - u) = \text{round}(v - r) = v - r$. Otherwise the relation $\text{round}(u - r) \ne u$ implies that $|u| = b^p - 1$, $|r| = \frac{1}{2}$, $|u'| = b^p$; we have $v'' = \text{round}(w - u') = \text{round}(v + r) = v + r$, because r is also a tail of $-v$ in this case. ∎

Theorem A exhibits a regularity property of floating point addition, but it doesn't seem to be an especially useful result. The following identity is more significant:

Theorem B. *Under the hypotheses of Theorem A and* (41),

$$u + v = (u \oplus v) + \big((u \ominus u') \oplus (v \ominus v'')\big). \tag{45}$$

Proof. In fact, we can show that $u \ominus u' = u - u'$, $v \ominus v'' = v - v''$, and $(u - u') \oplus (v - v'') = (u - u') + (v - v'')$, hence (45) will follow from Theorem A.

Using the notation of the preceding proof, these relations are respectively equivalent to

$$\text{round}(t + r) = t + r, \qquad \text{round}(t) = t, \qquad \text{round}(r) = r. \tag{46}$$

Exercise 12 establishes the theorem in the special case $|e_u - e_v| \geq p$. Otherwise $u + v$ has at most $2p$ significant digits and it is easy to see that $\text{round}(r) = r$. If now $e > 0$, the proof of Theorem A shows that $t = -r$ or $t = r = \pm\frac{1}{2}$. If $e \leq 0$ we have $t + r \equiv u$ and $t \equiv -v$ (modulo b^e); this is enough to prove that $t + r$ and r round to themselves, provided that $e_u \geq e$ and $e_v \geq e$. But either $e_u < 0$ or $e_v < 0$ would contradict our hypothesis that $|e_u - e_v| < p$, since $e_w = p$. ∎

Theorem B gives *an explicit formula for the difference* between $u + v$ and $u \oplus v$, in terms of quantities that can be calculated directly using five operations of floating point arithmetic. If the radix b is 2 or 3, we can improve on this result, obtaining the exact value of the correction term with only two floating point operations and one (fixed point) comparison of absolute values:

Theorem C. *If $b \leq 3$ and $|u| \geq |v|$, then*

$$u + v = (u \oplus v) + \big(u \ominus (u \oplus v)\big) \oplus v. \tag{47}$$

Proof. Following the conventions of preceding proofs again, we wish to show that $v \ominus v' = r$. It suffices to show that $v' = w - u$, because (46) will then yield $v \ominus v' = \text{round}(v - v') = \text{round}(u + v - w) = \text{round}(r) = r$.

We shall in fact prove (47) whenever $b \leq 3$ and $e_u \geq e_v$. If $e_u \geq p$, then r is a tail of v modulo 1, hence $v' = w \ominus u = v \ominus r = v - r = w - u$ as desired. If $e_u < p$, then we must have $e_u = p - 1$, and $w - u$ is a multiple of b^{-1}; it will therefore round to itself if its magnitude is less than $b^{p-1} + b^{-1}$. Since $b \leq 3$, we have indeed $|w - u| \leq |w - u - v| + |v| \leq \frac{1}{2} + (b^{p-1} - b^{-1}) < b^{p-1} + b^{-1}$. This completes the proof. ∎

The proofs of Theorems A, B, and C do not rely on the precise definitions of $\text{round}(x)$ in the ambiguous cases when x is exactly midway between consecutive floating point numbers; any way of resolving the ambiguity will suffice for the validity of everything we have proved so far.

No rounding rule can be best for every application. For example, we generally want a special rule when computing our income tax. But for most numerical calculations the best policy appears to be the rounding scheme specified in Algorithm 4.2.1N, which insists that the least significant digit should always be made even (or always odd) when an ambiguous value is rounded. This is not a trivial technicality, of interest only to nit-pickers; it is an important practical consideration, since the ambiguous case arises surprisingly often and a biased rounding rule produces significantly poor results. For example, consider decimal arithmetic and assume that remainders of 5 are always rounded upwards. Then if $u = 1.0000000$ and $v = 0.55555555$ we have $u \oplus v = 1.5555556$; and if

we floating-subtract v from this result we get $u' = 1.0000001$. Adding and subtracting v from u' gives 1.0000002, and the next time we get 1.0000003, etc.; the result keeps growing although we are adding and subtracting the same value.

This phenomenon, called *drift*, will not occur when we use a stable rounding rule based on the parity of the least significant digit. More precisely:

Theorem D. $(((u \oplus v) \ominus v) \oplus v) \ominus v = (u \oplus v) \ominus v$.

For example, if $u = 1.2345679$ and $v = -0.23456785$, we find $u \oplus v = 1.0000000$, $(u \oplus v) \ominus v = 1.2345678$, $((u \oplus v) \ominus v) \oplus v = 0.99999995$, and $(((u \oplus v) \ominus v) \oplus v) \ominus v = 1.2345678$. The proof for general u and v seems to require a case analysis even more detailed than that in the above theorems; see the references at the end of this section. ∎

Theorem D is valid both for "round to even" and "round to odd"; how should we choose between these possibilities? When the radix b is odd, ambiguous cases never arise except during floating point division, and the rounding in such cases is comparatively unimportant. For *even* radices, there is reason to prefer the following rule: "Round to even when $b/2$ is odd, round to odd when $b/2$ is even." The least significant digit of a floating point fraction occurs frequently as a remainder to be rounded off in subsequent calculations, and this rule avoids generating the digit $b/2$ in the least significant position whenever possible; its effect is to provide some memory of an ambiguous rounding so that subsequent rounding will tend to be unambiguous. For example, if we were to round to odd in the decimal system, repeated rounding of the number 2.44445 to one less place each time leads to the sequence 2.4445, 2.445, 2.45, 2.5, 3; but if we round to even, such situations do not occur. [Roy A. Keir, *Inf. Proc. Letters* **3** (1975), 188–189.] On the other hand, some people prefer rounding to even in all cases, so that the remainder will tend to be 0 more often. Neither alternative conclusively dominates the other; fortunately the base is usually $b = 2$ or $b = 10$, when everyone agrees that round-to-even is best.

A reader who has checked some of the details of the above proofs will realize the immense simplification that has been afforded by the simple rule $u \oplus v = \text{round}(u + v)$. If our floating point addition routine would fail to give this result even in a few rare cases, the proofs would become enormously more complicated and perhaps they would even break down completely.

Theorem B fails if truncation arithmetic is used in place of rounding, i.e., if we let $u \oplus v = \text{trunc}(u + v)$ and $u \ominus v = \text{trunc}(u - v)$, where $\text{trunc}(x)$ takes all positive real x into the largest floating point number $\leq x$. An exception to Theorem B would then occur for cases such as $(20, +.10000001) \oplus (10, -.10000001) = (20, +.10000000)$, when the difference between $u + v$ and $u \oplus v$ cannot be expressed exactly as a floating point number; and also for cases such as $12345678 \oplus .012345678$, when it can be.

Many people feel that, since floating point arithmetic is inexact by nature, there is no harm in making it just a little bit less exact in certain rather rare cases, if it is convenient to do so. This policy saves a few cents in the design of computer

hardware, or a small percentage of the average running time of a subroutine. But the above discussion shows that such a policy is mistaken. We could save about five percent of the running time of the FADD subroutine, Program 4.2.1A, and about 25 percent of its space, if we took the liberty of rounding incorrectly in a few cases, but we are much better off leaving it as it is. The reason is not to glorify "bit chasing"; a more fundamental issue is at stake here: *Numerical subroutines should deliver results that satisfy simple, useful mathematical laws whenever possible.* The crucial formula $u \oplus v = \text{round}(u + v)$ is a "regularity" property that makes a great deal of difference between whether mathematical analysis of computational algorithms is worth doing or worth avoiding. Without any underlying symmetry properties, the job of proving interesting results becomes extremely unpleasant. *The enjoyment of one's tools is an essential ingredient of successful work.*

B. Unnormalized floating point arithmetic. The policy of normalizing all floating point numbers may be construed in two ways: We may look on it favorably by saying that it is an attempt to get the maximum possible accuracy obtainable with a given degree of precision, or we may consider it to be potentially dangerous since it tends to imply that the results are more accurate than they really are. When we normalize the result of $(1, +.31428571) \ominus (1, +.31415927)$ to $(-2, +.12644000)$, we are suppressing information about the possibly greater inaccuracy of the latter quantity. Such information would be retained if the answer were left as $(1, +.00012644)$.

The input data to a problem is frequently not known as precisely as the floating point representation allows. For example, the values of Avogadro's number and Planck's constant are not known to eight significant digits, and it might be more appropriate to denote them, respectively, by

$$(27, +.00060225) \qquad \text{and} \qquad (-23, +.00010545)$$

instead of by $(24, +.60225200)$ and $(-26, +.10545000)$. It would be nice if we could give our input data for each problem in an unnormalized form that expresses how much precison is assumed, and if the output would indicate just how much precision is known in the answer. Unfortunately, this is a terribly difficult problem, although the use of unnormalized arithmetic can help to give some indication. For example, we can say with a fair degree of certainty that the product of Avogadro's number by Planck's constant is $(0, +.00063507)$, and that their sum is $(27, +.00060225)$. (The purpose of this example is not to suggest that any important physical significance should be attached to the sum and product of these fundamental constants; the point is that it is possible to preserve a little of the information about precision in the result of calculations with imprecise quantities, when the original operands are independent of each other.)

The rules for unnormalized arithmetic are simply this: Let l_u be the number of leading zeros in the fraction part of $u = (e_u, f_u)$, so that l_u is the largest integer $\leq p$ with $|f_u| < b^{-l_u}$. Then addition and subtraction are performed

just as in Algorithm 4.2.1A, except that all scaling to the left is suppressed. Multiplication and division are performed as in Algorithm 4.2.1M, except that the answer is scaled right or left so that precisely $\max(l_u, l_v)$ leading zeros appear. Essentially the same rules have been used in manual calculation for many years.

It follows that, for unnormalized computations,

$$e_{u\oplus v},\ e_{u\ominus v} = \max(e_u, e_v) + (0 \text{ or } 1) \tag{48}$$

$$e_{u\otimes v} = e_u + e_v - q - \min(l_u, l_v) - (0 \text{ or } 1) \tag{49}$$

$$e_{u\oslash v} = e_u - e_v + q - l_u + l_v + \max(l_u, l_v) + (0 \text{ or } 1). \tag{50}$$

When the result of a calculation is zero, an unnormalized zero (often called an "order of magnitude zero") is given as the answer; this indicates that the answer may not truly be zero, we just don't know any of its significant digits.

Error analysis takes a somewhat different form with unnormalized floating point arithmetic. Let us define

$$\delta_u = \tfrac{1}{2} b^{e_u - q - p} \qquad \text{if } u = (e_u, f_u). \tag{51}$$

This quantity depends on the representation of u, not just on the value $b^{e_u-q} f_u$. Our rounding rule tells us that

$$|u \oplus v - (u + v)| \le \delta_{u\oplus v}, \qquad |u \ominus v - (u - v)| \le \delta_{u\ominus v},$$
$$|u \otimes v - (u \times v)| \le \delta_{u\otimes v}, \qquad |u \oslash v - (u \,/\, v)| \le \delta_{u\oslash v}.$$

These inequalities apply to normalized as well as unnormalized arithmetic; the main difference between the two types of error analysis is the definition of the exponent of the result of each operation (Eqs. (48) to (50)).

We have remarked that the relations $\prec$, $\sim$, $\succ$, and $\approx$ defined earlier in this section are valid and meaningful for unnormalized numbers as well as for normalized numbers. As an example of the use of these relations, let us prove an approximate associative law for unnormalized addition, analogous to (39):

$$(u \oplus v) \oplus w \approx u \oplus (v \oplus w) \quad (\epsilon), \tag{52}$$

for suitable ϵ. We have

$$\begin{aligned} |(u \oplus v) \oplus w - (u + v + w)| &\le |(u \oplus v) \oplus w - ((u \oplus v) + w)| \\ &\quad + |u \oplus v - (u + v)| \\ &\le \delta_{(u\oplus v)\oplus w} + \delta_{u\oplus v} \\ &\le 2\delta_{(u\oplus v)\oplus w}. \end{aligned}$$

A similar formula holds for $|u \oplus (v \oplus w) - (u + v + w)|$. Now since $e_{(u\oplus v)\oplus w} = \max(e_u, e_v, e_w) + (0, 1, \text{or } 2)$, we have $\delta_{(u\oplus v)\oplus w)} \le b^2 \delta_{u\oplus(v\oplus w)}$. Therefore we

find that (52) is valid when $\epsilon \geq 2b^{2-p}$; unnormalized addition is not as erratic as normalized addition with respect to the associative law.

It should be emphasized that unnormalized arithmetic is by no means a panacea. There are examples where it indicates greater accuracy than is present (e.g., addition of a great many small quantities of about the same magnitude, or evaluation of x^n for large n); and there are many more examples when it indicates poor accuracy while normalized arithmetic actually does produce good results. There is an important reason why no straightforward one-operation-at-a-time method of error analysis can be completely satisfactory, namely the fact that operands are usually not independent of each other. This means that errors tend to cancel or reinforce each other in strange ways. For example, suppose that x is approximately $\frac{1}{2}$, and suppose that we have an approximation $y = x + \delta$ with absolute error δ. If we now wish to compute $x(1-x)$, we can form $y(1-y)$; if $x = \frac{1}{2} + \epsilon$ we find $y(1-y) = x(1-x) - 2\epsilon\delta - \delta^2$, so the error has decreased substantially: it has been multiplied by a factor of $2\epsilon + \delta$. This is just one case where multiplication of imprecise quantities can lead to a quite accurate result when the operands are not independent of each other. A more obvious example is the computation of $x \ominus x$, which can be obtained with perfect accuracy regardless of how bad an approximation to x we begin with.

The extra information that unnormalized arithmetic gives us can often be more important than the information it destroys during an extended calculation, but (as usual) we must use it with care. Examples of the proper use of unnormalized arithmetic are discussed by R. L. Ashenhurst and N. Metropolis in *Computers and Computing, AMM* Slaught Memorial Papers **10** (February, 1965), 47–59; by N. Metropolis in *Numer. Math.* **7** (1965), 104–112; and by R. L. Ashenhurst in *Error in Digital Computation* **2**, ed. by L. B. Rall (New York: Wiley, 1965), 3–37. Appropriate methods for computing standard mathematical functions with both input and output in unnormalized form are given by R. L. Ashenhurst in *JACM* **11** (1964), 168–187. An extension of unnormalized arithmetic, which remembers that certain values are known to be *exact*, has been discussed by N. Metropolis in *IEEE Trans.* **C–22** (1973), 573–576.

C. Interval arithmetic. Another approach to the problem of error determination is the so-called interval or range arithmetic, in which upper and lower bounds on each number are maintained during the calculations. Thus, for example, if we know that $u_0 \leq u \leq u_1$ and $v_0 \leq v \leq v_1$, we represent this by the interval notation $u = [u_0, u_1]$, $v = [v_0, v_1]$. The sum $u \oplus v$ is $[u_0 \bigtriangledown v_0, u_1 \bigtriangleup v_1]$, where $\bigtriangledown$ denotes "lower floating point addition," the greatest representable number less than or equal to the true sum, and $\bigtriangleup$ is defined similarly (see exercise 4.2.1–13). Furthermore $u \ominus v = [u_0 \bigtriangledown v_1, u_1 \bigtriangleup v_0]$; and if u_0 and v_0 are positive, we have $u \otimes v = [u_0 \bigtriangledown v_0, u_1 \bigtriangleup v_1]$, $u \oslash v = [u_0 \bigtriangledown v_1, u_1 \bigtriangleup v_0]$. For example, we might represent Avogadro's number and Planck's constant as

$$N = [(24, +.60222400), (24, +.60228000)],$$
$$\hbar = [(-26, +.10544300), (-26, +.10545700)];$$

their sum and product would then turn out to be

$$N \oplus \hbar = [(24, +.60222400), (24, +.60228001)],$$
$$N \otimes \hbar = [(-3, +.63500305), (-3, +.63514642)].$$

If we try to divide by $[v_0, v_1]$ when $v_0 < 0 < v_1$, there is a possibility of division by zero. Since the philosophy underlying interval arithmetic is to provide rigorous error estimates, a divide-by-zero error should be signalled in this case. However, overflow and underflow need not be treated as errors in interval arithmetic, if special conventions are introduced as discussed in exercise 24.

Interval arithmetic takes only about twice as long as ordinary arithmetic, and it provides truly reliable error estimates. Considering the difficulty of mathematical error analyses, this is indeed a small price to pay. Since the intermediate values in a calculation often depend on each other, as explained above, the final estimates obtained with interval arithmetic will tend to be pessimistic; and iterative numerical methods often have to be redesigned if we want to deal with intervals. The prospects for effective use of interval arithmetic look very good, however, and efforts should be made to increase its availability.

D. History and bibliography. Jules Tannery's classic treatise on decimal calculations, *Leçons d'Arithmétique* (Paris: Colin, 1894), stated that positive numbers should be rounded upwards if the first discarded digit is 5 or more; since exactly half of the decimal digits are 5 or more, he felt that this rule would round upwards exactly half of the time, on the average, so it would produce compensating errors. The idea of "round to even" in the ambiguous cases seems to have been mentioned first by James B. Scarborough in the first edition of his pioneering book *Numerical Mathematical Analysis* (Baltimore: Johns Hopkins Press, 1930), p. 2; in the second (1950) edition he amplified his earlier remarks, stating that "It should be obvious to any thinking person that when a 5 is cut off, the preceding digit should be increased by 1 in only *half* the cases," and he recommended round-to-even in order to achieve this.

The first analysis of floating point arithmetic was given by F. L. Bauer and K. Samelson, *Zeitschrift für angewandte Math. und Physik* **4** (1953), 312–316. The next publication was not until over five years later: J. W. Carr III, *CACM* **2**, 5 (May 1959), 10–15. See also P. C. Fischer, *Proc. ACM Nat. Meeting* **13** (Urbana, Illinois, 1958), paper 39. The book *Rounding Errors in Algebraic Processes* (Englewood Cliffs: Prentice-Hall, 1963), by J. H. Wilkinson, shows how to apply error analysis of the individual arithmetic operations to the error analysis of large-scale problems; see also his treatise on *The Algebraic Eigenvalue Problem* (Oxford: Clarendon Press, 1965).

More recent work on floating point accuracy is summarized in two important papers that can be especially recommended for further study: W. M. Kahan, *Proc. IFIP Congress* (1971), **2**, 1214–1239; R. P. Brent, *IEEE Trans.* **C–22** (1973), 601–607. Both papers include useful theory and demonstrate that it pays off in practice.

The relations $\prec$, $\sim$, $\succ$, $\approx$ introduced in this section are similar to ideas published by A. van Wijngaarden in *BIT* **6** (1966), 66–81. Theorems A and B above were inspired by some related work of Ole Møller, *BIT* **5** (1965), 37–50, 251–255; Theorem C is due to T. J. Dekker, *Numer. Math.* **18** (1971), 224–242. Extensions and refinements of all three theorems have been published by S. Linnainmaa, *BIT* **14** (1974), 167–202. W. M. Kahan introduced Theorem D in some unpublished notes; for a complete proof and further commentary, see J. F. Reiser and D. E. Knuth, *Inf. Proc. Letters* **3** (1975), 84–87, 164.

Unnormalized floating point arithmetic was recommended by F. L. Bauer and K. Samelson in the article cited above, and it was independently used by J. W. Carr III at the University of Michigan in 1953. Several years later, the MANIAC III computer was designed to include both kinds of arithmetic in its hardware; see R. L. Ashenhurst and N. Metropolis, *JACM* **6** (1959), 415–428, *IEEE Trans.* **EC–12** (1963), 896–901; R. L. Ashenhurst, *Proc. Spring Joint Computer Conf.* **21** (1962), 195–202. See also H. L. Gray and C. Harrison, Jr., *Proc. Eastern Joint Computer Conf.* **16** (1959), 244–248, and W. G. Wadey, *JACM* **7** (1960), 129–139, for further early discussions of unnormalized arithmetic.

For early developments in interval arithmetic, and some modifications, see A. Gibb, *CACM* **4** (1961), 319–320; B. A. Chartres, *JACM* **13** (1966), 386–403; and the book *Interval Analysis* by Ramon E. Moore (Prentice–Hall, 1966). The subsequent flourishing of this subject is described in Moore's later book, *Methods and Applications of Interval Analysis* (SIAM, 1979).

The book *Grundlagen des Numerischen Rechnens: Mathematische Begrundung der Rechenarithmetik* by Ulrich Kulisch (Mannheim: Bibl. Inst., 1976) is entirely devoted to the study of floating point arithmetic systems; see also Kulisch's article in *IEEE Trans.* **C–26** (1977), 610–621, and his more recent book written jointly with W. L. Miranker, entitled *Computer Arithmetic in Theory and Practice* (New York: Academic Press, 1980).

EXERCISES

Note: Normalized floating point arithmetic is assumed unless the contrary is specified.

1. [*M18*] Prove that identity (7) is a consequence of (2) through (6).

2. [*M20*] Use identities (2) through (8) to prove that $(u \oplus x) \oplus (v \oplus y) \geq u \oplus v$ whenever $x \geq 0$ and $y \geq 0$.

3. [*M20*] Find eight-digit floating decimal numbers u, v, and w such that

$$u \otimes (v \otimes w) \neq (u \otimes v) \otimes w,$$

and such that no exponent overflow or underflow occurs during the computations.

4. [*10*] Is it possible to have floating point numbers u, v, and w for which exponent overflow occurs during the calculation of $u \otimes (v \otimes w)$ but not during the calculation of $(u \otimes v) \otimes w$?

5. [*M20*] Is $u \oslash v = u \otimes (1 \oslash v)$ an identity, for all floating point numbers u and $v \neq 0$ such that no exponent overflow or underflow occurs?

6. [*M22*] Are either of the following two identities valid for all floating point numbers u? (a) $0 \ominus (0 \ominus u) = u$; (b) $1 \oslash (1 \oslash u) = u$.

7. [*M21*] Let $u^{(2)}$ stand for $u \otimes u$. Find floating binary numbers u and v such that $2(u^{(2)} + v^{(2)}) < (u \oplus v)^{(2)}$.

▶ **8.** [*20*] Let $\epsilon = 0.0001$; which of the relations

$$u \prec v \quad (\epsilon), \qquad u \sim v \quad (\epsilon), \qquad u \succ v \quad (\epsilon), \qquad u \approx v \quad (\epsilon)$$

hold for the following pairs of base 10, excess 0, eight-digit floating point numbers?

a) $u = (1, +.31415927)$, $v = (1, +.31416000)$;
b) $u = (0, +.99997000)$, $v = (1, +.10000039)$;
c) $u = (24, +.60225200)$, $v = (27, +.00060225)$;
d) $u = (24, +.60225200)$, $v = (31, +.00000006)$;
e) $u = (24, +.60225200)$, $v = (32, +.00000000)$.

9. [*M22*] Prove (33), and explain why the conclusion cannot be strengthened to the relation $u \approx w\ (\epsilon_1 + \epsilon_2)$.

▶ **10.** [*M25*] (W. M. Kahan.) A certain computer performs floating point arithmetic without proper rounding, and, in fact, its floating point multiplication routine ignores all but the first p most significant digits of the $2p$-digit product $f_u f_v$. (Thus when $f_u f_v < 1/b$, the least-significant digit of $u \otimes v$ always comes out to be zero, due to subsequent normalization.) Show that this causes the monotonicity of multiplication to fail; i.e., there are positive normalized floating point numbers u, v, w such that $u < v$ but $u \otimes w > v \otimes w$.

11. [*M20*] Prove Lemma T.

12. [*M24*] Carry out the proof of Theorem B and (46) when $|e_u - e_v| \geq p$.

▶ **13.** [*M25*] Some programming languages (and even some computers) make use of floating point arithmetic only, with no provision for exact calculations with integers. If operations on integers are desired, we can, of course, represent an integer as a floating point number; and when the floating point operations satisfy the basic definitions in (9), we know that all floating point operations will be exact, provided that the operands and the answer can each be represented exactly with p significant digits. Therefore—so long as we know that the numbers aren't too large—we can add, subtract, or multiply integers with no inaccuracy due to rounding errors.

But suppose that a programmer wants to determine if m is an exact multiple of n, when m and $n \neq 0$ are integers. Suppose further that a subroutine is available to calculate the quantity $\text{round}(u \bmod 1) = u \bmod 1$ for any given floating point number u, as in exercise 4.2.1–15. One good way to determine whether or not m is a multiple of n might be to test whether or not $(m \oslash n) \bmod 1 = 0$, using the assumed subroutine; but perhaps rounding errors in the floating point calculations will invalidate this test in certain cases.

Find suitable conditions on the range of integer values $n \neq 0$ and m, such that m is a multiple of n if and only if $(m \oslash n) \bmod 1 = 0$. In other words, show that if m and n are not too large, this test is valid.

14. [*M27*] Find a suitable ϵ such that $(u \otimes v) \otimes w \approx u \otimes (v \otimes w)$ (ϵ), when *unnormalized* multiplication is being used. (This generalizes (39), since unnormalized multiplication is exactly the same as normalized multiplication when the input operands u, v, and w are normalized.)

▶ **15.** [*M24*] (H. Björk.) Does the computed midpoint of an interval always lie between the endpoints? (In other words, does $u \le v$ imply that $u \le (u \oplus v) \oslash 2 \le v$?)

16. [*M28*] (a) What is $(\cdots((x_1 \oplus x_2) \oplus x_3) \oplus \cdots \oplus x_n)$ when $n = 10^6$ and $x_k = 1.1111111$ for all k, using eight-digit floating decimal arithmetic? (b) What happens when Eq. (14) is used to calculate the standard deviation of these particular values x_k? What happens when Eqs. (15) and (16) are used instead? (c) Prove that $S_k \ge 0$ in (16), for all choices of $x_1, \ldots, x_k$.

17. [*28*] Write a MIX subroutine, FCMP, that compares the floating point number u in location ACC with the floating point number v in register A, and that sets the comparison indicator to LESS, EQUAL, or GREATER, according as $u \prec v$, $u \sim v$, or $u \succ v$ (ϵ); here ϵ is stored in location EPSILON as a nonnegative fixed point quantity with the decimal point assumed at the left of the word. Assume normalized inputs.

18. [*M40*] In unnormalized arithmetic is there a suitable number ϵ such that

$$u \otimes (v \oplus w) \approx (u \otimes v) \oplus (u \otimes w) \quad (\epsilon)?$$

▶ **19.** [*M30*] (W. M. Kahan.) Consider the following procedure for floating point summation of $x_1, \ldots, x_n$:

$$s_0 = c_0 = 0;$$
$$y_k = x_k \ominus c_{k-1}, \quad s_k = s_{k-1} \oplus y_k, \quad c_k = (s_k \ominus s_{k-1}) \ominus y_k, \qquad \text{for } 1 \le k \le n.$$

Let the relative errors in these operations be defined by the equations

$$y_k = (x_k - c_{k-1})(1 + \eta_k), \qquad s_k = (s_{k-1} + y_k)(1 + \sigma_k),$$
$$c_k = ((s_k - s_{k-1})(1 + \gamma_k) - y_k)(1 + \delta_k),$$

where $|\eta_k|, |\sigma_k|, |\gamma_k|, |\delta_k| \le \epsilon$. Prove that $s_n = \sum_{1 \le k \le n} (1 + \theta_k) x_k$, where $|\theta_k| \le 2\epsilon + O(n\epsilon^2)$. [Theorem C says that if $b = 2$ and $|s_{k-1}| \ge |y_k|$ we have $s_{k-1} + y_k = s_k - c_k$ exactly. But in this exercise we want to obtain an estimate that is valid *even when floating point operations are not carefully rounded*, assuming only that each operation has bounded relative error.]

20. [*25*] (S. Linnainmaa.) Find all u, v for which $|u| \ge |v|$ and (47) fails.

21. [*M35*] (T. J. Dekker.) Theorem C shows how to do exact addition of floating binary numbers. Explain how to do *exact multiplication*: Express the product uv in the form $w + w'$, where w and w' are computed from two given floating binary numbers u and v, using only the operations $\oplus$, $\ominus$, and $\otimes$.

22. [*M30*] Can drift occur in floating point multiplication/division? Consider the sequence $x_0 = u$, $x_{2n+1} = x_{2n} \otimes v$, $x_{2n+2} = x_{2n+1} \oslash v$, given u and v; what is the largest subscript k such that $x_k \ne x_{k+2}$ is possible?

▶ **23.** [*M26*] Prove or disprove: $u \ominus (u \bmod 1) = \lfloor u \rfloor$, for all floating point u.

24. [*M27*] Consider the set of all intervals $[u_l, u_r]$, where u_l and u_r are either nonzero floating point numbers or the special symbols $+0$, -0, $+\infty$, $-\infty$; each interval must have $u_l \le u_r$, and $u_l = u_r$ is allowed only when u_l is finite and nonzero. The interval $[u_l, u_r]$ stands for all floating point x such that $u_l \le x \le u_r$, where we regard

$$-\infty < -x < -0 < +0 < +x < +\infty$$

for all positive x. (Thus, $[1, 2]$ means $1 \le x \le 2$; $[+0, 1]$ means $0 < x \le 1$; $[-0, 1]$ means $0 \le x \le 1$; $[-0, +0]$ denotes the single value 0; and $[-\infty, +\infty]$ stands for everything.) Show how to define appropriate arithmetic operations on all such intervals, without resorting to "overflow" or "underflow" or other anomalous indications except when dividing by an interval that includes zero.

▶ **25.** [*15*] When people speak about inaccuracy in floating point arithmetic they often ascribe errors to "cancellation" that occurs during the subtraction of nearly equal quantities. But when u and v are approximately equal, the difference $u \ominus v$ is obtained exactly, with no error. What do these people really mean?

26. [*HM30*] (H. G. Diamond.) Suppose $f(x)$ is a strictly increasing function on some interval $[x_0, x_1]$, and let $g(x)$ be the inverse function. (For example, f and g might be "exp" and "ln", or "tan" and "arctan".) If x is a floating point number such that $x_0 \le x \le x_1$, let $\hat{f}(x) = \text{round}(f(x))$, and if y is a floating point number such that $f(x_0) \le y \le f(x_1)$, let $\hat{g}(y) = \text{round}(g(y))$; furthermore, let $h(x) = \hat{g}(\hat{f}(x))$, whenever this is defined. Although $h(x)$ won't always be equal to x, due to rounding, we expect $h(x)$ to be "near" x.

Prove that if the precision b^p is at least 3, and if f is strictly concave or strictly convex (i.e., $f''(x) < 0$ or $f''(x) > 0$ for all x in $[x_0, x_1]$), then repeated application of h will be *stable* in the sense that

$$h(h(h(x))) = h(h(x)),$$

for all x such that both sides of this equation are defined. In other words, there will be no "drift" if the subroutines are properly implemented.

▶ **27.** [*M25*] (W. M. Kahan.) Let $f(x) = 1 + x + \cdots + x^{106} = (1 - x^{107})/(1 - x)$ for $x < 1$, and let $g(y) = f((\frac{1}{3} - y^2)(3 + 3.45y^2))$ for $0 < y < 1$. Evaluate $g(y)$ on one or more "pocket calculators," for $y = 10^{-3}$, 10^{-4}, 10^{-5}, 10^{-6}, and explain all inaccuracies in the results you obtain. (Since most present-day calculators do not round correctly, the results are often surprising. Note that $g(\epsilon) = 107 - 10491.35\epsilon^2 + O(\epsilon^4)$.)

*4.2.3. Double-Precision Calculations

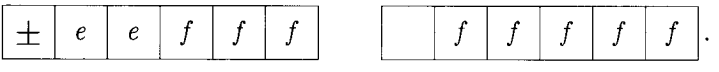
Up to now we have considered "single-precision" floating point arithmetic, which essentially means that the floating point values we have dealt with can be stored in a single machine word. When single-precision floating point arithmetic does not yield sufficient accuracy for a given application, the precision can be increased by suitable programming techniques that use two or more words of memory to represent each number.

Although we shall discuss the general question of high-precision calculations in Section 4.3, it is appropriate to give a separate discussion of double-precision

here. Special techniques apply to double precision that are comparatively inappropriate for higher precisions; and double precision is a reasonably important topic in its own right, since it is the first step beyond single precision and it is applicable to many problems that do not require extremely high precision.

Double-precision calculations are almost always required for floating point rather than fixed point arithmetic, except perhaps in statistical work where fixed point double-precision is commonly used to calculate sums of squares and cross products; since fixed point versions of double-precision arithmetic are simpler than floating point versions, we shall confine our discussion here to the latter.

Double precision is quite frequently desired not only to extend the precision of the fraction parts of floating point numbers, but also to increase the range of the exponent part. Thus we shall deal in this section with the following two-word format for double-precision floating point numbers in the MIX computer:



(1)

Here two bytes are used for the exponent and eight bytes are used for the fraction. The exponent is "excess $b^2/2$," where b is the byte size. The sign will appear in the most significant word; it is convenient to ignore the sign of the other word completely.

Our discussion of double-precision arithmetic will be quite machine-oriented, because it is only by studying the problems involved in coding these routines that a person can properly appreciate the subject. A careful study of the MIX programs below is therefore essential to the understanding of the material.

In this section we shall depart from the idealistic goals of accuracy stated in the previous two sections; our double-precision routines will *not* round their results, and a little bit of error will sometimes be allowed to creep in. Users dare not trust these routines too much. There was ample reason to squeeze out every possible drop of accuracy in the single-precision case, but now we face a different situation: (a) The extra programming required to ensure true double-precision rounding in all cases is considerable; fully accurate routines would take, say, twice as much space and half again as much more time. It was comparatively easy to make our single-precision routines perfect, but double precision brings us face to face with our machine's limitations. (A similar situation occurs with respect to other floating point subroutines; we can't expect the cosine routine to compute round($\cos x$) exactly for all x, since that turns out to be virtually impossible. Instead, the cosine routine should provide the best relative error it can achieve with reasonable speed, for all reasonable values of x. Of course, the designer of the routine should try to make the computed function satisfy simple mathematical laws whenever possible (e.g., $\textcircled{\cos}(-x) = \textcircled{\cos}\, x$, $|\textcircled{\cos}\, x| \le 1$, and $\textcircled{\cos}\, x \ge \textcircled{\cos}\, y$ for $0 \le x \le y < \pi$).) (b) Single-precision arithmetic is a "staple food" that everybody who wants to employ floating point arithmetic must use, but double precision is usually for situations where such clean results aren't as important. The difference between seven- and eight-place accuracy can be noticeable, but we rarely care about the difference between 15- and 16-place

accuracy. Double precision is most often used for intermediate steps during the calculation of single-precision results; its full potential isn't needed. (c) It will be instructive for us to analyze these procedures in order to see how inaccurate they can be, since they typify the types of short cuts generally taken in bad single-precision routines (see exercises 7 and 8).

Let us now consider addition and subtraction operations from this standpoint. Subtraction is, of course, converted to addition by changing the sign of the second operand. Addition is performed by separately adding together the least-significant halves and the most-significant halves, propagating "carries" appropriately.

A difficulty arises, however, since we are doing signed-magnitude arithmetic: it is possible to add the least-significant halves and to get the wrong sign (namely, when the signs of the operands are opposite and the least-significant half of the smaller operand is bigger than the least-significant half of the larger operand). The simplest solution is to anticipate the correct sign; so in step A2 (cf. Algorithm 4.2.1A), we not only assume that $e_u \geq e_v$, we also assume that $|u| \geq |v|$. This means we can be sure that the final sign will be the sign of u. In other respects, double-precision addition is very much like its single-precision counterpart, only everything is done twice.

Program A (*Double-precision addition*). The subroutine DFADD adds a double-precision floating point number v, having the form (1), to a double-precision floating point number u, assuming that v is initially in rAX (i.e., registers A and X), and that u is initially stored in locations ACC and ACCX. The answer appears both in rAX and in (ACC, ACCX). The subroutine DFSUB subtracts v from u under the same conventions.

Both input operands are assumed to be normalized, and the answer is normalized. The last portion of this program is a double-precision normalization procedure that is used by other subroutines of this section. Exercise 5 shows how to improve the program significantly.

```

```

When the least-significant halves are added together in this program, an extra digit "1" is inserted at the left of the word that is known to have the correct sign. After the addition, this byte can be 0, 1, or 2, depending on the circumstances, and all three cases are handled simultaneously in this way. (Compare this with the rather cumbersome method of complementation that is used in Program 4.2.1A.)

It is worth noting that register A can be zero after the instruction on line 40 has been performed; and, because of the way MIX defines the sign of a zero result, the accumulator contains the correct sign that is to be attached to the result if register X is nonzero. If lines 39 and 40 were interchanged, the program would be incorrect, even though both instructions are "ADD"!

Now let us consider double-precision multiplication. The product has four components, shown schematically in Fig. 4. Since we need only the leftmost eight bytes, it is convenient to work only with the digits to the left of the vertical line in the diagram, and this means in particular that we need not even compute the product of the two least-significant halves.

Program M (*Double-precision multiplication*). The input and output conventions for this subroutine are the same as for Program A.

```
01  BYTE   EQU  1(4:4)          Byte size
02  QQ     EQU  BYTE*BYTE/2     Excess of double-precision exponent
03  DFMUL  STJ  EXITDF          Double-precision multiplication:
04         STA  TEMP
05         SLAX 2               Remove exponent.

         JMP  DNORM          Normalize and exit.  ▮
```

Note the careful treatment of signs in this program, and note also the fact that the range of exponents makes it impossible to compute the final exponent using an index register. Program M is perhaps too slipshod in accuracy, since it throws away all the information to the right of the vertical line in Fig. 4; this can make the least significant byte as much as 2 in error. A little more accuracy can be achieved as discussed in exercise 4.

Double-precision floating division is the most difficult routine, or at least the most frightening prospect we have encountered so far in this chapter. Actually, it is not terribly complicated, once we see how to do it; let us write the numbers to be divided in the form $(u_m + \epsilon u_l)/(v_m + \epsilon v_l)$, where ϵ is the reciprocal of the word size of the computer, and where v_m is assumed to be normalized. The fraction can now be expanded as follows:

$$\begin{aligned}\frac{u_m + \epsilon u_l}{v_m + \epsilon v_l} &= \frac{u_m + \epsilon u_l}{v_m}\left(\frac{1}{1 + \epsilon(v_l/v_m)}\right)\\ &= \frac{u_m + \epsilon u_l}{v_m}\left(1 - \epsilon\left(\frac{v_l}{v_m}\right) + \epsilon^2\left(\frac{v_l}{v_m}\right)^2 - \cdots\right).\end{aligned} \qquad (2)$$

Since $0 \le |v_l| < 1$ and $1/b \le |v_m| < 1$, we have $|v_l/v_m| < b$, and the error from dropping terms involving ϵ^2 can be disregarded. Our method therefore is to compute $w_m + \epsilon w_l = (u_m + \epsilon u_l)/v_m$, and then to subtract ϵ times $w_m v_l/v_m$ from the result.

In the following program, lines 27–32 do the lower half of a double-precision addition, using another method for forcing the appropriate sign as an alternative to the trick of Program A.

Program D (*Double-precision division*). This program adheres to the same conventions as Programs A and M.

```

Here is a table of the approximate average computation times for these double-precision subroutines, compared to the single-precision subroutines that appear in Section 4.2.1:

	Single precision	Double precision
Addition	$45.5u$	$84u$
Subtraction	$49.5u$	$88u$
Multiplication	$48u$	$109u$
Division	$52u$	$126.5u$

For extension of the methods of this section to triple-precision floating point fraction parts, see Y. Ikebe, *CACM* 8 (1965), 175–177.

EXERCISES

1. [*16*] Try the double-precision division technique by hand, with $\epsilon = \frac{1}{1000}$, when dividing 180000 by 314159. (Thus, let $(u_m, u_l) = (.180, .000)$ and $(v_m, v_l) = (.314, .159)$, and find the quotient using the method suggested in the text following (2).)

2. [*20*] Would it be a good idea to insert the instruction "ENTX 0" between lines 30 and 31 of Program M, in order to keep unwanted information left over in register X from interfering with the accuracy of the results?

3. [*M20*] Explain why overflow cannot occur during Program M.

4. [*22*] How should Program M be changed so that extra accuracy is achieved, essentially by moving the vertical line in Fig. 4 over to the right one position? Specify all changes that are required, and determine the difference in execution time caused by these changes.

▸ **5.** [*24*] How should Program A be changed so that extra accuracy is achieved, essentially by working with a nine-byte accumulator instead of an eight-byte accumulator to the right of the decimal point? Specify all changes that are required, and determine the difference in execution time caused by these changes.

6. [*23*] Assume that the double-precision subroutines of this section and the single-precision subroutines of Section 4.2.1 are being used in the same main program. Write a subroutine that converts a single-precision floating point number into double-precision form (1), and write another subroutine that converts a double-precision floating point number into single-precision form (reporting exponent overflow or underflow if the conversion is impossible).

▸ **7.** [*M30*] Estimate the accuracy of the double-precision subroutines in this section, by finding bounds δ_1, δ_2, and δ_3 on the relative errors

$$\left|((u \oplus v) - (u + v))/(u + v)\right|, \qquad \left|((u \otimes v) - (u \times v))/(u \times v)\right|,$$
$$\left|((u \oslash v) - (u/v))/(u/v)\right|.$$

8. [*M28*] Estimate the accuracy of the "improved" double-precision subroutines of exercises 4 and 5, in the sense of exercise 7.

9. [*M42*] T. J. Dekker [*Numer. Math.* **18** (1971), 224–242] has suggested an alternative approach to double precision, based entirely on single-precision floating binary calculations. For example, Theorem 4.2.2C states that $u+v = w+r$, where $w = u \oplus v$ and $r = (u \ominus w) \oplus v$, if $|u| \geq |v|$ and the radix is 2; here $|r| \leq |w|/2^p$, so the pair (w, r) may be considered a double-precision version of $u + v$. To add two such pairs $(u, u') \oplus (v, v')$, where $|u'| \leq |u|/2^p$ and $|v'| \leq |v|/2^p$ and $|u| \geq |v|$, Dekker suggests computing $u+v = w+r$ (exactly), then $s = (r \oplus v') \oplus u'$ (an approximate remainder), and finally returning the value $(w \oplus s, (w \ominus (w \oplus s)) \oplus s)$.

Study the accuracy and efficiency of this approach when it is used recursively to produce quadruple-precision calculations.

Table 1

4.2.4. Distribution of Floating Point Numbers

In order to analyze the average behavior of floating point arithmetic algorithms (and in particular to determine their average running time), we need some statistical information that allows us to determine how often various cases arise. The purpose of this section is to discuss the empirical and theoretical properties of the distribution of floating point numbers.

A. Addition and subtraction routines. The execution time for a floating point addition or subtraction depends largely on the initial difference of exponents, and also on the number of normalization steps required (to the left or to the right). No way is known to give a good theoretical model that tells what characteristics to expect, but extensive empirical investigations have been made by D. W. Sweeney [*IBM Systems J.* 4 (1965), 31–42].

By means of a special tracing routine, Sweeney ran six "typical" large-scale numerical programs, selected from several different computing laboratories, and examined each floating addition or subtraction operation very carefully. Over 250,000 floating point addition-subtractions were involved in gathering this data. About one out of every ten instructions executed by the tested programs was either FADD or FSUB.

Let us consider subtraction to be addition preceded by negating the second operand; therefore we may give all the statistics as if we were merely doing addition. Sweeney's results can be summarized as follows:

One of the two operands to be added was found to be equal to zero about 9 percent of the time, and this was usually the accumulator (ACC). The other 91 percent of the cases split about equally between operands of the same or of opposite signs, and about equally between cases where $|u| \leq |v|$ or $|v| \leq |u|$. The computed answer was zero about 1.4 percent of the time.

The difference between exponents had a behavior approximately given by the probabilities shown in Table 1, for various radices b. (The "over 5" line of that table includes essentially all of the cases when one operand was zero, but the "average" line does not include these cases.)

Table 2
EMPIRICAL DATA FOR NORMALIZATION AFTER ADDITION

	$b = 2$	$b = 10$	$b = 16$	$b = 64$
Shift right 1	0.20	0.07	0.06	0.03
No shift	0.59	0.80	0.82	0.87
Shift left 1	0.07	0.08	0.07	0.06
Shift left 2	0.03	0.02	0.01	0.01
Shift left 3	0.02	0.00	0.01	0.00
Shift left 4	0.02	0.01	0.00	0.01
Shift left >4	0.06	0.02	0.02	0.02

When u and v have the same sign and are normalized, then $u + v$ either requires one shift to the *right* (for fraction overflow), or no normalization shifts whatever. When u and v have opposite signs, we have zero or more *left* shifts during the normalization. Table 2 gives the observed number of shifts required; the last line of that table includes all cases where the result was zero. The average number of left shifts per normalization was about 0.9 when $b = 2$; about 0.2 when $b = 10$ or 16; and about 0.1 when $b = 64$.

B. The fraction parts. Further analysis of floating point routines can be based on the *statistical distribution of the fraction parts* of randomly chosen normalized floating point numbers. In this case the facts are quite surprising, and there is an interesting theory that accounts for the unusual phenomena that are observed.

For convenience let us temporarily assume that we are dealing with floating *decimal* (i.e., radix 10) arithmetic; modifications of the following discussion to any other positive integer base b will be very straightforward. Suppose we are given a "random" positive normalized number $(e, f) = 10^e \cdot f$. Since f is normalized, we know that its leading digit is 1, 2, 3, 4, 5, 6, 7, 8, or 9, and it seems natural to assume that each of these nine possible leading digits will occur about one-ninth of the time. But, in fact, the behavior in practice is quite different. For example, the leading digit tends to be equal to 1 over 30 percent of the time!

One way to test the assertion just made is to take a table of physical constants (e.g., the speed of light, the acceleration of gravity) from some standard reference. If we look at the *Handbook of Mathematical Functions* (U.S. Dept of Commerce, 1964), for example, we find that 8 of the 28 different physical constants given in Table 2.3, roughly 29 percent, have leading digit equal to 1. The decimal values of $n!$ for $1 \le n \le 100$ include exactly 30 entries beginning with 1; so do the decimal values of 2^n and of F_n, for $1 \le n \le 100$. We might also try looking at census reports, or a Farmer's Almanack (but not a telephone directory).

In the days before pocket calculators, the pages in well-used tables of logarithms tended to get quite dirty in the front, while the last pages stayed relatively clean and neat. This phenomenon was apparently first mentioned in print by the American astronomer Simon Newcomb [*Amer. J. Math.* **4** (1881), 39–40], who

gave good grounds for believing that the leading digit d occurs with probability $\log_{10}(1 + 1/d)$. The same distribution was discovered empirically, many years later, by Frank Benford, who reported the results of 20,229 observations taken from different sources [*Proc. Amer. Philosophical Soc.* **78** (1938), 551–572].

In order to account for this leading-digit law, let's take a closer look at the way we write numbers in floating point notation. If we take any positive number u, its leading digits are determined by the value $(\log_{10} u) \bmod 1$: The leading digit is less than d if and only if

$$(\log_{10} u) \bmod 1 < \log_{10} d, \tag{1}$$

since $10f_u = 10^{(\log_{10} u) \bmod 1}$.

Now if we have a "random" positive number U, chosen from some reasonable distribution that might occur in nature, we might expect that $(\log_{10} U) \bmod 1$ would be uniformly distributed between zero and one, at least to a very good approximation. (Similarly, we expect $U \bmod 1$, $U^2 \bmod 1$, $\sqrt{U + \pi} \bmod 1$, etc., to be uniformly distributed. We expect a roulette wheel to be unbiased, for essentially the same reason.) Therefore by (1) the leading digit will be 1 with probability $\log_{10} 2 \approx 30.103$ percent; it will be 2 with probability $\log_{10} 3 - \log_{10} 2 \approx 17.609$ percent; and, in general, if r is any real value between 1 and 10, we ought to have $10f_U \le r$ approximately $\log_{10} r$ of the time.

Another way to explain this law is to say that a random value U should appear at a random point on a slide rule, according to the uniform distribution, since the distance from the left end of a slide rule to the position of U is proportional to $(\log_{10} U) \bmod 1$. The analogy between slide rules and floating point calculation is very close when multiplication and division are being considered.

The fact that leading digits tend to be small is important to keep in mind; it makes the most obvious techniques of "average error" estimation for floating point calculations invalid. The relative error due to rounding is usually a little more than expected.

Of course, it may justly be said that the heuristic argument above does not prove the stated law. It merely shows us a plausible reason why the leading digits behave the way they do. An interesting approach to the analysis of leading digits has been suggested by R. Hamming: Let $p(r)$ be the probability that $10f_U \le r$, where $1 \le r \le 10$ and f_U is the normalized fraction part of a random normalized floating point number U. If we think of random quantities in the real world, we observe that they are measured in terms of arbitrary units; and if we were to change the definition of a meter or a gram, many of the fundamental physical constants would have different values. Suppose then that all of the numbers in the universe are suddenly multiplied by a constant factor c; our universe of random floating point quantities should be essentially unchanged by this transformation, so $p(r)$ should not be affected.

Multiplying everything by c has the effect of transforming $(\log_{10} U) \bmod 1$ into $(\log_{10} U + \log_{10} c) \bmod 1$. It is now time to set up formulas that describe the desired behavior; we may assume that $1 \le c \le 10$. By definition,

$$p(r) = \text{probability that } (\log_{10} U) \bmod 1 \le \log_{10} r.$$

By our assumption, we should also have

$$\begin{aligned} p(r) &= \text{probability that } (\log_{10} U + \log_{10} c) \bmod 1 \le \log_{10} r \\ &= \begin{cases} \text{probability that } (\log_{10} U \bmod 1) \le \log_{10} r - \log_{10} c \\ \qquad \text{or } (\log_{10} U \bmod 1) \ge 1 - \log_{10} c, & \text{if } c \le r; \\ \text{probability that } (\log_{10} U \bmod 1) \le \log_{10} r + 1 - \log_{10} c \\ \qquad \text{and } (\log_{10} U \bmod 1) \ge 1 - \log_{10} c, & \text{if } c \ge r; \end{cases} \\ &= \begin{cases} p(r/c) + 1 - p(10/c), & \text{if } c \le r; \\ p(10r/c) - p(10/c), & \text{if } c \ge r. \end{cases} \end{aligned} \tag{2}$$

Let us now extend the function $p(r)$ to values outside the range $1 \le r \le 10$, by defining $p(10^n r) = p(r) + n$; then if we replace $10/c$ by d, the last equation of (2) may be written

$$p(rd) = p(r) + p(d). \tag{3}$$

If our assumption about invariance of the distribution under multiplication by a constant factor is valid, then Eq. (3) must hold for all $r > 0$ and $1 \le d \le 10$. The facts that $p(1) = 0$, $p(10) = 1$ now imply that

$$1 = p(10) = p\big((\sqrt[n]{10})^n\big) = p(\sqrt[n]{10}) + p\big((\sqrt[n]{10})^{n-1}\big) = \cdots = np(\sqrt[n]{10});$$

hence we deduce that $p(10^{m/n}) = m/n$ for all positive integers m and n. If we now decide to require that p is continuous, we are forced to conclude that $p(r) = \log_{10} r$, and this is the desired law.

Although this argument may be more convincing than the first one, it doesn't really hold up under scrutiny if we stick to conventional notions of probability. The traditional way to make the above argument rigorous is to assume that there is some underlying distribution of numbers $F(u)$ such that a given positive number U is $\le u$ with probability $F(u)$; then the probability of concern to us is

$$p(r) = \sum_m \big(F(10^m r) - F(10^m)\big), \tag{4}$$

summed over all values $-\infty < m < \infty$. Our assumptions about scale invariance and continuity have led us to conclude that

$$p(r) = \log_{10} r.$$

Using the same argument, we could "prove" that

$$\sum_m \big(F(b^m r) - F(b^m)\big) = \log_b r, \tag{5}$$

for each integer $b \ge 2$, when $1 \le r \le b$. But there *is* no distribution function F that satisfies this equation for all such b and r! (See exercise 7.)

One way out of the difficulty is to regard the logarithm law $p(r) = \log_{10} r$ as only a very close *approximation* to the true distribution. The true distribution itself may perhaps be changing as the universe expands, becoming a better and better approximation as time goes on; and if we replace 10 by an arbitrary base b, the approximation might be less accurate (at any given time) as b gets larger. Another rather appealing way to resolve the dilemma, by abandoning the traditional idea of a distribution function, has been suggested by R. A. Raimi, *AMM* **76** (1969), 342–348.

The hedging in the last paragraph is probably a very unsatisfactory explanation, and so the following further calculation (which sticks to rigorous mathematics and avoids any intuitive, yet paradoxical, notions of probability) should be welcome. Let us consider the distribution of the leading digits of the *positive integers*, instead of the distribution for some imagined set of real numbers. The investigation of this topic is quite interesting, not only because it sheds some light on the probability distributions of floating point data, but also because it makes a particularly instructive example of how to combine the methods of discrete mathematics with the methods of infinitesimal calculus.

In the following discussion, let r be a fixed real number, $1 \le r \le 10$; we will attempt to make a reasonable definition of $p(r)$, the "probability" that the representation $10^{e_N} \cdot f_N$ of a "random" positive integer N has $10f_N < r$, assuming infinite precision.

To start, let us try to find the probability using a limiting method like the definition of "Pr" in Section 3.5. One nice way to rephrase that definition is to define

$$P_0(n) = \begin{cases} 1, & \text{if } n = 10^e \cdot f \text{ where } 10f < r, \\ & \quad \text{i.e., if } (\log_{10} n) \bmod 1 < \log_{10} r; \\ 0, & \text{otherwise.} \end{cases} \tag{6}$$

Now $P_0(1)$, $P_0(2)$, ... is an infinite sequence of zeros and ones, with ones to represent the cases that contribute to the probability we are seeking. We can try to "average out" this sequence, by defining

$$P_1(n) = \frac{1}{n} \sum_{1 \le k \le n} P_0(k). \tag{7}$$

Thus if we generate a random integer between 1 and n using the techniques of Chapter 3, and convert it to floating decimal form (e, f), the probability that $10f < r$ is exactly $P_1(n)$. It is natural to let $\lim_{n\to\infty} P_1(n)$ be the "probability" $p(r)$ we are after, and that is just what we did in Section 3.5.

But in this case the limit does not exist: For example, let us consider the subsequence

$$P_1(s),\ P_1(10s),\ P_1(100s),\ \ldots,\ P_1(10^n s),\ \ldots,$$

where s is a real number, $1 \le s \le 10$. If $s \le r$, we find that

$$\begin{aligned} P_1(10^n s) &= \frac{1}{10^n s}\big(\lceil r\rceil - 1 + \lceil 10r\rceil - 10 + \cdots + \lceil 10^{n-1}r\rceil \\ &\qquad - 10^{n-1} + \lfloor 10^n s\rfloor + 1 - 10^n\big) \\ &= \frac{1}{10^n s}\big(r(1 + 10 + \cdots + 10^{n-1}) + O(n) \\ &\qquad + \lfloor 10^n s\rfloor - 1 - 10 - \cdots - 10^n\big) \\ &= \frac{1}{10^n s}\big(\tfrac{1}{9}(10^n r - 10^{n+1}) + \lfloor 10^n s\rfloor + O(n)\big). \end{aligned} \tag{8}$$

As $n \to \infty$, $P_1(10^n s)$ therefore approaches the limiting value $1 + (r - 10)/9s$. The above calculation for the case $s \le r$ can be modified so that it is valid for $s > r$ if we replace $\lfloor 10^n s\rfloor + 1$ by $\lceil 10^n r\rceil$; when $s \ge r$, we therefore obtain the limiting value $10(r - 1)/9s$. [See J. Franel, *Naturforschende Gesellschaft, Vierteljahrsschrift* **62** (Zürich, 1917), 286–295.]

In other words, the sequence $\langle P_1(n)\rangle$ has subsequences $\langle P_1(10^n s)\rangle$ whose limit goes from $(r - 1)/9$ up to $10(r - 1)/9r$ and down again to $(r - 1)/9$, as s goes from 1 to r to 10. We see that $P_1(n)$ has no limit as $n \to \infty$; and the values of $P_1(n)$ for large n are not particularly good approximations to our conjectured limit $\log_{10} r$ either!

Since $P_1(n)$ doesn't approach a limit, we can try to use the same idea as (7) once again, to "average out" the anomalous behavior. In general, let

$$P_{m+1}(n) = \frac{1}{n}\sum_{1 \le k \le n} P_m(k). \tag{9}$$

Then $P_{m+1}(n)$ will tend to be a more well-behaved sequence than $P_m(n)$. Let us try to confirm this with quantitative calculations; our experience with the special case $m = 0$ indicates that it might be worthwhile to consider the subsequence $P_{m+1}(10^n s)$. The following results can, in fact, be derived:

Lemma Q. *For any integer $m \ge 1$ and any real number $\epsilon > 0$, there are functions $Q_m(s)$, $R_m(s)$ and an integer $N_m(\epsilon)$, such that whenever $n > N_m(\epsilon)$ and $1 \le s \le 10$, we have*

$$\begin{aligned} |P_m(10^n s) - Q_m(s)| &< \epsilon, \qquad \text{if } s \le r; \\ |P_m(10^n s) - \big(Q_m(s) + R_m(s)\big)| &< \epsilon, \qquad \text{if } s > r. \end{aligned} \tag{10}$$

Furthermore the functions $Q_m(s)$ and $R_m(s)$ satisfy the relations

$$\begin{aligned} Q_m(s) &= \frac{1}{s}\Big(\frac{1}{9}\int_1^{10} Q_{m-1}(t)\,dt + \int_1^s Q_{m-1}(t)\,dt + \frac{1}{9}\int_r^{10} R_{m-1}(t)\,dt\Big); \\ R_m(s) &= \frac{1}{s}\int_r^s R_{m-1}(t)\,dt; \\ Q_0(s) &= 1, \qquad R_0(s) = -1. \end{aligned} \tag{11}$$

Proof. Consider the functions $Q_m(s)$ and $R_m(s)$ defined by (11), and let

$$S_m(t) = \begin{cases} Q_m(t), & t \le r. \\ Q_m(t) + R_m(t), & t > r. \end{cases} \tag{12}$$

We will prove the lemma by induction on m.

First note that $Q_1(s) = \big(1 + (s-1) + (r-10)/9\big)/s = 1 + (r-10)/9s$, and $R_1(s) = (r-s)/s$. From (8) we find that $|P_1(10^n s) - S_1(s)| = O(n)/10^n$; this establishes the lemma when $m = 1$.

Now for $m > 1$, we have

$$P_m(10^n s) = \frac{1}{s}\Bigg(\sum_{0\le j<n} \frac{1}{10^{n-j}} \sum_{10^j \le k < 10^{j+1}} \frac{1}{10^j} P_{m-1}(k) + \sum_{10^n \le k \le 10^n s} \frac{1}{10^n} P_{m-1}(k)\Bigg),$$

and we want to approximate this quantity. By induction, the difference

$$\left| \sum_{10^j \le k \le 10^j q} \frac{1}{10^j} P_{m-1}(k) - \sum_{10^j \le k \le 10^j q} \frac{1}{10^j} S_{m-1}\Big(\frac{k}{10^j}\Big) \right| \tag{13}$$

is less than $q\epsilon$ when $1 \le q \le 10$ and $j > N_{m-1}(\epsilon)$. Since $S_{m-1}(t)$ is continuous, it is a Riemann-integrable function; and the difference

$$\left| \sum_{10^j \le k \le 10^j q} \frac{1}{10^j} S_{m-1}\Big(\frac{k}{10^j}\Big) - \int_1^q S_{m-1}(t)\,dt \right| \tag{14}$$

is less than ϵ for all j greater than some number N, independent of q, by the definition of integration. We may choose N to be $> N_{m-1}(\epsilon)$. Therefore for $n > N$, the difference

$$\left| P_m(10^n s) - \frac{1}{s}\Bigg(\sum_{0\le j<n} \frac{1}{10^{n-j}} \int_1^{10} S_{m-1}(t)\,dt + \int_1^s S_{m-1}(t)\,dt\Bigg) \right| \tag{15}$$

is bounded by $\sum_{0\le j\le N}(M/10^{n-j}) + \sum_{N<j<n}(11\epsilon/10^{n-j}) + 11\epsilon$, if M is an upper bound for (13) + (14) that is valid for all positive integers j. Finally, the sum $\sum_{0\le j<n}(1/10^{n-j})$, which appears in (15), is equal to $(1 - 1/10^n)/9$; so

$$\left| P_m(10^n s) - \frac{1}{s}\Big(\frac{1}{9}\int_1^{10} S_{m-1}(t)\,dt + \int_1^s S_{m-1}(t)\,dt\Big) \right|$$

can be made smaller than, say, 20ϵ, if n is taken large enough. Comparing this with (10) and (11) completes the proof. ∎

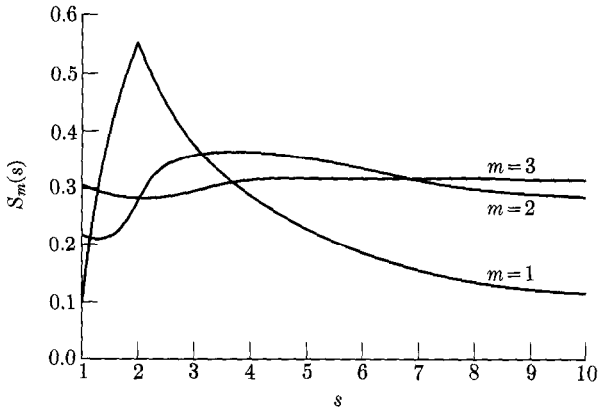

Fig. 5. The probability that the leading digit is 1.

The gist of Lemma Q is that we have the limiting relationship

$$\lim_{n\to\infty} P_m(10^n s) = S_m(s). \tag{16}$$

Also, since $S_m(s)$ is not constant as s varies, the limit

$$\lim_{n\to\infty} P_m(n)$$

(which would be our desired "probability") does not exist for any m. The situation is shown in Fig. 5, which shows the values of $S_m(s)$ when m is small and $r = 2$.

Even though $S_m(s)$ is not a constant, so that we do not have a definite limit for $P_m(n)$, note that already for $m = 3$ in Fig. 5 the value of $S_m(s)$ stays very close to $\log_{10} 2 = 0.30103\ldots$. Therefore we have good reason to suspect that $S_m(s)$ is very close to $\log_{10} r$ for all large m, and, in fact, that the sequence of functions $\langle S_m(s)\rangle$ converges uniformly to the constant function $\log_{10} r$.

It is interesting to prove this conjecture by explicitly calculating $Q_m(s)$ and $R_m(s)$ for all m, as in the proof of the following theorem:

Theorem F. *Let $S_m(s)$ be the limit defined in* (16). *For all $\epsilon > 0$, there exists a number $N(\epsilon)$ such that*

$$|S_m(s) - \log_{10} r| < \epsilon, \qquad \text{for } 1 \le s \le 10, \tag{17}$$

whenever $m > N(\epsilon)$.

Proof. In view of Lemma Q, we can prove this result if we can show that there is a number M depending on ϵ such that, for $1 \le s \le 10$ and for all $m > M$, we have

$$|Q_m(s) - \log_{10} r| < \epsilon \qquad \text{and} \qquad |R_m(s)| < \epsilon. \tag{18}$$

It is not difficult to solve the recurrence formula (11) for R_m: We have $R_0(s) = -1$, $R_1(s) = -1 + r/s$, $R_2(s) = -1 + (r/s)(1 + \ln(s/r))$, and in general

$$R_m(s) = -1 + \frac{r}{s}\left(1 + \frac{1}{1!}\ln\left(\frac{s}{r}\right) + \cdots + \frac{1}{(m-1)!}\left(\ln\left(\frac{s}{r}\right)\right)^{m-1}\right). \tag{19}$$

For the stated range of s, this converges uniformly to

$$-1 + (r/s)\exp(\ln(s/r)) = 0.$$

The recurrence (11) for Q_m takes the form

$$Q_m(s) = \frac{1}{s}\left(c_m + 1 + \int_1^s Q_{m-1}(t)\,dt\right), \tag{20}$$

where

$$c_m = \frac{1}{9}\left(\int_1^{10} Q_{m-1}(t)\,dt + \int_r^{10} R_{m-1}(t)\,dt\right) - 1. \tag{21}$$

The solution to recurrence (20) is easily found by trying out the first few cases and guessing at a formula that can be proved by induction; we find that

$$Q_m(s) = 1 + \frac{1}{s}\left(c_m + \frac{1}{1!}c_{m-1}\ln s + \cdots + \frac{1}{(m-1)!}c_1(\ln s)^{m-1}\right). \tag{22}$$

It remains for us to calculate the coefficients c_m, which by (19), (21), and (22) satisfy the relations

$$\begin{aligned} c_1 &= (r-10)/9; \\ c_{m+1} &= \frac{1}{9}\left(c_m\ln 10 + \frac{1}{2!}c_{m-1}(\ln 10)^2 + \cdots + \frac{1}{m!}c_1(\ln 10)^m \right. \\ &\qquad \left. + r\left(1 + \frac{1}{1!}\ln\frac{10}{r} + \cdots + \frac{1}{m!}\left(\ln\frac{10}{r}\right)^m\right) - 10\right). \end{aligned} \tag{23}$$

This sequence appears at first to be very complicated, but actually we can analyze it without difficulty with the help of generating functions. Let

$$C(z) = c_1 z + c_2 z^2 + c_3 z^3 + \cdots;$$

then since $10^z = 1 + z\ln 10 + (1/2!)(z\ln 10)^2 + \cdots$, we deduce that

$$\begin{aligned} c_{m+1} &= \frac{1}{10}c_{m+1} + \frac{9}{10}c_{m+1} \\ &= \frac{1}{10}\left(c_{m+1} + c_m\ln 10 + \cdots + \frac{1}{m!}c_1(\ln 10)^m\right) \\ &\qquad + \frac{r}{10}\left(1 + \cdots + \frac{1}{m!}\left(\ln\frac{10}{r}\right)^m\right) - 1 \end{aligned}$$

is the coefficient of z^{m+1} in the function

$$\frac{1}{10}C(z)10^z + \frac{r}{10}\left(\frac{10}{r}\right)^z\left(\frac{z}{1-z}\right) - \frac{z}{1-z}. \tag{24}$$

This condition holds for all values of m, so (24) must equal $C(z)$, and we obtain the explicit formula

$$C(z) = \frac{-z}{1-z}\left(\frac{(10/r)^{z-1}-1}{10^{z-1}-1}\right). \tag{25}$$

We want to study asymptotic properties of the coefficients of $C(z)$, to complete our analysis. The large parenthesized factor in (25) approaches $\ln(10/r)/\ln 10 = 1 - \log_{10} r$ as $z \to 1$, so we see that

$$C(z) + \frac{1-\log_{10} r}{1-z} = R(z) \tag{26}$$

is an analytic function of the complex variable z in the circle

$$|z| < \left|1 + \frac{2\pi i}{\ln 10}\right|.$$

In particular, $R(z)$ converges for $z = 1$, so its coefficients approach zero. This proves that the coefficients of $C(z)$ behave like those of $(\log_{10} r - 1)/(1-z)$, that is,

$$\lim_{m\to\infty} c_m = \log_{10} r - 1.$$

Finally, we may combine this with (22), to show that $Q_m(s)$ approaches

$$1 + \frac{\log_{10} r - 1}{s}\left(1 + \ln s + \frac{1}{2!}(\ln s)^2 + \cdots\right) = \log_{10} r$$

uniformly for $1 \le s \le 10$. ∎

Therefore we have established the logarithmic law for integers by direct calculation, at the same time seeing that it is an extremely good approximation to the average behavior although it is never precisely achieved.

The above proofs of Lemma Q and Theorem F are slight simplifications and amplifications of methods due to B. J. Flehinger, *AMM* **73** (1966), 1056–1061. Many authors have written about the distribution of initial digits, showing that the logarithmic law is a good approximation for many underlying distributions; see the survey by Ralph A. Raimi, *AMM* **83** (1976), 521–538, for a comprehensive review of the literature. Another interesting (and different) treatment of floating point distribution has been given by Alan G. Konheim, *Math. Comp.* **19** (1965), 143–144.

Exercise 17 discusses an approach to the definition of probability under which the logarithmic law holds exactly, over the integers. Furthermore, exercise 18 demonstrates that *any* reasonable definition of probability over the integers must lead to the logarithmic law, if it assigns a value to the probability of leading digits.

EXERCISES

1. [*13*] Given that u and v are nonzero floating decimal numbers *with the same sign*, what is the approximate probability that fraction overflow occurs during the calculation of $u \oplus v$, according to Tables 1 and 2?

2. [*42*] Make further tests of floating point addition and subtraction, to confirm or improve on the accuracy of Tables 1 and 2.

3. [*15*] What is the probability that the two leading digits of a floating decimal number are "23", according to the logarithmic law?

4. [*M18*] The text points out that the front pages of a well-used table of logarithms get dirtier than the back pages do. What if we had an *antilogarithm* table instead, i.e., a table giving the value of x when $\log_{10} x$ is given; which pages of such a table would be the dirtiest?

▶ **5.** [*M20*] Let U be a random real number that is uniformly distributed in the interval $0 < U < 1$. What is the distribution of the leading digits of U?

6. [*23*] If we have binary computer words containing $n + 1$ bits, we might use p bits for the fraction part of floating binary numbers, one bit for the sign, and $n - p$ bits for the exponent. This means that the range of values representable, i.e., the ratio of the largest positive normalized value to the smallest, is essentially $2^{2^{n-p}}$. The same computer word could be used to represent floating *hexadecimal* numbers, i.e., floating point numbers with radix 16, with $p + 2$ bits for the fraction part ($(p + 2)/4$ hexadecimal digits) and $n - p - 2$ bits for the exponent; then the range of values would be $16^{2^{n-p-2}} = 2^{2^{n-p}}$, the same as before, and with more bits in the fraction part. This may sound as if we are getting something for nothing, but the normalization condition for base 16 is weaker in that there may be up to three leading zero bits in the fraction part; thus not all of the $p + 2$ bits are "significant."

On the basis of the logarithmic law, what are the probabilities that the fraction part of a positive normalized radix 16 floating point number has exactly 0, 1, 2, and 3 leading zero bits? Discuss the desirability of hexadecimal versus binary.

7. [*HM28*] Prove that there is no distribution function $F(u)$ that satisfies (5) for each integer $b \geq 2$, and for all real values r in the range $1 \leq r \leq b$.

8. [*HM23*] Does (10) hold when $m = 0$ for suitable $N_0(\epsilon)$?

9. [*HM24*] (P. Diaconis.) Let $P_1(n)$, $P_2(n)$, ... be any sequence of functions defined by repeatedly averaging a given function $P_0(n)$ according to Eq. (9). Prove that $\lim_{m\to\infty} P_m(n) = P_0(1)$ for all fixed n.

▶ **10.** [*HM28*] The text shows that $c_m = \log_{10} r - 1 + \epsilon_m$, where ϵ_m approaches zero as $m \to \infty$. Obtain the next term in the asymptotic expansion of c_m.

11. [*M15*] Given that U is a random variable distributed according to the logarithmic law, prove that $1/U$ is also.

12. [*HM25*] (R. W. Hamming.) The purpose of this exercise is to show that the result of floating point multiplication tends to obey the logarithmic law more perfectly than the operands do. Let U and V be random, normalized, positive floating point numbers, whose fraction parts are independently distributed with the respective density functions $f(x)$ and $g(x)$. Thus, $f_u \leq r$ and $f_v \leq s$ with probability $\int_{1/b}^{r}\int_{1/b}^{s} f(x)g(y)\,dy\,dx$, for $1/b \leq r, s \leq 1$. Let $h(x)$ be the density function of the fraction part of $U \times V$ (unrounded). Define the *abnormality* $A(f)$ of a density function f to be the maximum

relative error,

$$A(f) = \max_{1/b \le x \le 1} \left| \frac{f(x) - l(x)}{l(x)} \right|,$$

where $l(x) = 1/(x \ln b)$ is the density of the logarithmic distribution.

Prove that $A(h) \le \min(A(f), A(g))$. (In particular, if either factor has logarithmic distribution the product does also.)

▶ **13.** [*M20*] The floating point multiplication routine, Algorithm 4.2.1M, requires zero or one left shifts during normalization, depending on whether $f_u f_v \ge 1/b$ or not. Assuming that the input operands are independently distributed according to the logarithmic law, what is the probability that no left shift is needed for normalization of the result?

▶ **14.** [*HM30*] Let U and V be random, normalized, positive floating point numbers whose fraction parts are independently distributed according to the logarithmic law, and let p_k be the probability that the difference in their exponents is k. Assuming that the distribution of the exponents is independent of the fraction parts, give an equation for the probability that "fraction overflow" occurs during the floating point addition of $U \oplus V$, in terms of the base b and the quantities $p_0, p_1, p_2, \ldots$. Compare this result with exercise 1. (Ignore rounding.)

15. [*HM28*] Let U, V, p_0, p_1, ... be as in exercise 14, and assume that radix 10 arithmetic is being used. Show that regardless of the values of $p_0, p_1, p_2, \ldots$, the sum $U \oplus V$ will *not* obey the logarithmic law exactly, and in fact the probability that $U \oplus V$ has leading digit 1 is always strictly *less* than $\log_{10} 2$.

16. [*HM28*] (P. Diaconis.) Let $P_0(n)$ be 0 or 1 for each n, and define "probabilities" $P_{m+1}(n)$ by repeated averaging, as in (9). Show that if $\lim_{n\to\infty} P_1(n)$ does not exist, neither does $\lim_{n\to\infty} P_m(n)$ for any m. [*Hint:* Prove that $a_n \to 0$ whenever we have $(a_1 + \cdots + a_n)/n \to 0$ and $a_{n+1} \le a_n + M/n$, for some fixed constant $M > 0$.]

▶ **17.** [*HM25*] (R. L. Duncan.) Another way to define the value of $\Pr(S(n))$ is to evaluate the quantity $\lim_{n\to\infty}((\sum_{S(k) \text{ and } 1\le k\le n} 1/k)/H_n)$; it can be shown that this "harmonic probability" exists and is equal to $\Pr(S(n))$, whenever the latter exists according to Definition 3.5A. Prove that the harmonic probability of the statement "$(\log_{10} n) \bmod 1 < r$" exists and equals r. (Thus, initial digits of integers *exactly* satisfy the logarithmic law in this sense.)

▶ **18.** [*HM30*] Let $P(S)$ be any real-valued function defined on sets S of positive integers, but not necessarily on all such sets, satisfying the following rather weak axioms:

i) If $P(S)$ and $P(T)$ are defined and $S \cap T = \emptyset$, then $P(S \cup T) = P(S) + P(T)$.
ii) If $P(S)$ is defined, then $P(S + 1) = P(S)$, where $S + 1 = \{ n + 1 \mid n \in S \}$.
iii) If $P(S)$ is defined, then $P(2S) = \frac{1}{2}P(S)$, where $2S = \{ 2n \mid n \in S \}$.
iv) If S is the set of *all* positive integers, then $P(S) = 1$.
v) If $P(S)$ is defined, then $P(S) \ge 0$.

Assume furthermore that $P(L_a)$ is defined for all positive integers a, where L_a is the set of all integers whose decimal representation begins with a:

$$L_a = \{ n \mid 10^m a \le n < 10^m (a + 1) \text{ for some integer } m \}.$$

(In this definition, m may be negative; for example, 1 is an element of L_{10}, but not of L_{11}.) Prove that $P(L_a) = \log_{10}(1 + 1/a)$ for all integers $a \ge 1$.

4.3. MULTIPLE-PRECISION ARITHMETIC

LET US NOW consider operations on numbers that have arbitrarily high precision. For simplicity in exposition, we shall assume that we are working with integers, instead of with numbers that have an embedded radix point.

4.3.1. The Classical Algorithms

In this section we shall discuss algorithms for

a) addition or subtraction of n-place integers, giving an n-place answer and a carry;

b) multiplication of an n-place integer by an m-place integer, giving an $(m+n)$-place answer;

c) division of an $(m+n)$-place integer by an n-place integer, giving an $(m+1)$-place quotient and an n-place remainder.

These may be called "the classical algorithms," since the word "algorithm" was used only in connection with these processes for several centuries. The term "n-place integer" means any integer less than b^n, where b is the radix of ordinary positional notation in which the numbers are expressed; such numbers can be written using at most n "places" in this notation.

It is a straightforward matter to apply the classical algorithms for integers to numbers with embedded radix points or to extended-precision floating point numbers, in the same way that arithmetic operations defined for integers in MIX are applied to these more general problems.

In this section we shall study algorithms that do operations (a), (b), and (c) above for integers expressed in radix b notation, where b is any given integer ≥ 2. Thus the algorithms are quite general definitions of arithmetic processes, and as such they are unrelated to any particular computer. But the discussion in this section will also be somewhat machine-oriented, since we are chiefly concerned with efficient methods for doing high-precision calculations by computer. Although our examples are based on the mythical MIX, essentially the same considerations apply to nearly every other machine. For convenience, we shall assume first that we have a computer (like MIX) that uses the signed-magnitude representation for numbers; suitable modifications for complement notations are discussed near the end of this section.

The most important fact to understand about extended-precision numbers is that they may be regarded as numbers written in radix w notation, where w is the computer's word size. For example, an integer that fills 10 words on a computer whose word size is $w = 10^{10}$ has 100 decimal digits; but we will consider it to be a 10-place number to the base 10^{10}. This viewpoint is justified for the same reason that we may convert, say, from binary to octal notation, simply by grouping the bits together. (See Eq. 4.1–5.)

In these terms, we are given the following primitive operations to work with:

a_0) addition or subtraction of one-place integers, giving a one-place answer and a carry;

b_0) multiplication of a one-place integer by another one-place integer, giving a two-place answer;

c_0) division of a two-place integer by a one-place integer, provided that the quotient is a one-place integer, and yielding also a one-place remainder.

By adjusting the word size, if necessary, nearly all computers will have these three operations available; so we will construct algorithms (a), (b), and (c) mentioned above in terms of the primitive operations (a_0), (b_0), and (c_0).

Since we are visualizing extended-precision integers as base b numbers, it is sometimes helpful to think of the situation when $b = 10$, and to imagine that we are doing the arithmetic by hand. Then operation (a_0) is analogous to memorizing the addition table; (b_0) is analogous to memorizing the multiplication table; and (c_0) is essentially memorizing the multiplication table in reverse. The more complicated operations (a), (b), (c) on high-precision numbers can now be done using the simple addition, subtraction, multiplication, and long-division procedures we are taught in elementary school. In fact, most of the algorithms we shall discuss in this section are essentially nothing more than mechanizations of familiar pencil-and-paper operations. Of course, we must state the algorithms much more precisely than they have ever been stated in the fifth grade, and we should also attempt to minimize computer memory and running time requirements.

To avoid a tedious discussion and cumbersome notations, let us assume that all numbers we deal with are *nonnegative*. The additional work of computing the signs, etc., is quite straightforward, and the reader will find it easy to fill in any details of this sort.

First comes addition, which of course is very simple, but it is worth studying since the same ideas occur in the other algorithms also:

Algorithm A (*Addition of nonnegative integers*). Given nonnegative n-place integers $(u_1u_2\ldots u_n)_b$ and $(v_1v_2\ldots v_n)_b$, this algorithm forms their radix-b sum, $(w_0w_1w_2\ldots w_n)_b$. (Here w_0 is the "carry," and it will always be equal to 0 or 1.)

A1. [Initialize.] Set $j \leftarrow n$, $k \leftarrow 0$. (The variable j will run through the various digit positions, and the variable k keeps track of carries at each step.)

A2. [Add digits.] Set $w_j \leftarrow (u_j + v_j + k) \bmod b$, and $k \leftarrow \lfloor (u_j + v_j + k)/b \rfloor$. (In other words, k is set to 1 or 0, depending on whether a "carry" occurs or not, i.e., whether $u_j + v_j + k \geq b$ or not. At most one carry is possible during the two additions, since we always have

$$u_j + v_j + k \leq (b-1) + (b-1) + 1 < 2b,$$

by induction on the computation.)

A3. [Loop on j.] Decrease j by one. Now if $j > 0$, go back to step A2; otherwise set $w_0 \leftarrow k$ and terminate the algorithm. ∎

For a formal proof that Algorithm A is a valid, see exercise 4.

A MIX program for this addition process might take the following form:

Program A (*Addition of nonnegative integers*). Let $\texttt{LOC}(u_j) \equiv \texttt{U}+j$, $\texttt{LOC}(v_j) \equiv \texttt{V}+j$, $\texttt{LOC}(w_j) \equiv \texttt{W}+j$, rI1 $\equiv j$, rA $\equiv k$, word size $\equiv b$, N $\equiv n$.

```
01        ENT1  N          1          A1. Initialize.  j ← n.
02        JOV   OFLO       1          Ensure overflow is off.
03   1H   ENTA  0        N+1-K        k ← 0.
04        J1Z   3F       N+1-K        To A3 if j = 0.
05   2H   ADD   U,1          N        A2. Add digits.
06        ADD   V,1          N
07        STA   W,1          N
08        DEC1  1            N        A3. Loop on j.
09        JNOV  1B           N        If no overflow, set k ← 0.
10        ENTA  1            K        Otherwise, set k ← 1.
11        J1P   2B           K        To A2 if j ≠ 0.
12   3H   STA   W            1        Store final carry in w0.  ∎
```

The running time for this program is $10N+6$ cycles, independent of the number of carries, K. The quantity K is analyzed in detail at the close of this section.

Many modifications of Algorithm A are possible, and only a few of these are mentioned in the exercises below. A chapter on generalizations of this algorithm might be entitled "How to design addition circuits for a digital computer."

The problem of subtraction is similar to addition, but the differences are worth noting:

Algorithm S (*Subtraction of nonnegative integers*). Given nonnegative n-place integers $(u_1u_2\ldots u_n)_b \geq (v_1v_2\ldots v_n)_b$, this algorithm forms their nonnegative radix-b difference, $(w_1w_2\ldots w_n)_b$.

S1. [Initialize.] Set $j \leftarrow n$, $k \leftarrow 0$.

S2. [Subtract digits.] Set $w_j \leftarrow (u_j - v_j + k) \bmod b$, and $k \leftarrow \lfloor (u_j - v_j + k)/b \rfloor$. (In other words, k is set to -1 or 0, depending on whether a "borrow" occurs or not, i.e., whether $u_j - v_j + k < 0$ or not. In the calculation of w_j, note that we must have $-b = 0 - (b-1) + (-1) \leq u_j - v_j + k \leq (b-1) - 0 + 0 < b$; hence $0 \leq u_j - v_j + k + b < 2b$, and this suggests the method of computer implementation explained below.)

S3. [Loop on j.] Decrease j by one. Now if $j > 0$, go back to step S2; otherwise terminate the algorithm. (When the algorithm terminates, we should have $k = 0$; the condition $k = -1$ will occur if and only if $v_1\ldots v_n > u_1\ldots u_n$, and this is contrary to the given assumptions. See exercise 12.) ∎

In a MIX program to implement subtraction, it is most convenient to retain the value $1+k$ instead of k throughout the algorithm, so that we can calculate $u_j - v_j + (1+k) + (b-1)$ in step S2. (Recall that b is the word size.) This is illustrated in the following code.

Program S (*Subtraction of nonnegative integers*). This program is analogous to the code in Program A; we have rI1 $\equiv j$, rA $\equiv 1 + k$. Here, as in other programs of this section, location WM1 contains the constant $b - 1$, the largest possible value that can be stored in a MIX word; cf. Program 4.2.3D, lines 38–39.

```
01       ENT1 N       1      S1. Initialize.  j ← n.
02       JOV  OFLO    1      Ensure overflow is off.
03   1H  J1Z  DONE    K+1    Terminate if j = 0.
04       ENTA 1       K      Set k ← 0.
05   2H  ADD  U,1     N      S2. Subtract digits.
06       SUB  V,1     N      Compute u_j − v_j + k + b.
07       ADD  WM1     N
08       STA  W,1     N      (May be minus zero)
09       DEC1 1       N      S3. Loop on j.
10       JOV  1B      N      If overflow, set k ← 0.
11       ENTA 0       N−K    Otherwise, set k ← −1.
12       J1P  2B      N−K    Back to S2.
13       HLT  5              (Error, v > u)  ∎
```

The running time for this program is $12N + 3$ cycles, slightly longer than the corresponding amount for Program A.

The reader may wonder if it would not be worthwhile to have a combined addition-subtraction routine in place of the two algorithms A and S. But an examination of the computer programs shows that it is generally better to use two different routines, so that the inner loops of the computations can be performed as rapidly as possible, since the programs are so short.

Our next problem is multiplication, and here we carry the ideas used in Algorithm A a little further:

Algorithm M (*Multiplication of nonnegative integers*). Given nonnegative integers $(u_1 u_2 \ldots u_n)_b$ and $(v_1 v_2 \ldots v_m)_b$, this algorithm forms their radix-b product $(w_1 w_2 \ldots w_{m+n})_b$. (The conventional pencil-and-paper method is based on forming the partial products $(u_1 u_2 \ldots u_n) \times v_j$ first, for $1 \le j \le m$, and then adding these products together with appropriate scale factors; but in a computer it is best to do the addition concurrently with the multiplication, as described in this algorithm.)

M1. [Initialize.] Set $w_{m+1}, w_{m+2}, \ldots, w_{m+n}$ all to zero. Set $j \leftarrow m$. (If $w_{m+1}, \ldots, w_{m+n}$ were not cleared to zero in this step, it turns out that the steps below would set

$$(w_1 \ldots w_{m+n})_b \leftarrow (u_1 \ldots u_n)_b \times (v_1 \ldots v_m)_b + (w_{m+1} \ldots w_{m+n})_b.$$

This more general operation is sometimes useful.)

M2. [Zero multiplier?] If $v_j = 0$, set $w_j \leftarrow 0$ and go to step M6. (This test saves a good deal of time if there is a reasonable chance that v_j is zero, but otherwise it may be omitted without affecting the validity of the algorithm.)

Table 1

MULTIPLICATION OF 914 BY 84.

Step	i	j	u_i	v_j	t	w_1	w_2	w_3	w_4	w_5
M5	3	2	4	4	16	x	x	0	0	6
M5	2	2	1	4	05	x	x	0	5	6
M5	1	2	9	4	36	x	x	6	5	6
M6	0	2	x	4	36	x	3	6	5	6
M5	3	1	4	8	37	x	3	6	7	6
M5	2	1	1	8	17	x	3	7	7	6
M5	1	1	9	8	76	x	6	7	7	6
M6	0	1	x	8	76	7	6	7	7	6

M3. [Initialize i.] Set $i \leftarrow n$, $k \leftarrow 0$.

M4. [Multiply and add.] Set $t \leftarrow u_i \times v_j + w_{i+j} + k$; then set $w_{i+j} \leftarrow t \bmod b$ and $k \leftarrow \lfloor t/b \rfloor$. (Here the "carry" k will always be in the range $0 \leq k < b$; see below.)

M5. [Loop on i.] Decrease i by one. Now if $i > 0$, go back to step M4; otherwise set $w_j \leftarrow k$.

M6. [Loop on j.] Decrease j by one. Now if $j > 0$, go back to step M2; otherwise the algorithm terminates. ∎

Algorithm M is illustrated in Table 1, assuming that $b = 10$, by showing the states of the computation at the beginning of steps M5 and M6. A proof of Algorithm M appears in the answer to exercise 14.

The two inequalities

$$0 \leq t < b^2, \qquad 0 \leq k < b \tag{1}$$

are crucial for an efficient implementation of this algorithm, since they point out how large a register is needed for the computations. These inequalities may be proved by induction as the algorithm proceeds, for if we have $k < b$ at the start of step M4, we have

$$u_i \times v_j + w_{i+j} + k \leq (b-1) \times (b-1) + (b-1) + (b-1) = b^2 - 1 < b^2.$$

The following MIX program shows the considerations that are necessary when Algorithm M is implemented on a computer. The coding for step M4 would be a little simpler if our computer had a "multiply-and-add" instruction, or if it had a double-length accumulator for addition.

Program M. (*Multiplication of nonnegative integers*). This program is analogous to Program A. rI1 $\equiv i$, rI2 $\equiv j$, rI3 $\equiv i + j$, CONTENTS(CARRY) $\equiv k$.

```

The execution time of Program M depends on the number of places, M, in the multiplier v; the number of places, N, in the multiplicand u; the number of zeros, Z, in the multiplier; and the number of carries, K and K', that occur during the addition to the lower half of the product in the computation of t. If we approximate both K and K' by the reasonable (although somewhat pessimistic) values $\frac{1}{2}(M - Z)N$, we find that the total running time comes to $28MN + 10M + 4N + 3 - Z(28N + 3)$ cycles. If step M2 were deleted, the running time would be $28MN + 7M + 4N + 3$ cycles, so this step is not advantageous unless the density of zero positions within the multiplier is $Z/M > 3/(28N + 3)$. If the multiplier is chosen completely at random, this ratio Z/M is expected to be only about $1/b$, which is extremely small; so step M2 is usually *not* worthwhile, unless b is small.

Algorithm M is not the fastest way to multiply when m and n are large, although it has the advantage of simplicity. Speedier methods are discussed in Section 4.3.3; even when $m = n = 4$, it is possible to multiply numbers in a little less time than is required by Algorithm M.

The final algorithm of concern to us in this section is long division, in which we want to divide $(n + m)$-place integers by n-place integers. Here the ordinary pencil-and-paper method involves a certain amount of guesswork and ingenuity on the part of the person doing the division; we must either eliminate this guesswork from the algorithm or develop some theory to explain it more carefully.

A moment's reflection about the ordinary process of long division shows that the general problem breaks down into simpler steps, each of which is the division

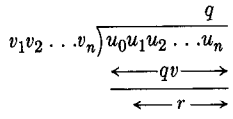

Fig. 6. Wanted: a way to determine q rapidly.

of an $(n+1)$-place number u by the n-place divisor v, where $0 \le u/v < b$; the remainder r after each step is less than v, so we may use the quantity $rb+$(next place of dividend) as the new u in the succeeding step. For example, if we are asked to divide 3142 by 47, we first divide 314 by 47, getting 6 and a remainder of 32; then we divide 322 by 47, getting 6 and a remainder of 40; thus we have a quotient of 66 and a remainder of 40. It is clear that this same idea works in general, and so our search for an appropriate division algorithm reduces to the following problem (Fig. 6):

Let $u = (u_0u_1\ldots u_n)_b$ and $v = (v_1v_2\ldots v_n)_b$ be nonnegative integers in radix-b notation, such that $u/v < b$. Find an algorithm to determine $q = \lfloor u/v \rfloor$.

We may observe that the condition $u/v < b$ is equivalent to the condition that $u/b < v$; i.e., $\lfloor u/b \rfloor < v$. This is simply the condition that $(u_0u_1\ldots u_{n-1})_b < (v_1v_2\ldots v_n)_b$. Furthermore, if we write $r = u - qv$, then q is the unique integer such that $0 \le r < v$.

The most obvious approach to this problem is to make a guess about q, based on the most significant digits of u and v. It isn't obvious that such a method will be reliable enough, but it is worth investigating; let us therefore set

$$\hat{q} = \min\left(\left\lfloor \frac{u_0b + u_1}{v_1} \right\rfloor, b-1\right). \tag{2}$$

This formula says $\hat{q}$ is obtained by dividing the two leading digits of u by the leading digit of v; and if the result is b or more we can replace it by $(b-1)$.

It is a remarkable fact, which we will now investigate, that this value $\hat{q}$ is always a very good approximation to the desired answer q, so long as v_1 is reasonably large. In order to analyze how close $\hat{q}$ comes to q, we will first prove that $\hat{q}$ is never too small.

Theorem A. *In the notation above, $\hat{q} \ge q$.*

Proof. Since $q \le b-1$, the theorem is certainly true if $\hat{q} = b-1$. Otherwise we have $\hat{q} = \lfloor (u_0b + u_1)/v_1 \rfloor$, hence $\hat{q}v_1 \ge u_0b + u_1 - v_1 + 1$. It follows that

$$\begin{aligned} u - \hat{q}v \le u - \hat{q}v_1b^{n-1} &\le u_0b^n + \cdots + u_n \\ &\quad - (u_0b^n + u_1b^{n-1} - v_1b^{n-1} + b^{n-1}) \\ &= u_2b^{n-2} + \cdots + u_n - b^{n-1} + v_1b^{n-1} < v_1b^{n-1} \le v. \end{aligned}$$

Since $u - \hat{q}v < v$, we must have $\hat{q} \ge q$. ∎

We will now prove that $\hat{q}$ cannot be much larger than q in practical situations. Assume that $\hat{q} \geq q + 3$. We have

$$\hat{q} \leq \frac{u_0 b + u_1}{v_1} = \frac{u_0 b^n + u_1 b^{n-1}}{v_1 b^{n-1}} \leq \frac{u}{v_1 b^{n-1}} < \frac{u}{v - b^{n-1}}.$$

(The case $v = b^{n-1}$ is impossible, for if $v = (100\ldots0)_b$ then $q = \hat{q}$.) Furthermore, the relation $q > (u/v) - 1$ implies that

$$3 \leq \hat{q} - q < \frac{u}{v - b^{n-1}} - \frac{u}{v} + 1 = \frac{u}{v}\left(\frac{b^{n-1}}{v - b^{n-1}}\right) + 1.$$

Therefore

$$\frac{u}{v} > 2\left(\frac{v - b^{n-1}}{b^{n-1}}\right) \geq 2(v_1 - 1).$$

Finally, since $b - 4 \geq \hat{q} - 3 \geq q = \lfloor u/v \rfloor \geq 2(v_1 - 1)$, we have $v_1 < \lfloor b/2 \rfloor$. This proves the result we seek:

Theorem B. *If $v_1 \geq \lfloor b/2 \rfloor$, then $\hat{q} - 2 \leq q \leq \hat{q}$.* ∎

The most important part of this theorem is that *the conclusion is independent of b*; no matter how large b is, the trial quotient $\hat{q}$ will never be more than 2 in error.

The condition that $v_1 \geq \lfloor b/2 \rfloor$ is very much like a normalization requirement; in fact, it is exactly the condition of floating-binary normalization in a binary computer. One simple way to ensure that v_1 is sufficiently large is to multiply both u and v by $\lfloor b/(v_1 + 1) \rfloor$; this does not change the value of u/v, nor does it increase the number of places in v, and exercise 23 proves that it will always make the new value of v_1 large enough. (*Note:* Another way to normalize the divisor is discussed in exercise 28.)

Now that we have armed ourselves with all of these facts, we are in a position to write the desired long-division algorithm. This algorithm uses a slightly improved choice of $\hat{q}$ in step D3, which guarantees that $q = \hat{q}$ or $\hat{q} - 1$; in fact, the improved choice of $\hat{q}$ made here is almost always accurate.

Algorithm D (*Division of nonnegative integers*). Given nonnegative integers $u = (u_1 u_2 \ldots u_{m+n})_b$ and $v = (v_1 v_2 \ldots v_n)_b$, where $v_1 \neq 0$ and $n > 1$, we form the radix-b quotient $\lfloor u/v \rfloor = (q_0 q_1 \ldots q_m)_b$ and the remainder $u \bmod v = (r_1 r_2 \ldots r_n)_b$. (This notation is slightly different from that used in the above proofs. When $n = 1$, the simpler algorithm of exercise 16 should be used.)

D1. [Normalize.] Set $d \leftarrow \lfloor b/(v_1 + 1) \rfloor$. Then set $(u_0 u_1 u_2 \ldots u_{m+n})_b$ equal to $(u_1 u_2 \ldots u_{m+n})_b$ times d, and set $(v_1 v_2 \ldots v_n)_b$ equal to $(v_1 v_2 \ldots v_n)_b$ times d. (Note the introduction of a new digit position u_0 at the left of u_1; if $d = 1$, all we need to do in this step is to set $u_0 \leftarrow 0$. On a binary computer it may be preferable to choose d to be a power of 2 instead of using the value suggested here; any value of d that results in $v_1 \geq \lfloor b/2 \rfloor$ will suffice. See also exercise 37.)

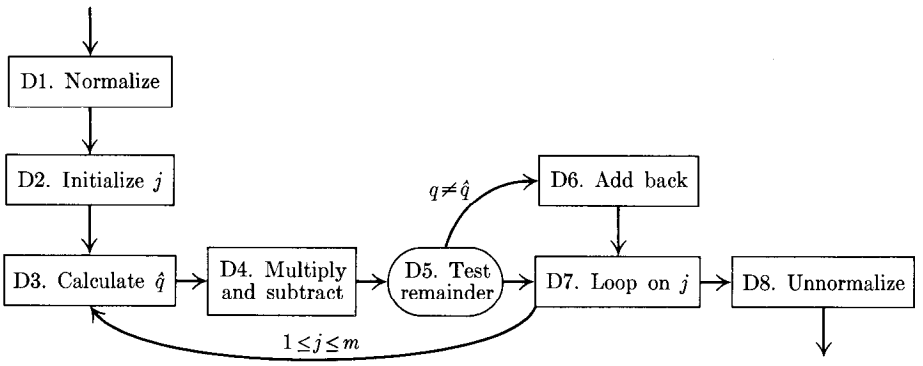

Fig. 7. Long division.

D2. [Initialize j.] Set $j \leftarrow 0$. (The loop on j, steps D2 through D7, will be essentially a division of $(u_j u_{j+1} \dots u_{j+n})_b$ by $(v_1 v_2 \dots v_n)_b$ to get a single quotient digit q_j; cf. Fig. 6.)

D3. [Calculate $\hat{q}$.] If $u_j = v_1$, set $\hat{q} \leftarrow b-1$; otherwise set $\hat{q} \leftarrow \lfloor (u_j b + u_{j+1})/v_1 \rfloor$. Now test if $v_2 \hat{q} > (u_j b + u_{j+1} - \hat{q} v_1) b + u_{j+2}$; if so, decrease $\hat{q}$ by 1 and repeat this test. (The latter test determines at high speed most of the cases in which the trial value $\hat{q}$ is one too large, and it eliminates *all* cases where $\hat{q}$ is two too large; see exercises 19, 20, 21.)

D4. [Multiply and subtract.] Replace $(u_j u_{j+1} \dots u_{j+n})_b$ by $(u_j u_{j+1} \dots u_{j+n})_b$ minus $\hat{q}$ times $(v_1 v_2 \dots v_n)_b$. This step (analogous to steps M3, M4, and M5 of Algorithm M) consists of a simple multiplication by a one-place number, combined with a subtraction. The digits $(u_j, u_{j+1}, \dots, u_{j+n})$ should be kept positive; if the result of this step is actually negative, $(u_j u_{j+1} \dots u_{j+n})_b$ should be left as the true value plus b^{n+1}, i.e., as the b's complement of the true value, and a "borrow" to the left should be remembered.

D5. [Test remainder.] Set $q_j \leftarrow \hat{q}$. If the result of step D4 was negative, go to step D6; otherwise go on to step D7.

D6. [Add back.] (The probability that this step is necessary is very small, on the order of only $2/b$, as shown in exercise 21; test data that activates this step should therefore be specifically contrived when debugging.) Decrease q_j by 1, and add $(0 v_1 v_2 \dots v_n)_b$ to $(u_j u_{j+1} u_{j+2} \dots u_{j+n})_b$. (A carry will occur to the left of u_j, and it should be ignored since it cancels with the "borrow" that occurred in D4.)

D7. [Loop on j.] Increase j by one. Now if $j \leq m$, go back to D3.

D8. [Unnormalize.] Now $(q_0 q_1 \dots q_m)_b$ is the desired quotient, and the desired remainder may be obtained by dividing $(u_{m+1} \dots u_{m+n})_b$ by d. ∎

The representation of Algorithm D as a MIX program has several points of interest:

Program D (*Division of nonnegative integers*). The conventions of this program are analogous to Program A; rI1 $\equiv i$, rI2 $\equiv j - m$, rI3 $\equiv i + j$.

```

Note how easily the rather complex-appearing calculations and decisions of step D3 can be handled inside the machine. Note also that the program for step D4 is analogous to Program M, except that the ideas of Program S have also been incorporated.

The running time for Program D can be estimated by considering the quantities M, N, E, K, and K' shown in the program. (These quantities ignore several situations that occur only with very low probability; for example, we may assume that lines 048–050, 063–064, and step D6 are never executed.) Here $M+1$ is the number of words in the quotient; N is the number of words in the divisor; E is the number of times $\hat{q}$ is adjusted downwards in step D3; K and K' are the number of times certain "carry" adjustments are made during the multiply-subtract loop. If we assume that $K+K'$ is approximately $(N+1)(M+1)$, and that E is approximately $\frac{1}{2}M$, we get a total running time of approximately

$$30MN + 30N + 89M + 111$$

cycles, plus $67N+235M+4$ more if $d > 1$. (The program segments of exercises 25 and 26 are included in these totals.) When M and N are large, this is only about seven percent longer than the time Program M takes to multiply the quotient by the divisor.

Further commentary on Algorithm D appears in the exercises at the close of this section.

It is possible to debug programs for multiple-precision arithmetic by using the multiplication and addition routines to check the result of the division routine, etc. The following type of test data is occasionally useful:

$$(t^m - 1)(t^n - 1) = t^{m+n} - t^n - t^m + 1.$$

If $m < n$, this number has the radix-t expansion

$$\underbrace{(t-1)\ \ldots\ (t-1)}_{m-1\text{ places}}\ (t-2)\ \underbrace{(t-1)\ \ldots\ (t-1)}_{n-m\text{ places}}\ \underbrace{0\ \ldots\ 0}_{m-1\text{ places}}\ 1;$$

for example, $(10^3 - 1)(10^5 - 1) = 99899001$. In the case of Program D, it is also necessary to find some test cases that cause the rarely executed parts of the program to be exercised; some portions of that program would probably never get tested even if a million random test cases were tried.

Now that we have seen how to operate with signed-magnitude numbers, let us consider what approach should be taken to the same problems when a computer with complement notation is being used. For two's complement and ones' complement notations, it is usually best to let the radix b be *one half* of the word size; thus for a 32-bit computer word we would use $b = 2^{31}$ in the above algorithms. The sign bit of all but the most significant word of a multiple-precision number will be zero, so that no anomalous sign correction takes place during the computer's multiplication and division operations. In fact, the basic meaning of complement notation requires that we consider all but the most significant word to be nonnegative. For example, assuming an 8-bit word, the two's complement number

$$11011111\quad 1111110\quad 1101011$$

(where the sign bit is shown only in the most significant word) is properly thought of as

$$-2^{21} + (1011111)_2 \cdot 2^{14} + (1111110)_2 \cdot 2^7 + (1101011)_2.$$

Addition of signed numbers is slightly easier when complement notations are being used, since the routine for adding n-place nonnegative integers can be used for arbitrary n-place integers; the sign appears only in the first word, so the less significant words may be added together irrespective of the actual sign. (Special attention must be given to the leftmost carry when ones' complement notation is being used, however; it must be added into the least significant word, and possibly propagated further to the left.) Similarly, we find that subtraction of signed numbers is slightly simpler with complement notation. On the other hand, multiplication and division seem to be done most easily by working with nonnegative quantities and doing suitable complementation operations beforehand to make sure that both operands are nonnegative; it may be possible to avoid this complementation by devising some tricks for working directly with negative numbers in a complement notation, and it is not hard to see how this could be done in double-precision multiplication, but care should be taken not to slow down the inner loops of the subroutines when high precision is required. Note that the product of two m-place numbers in two's complement notation may require $2m + 1$ places: the square of $(-b^m)$ is b^{2m}.

Let us now turn to an analysis of the quantity K that arises in Program A, i.e., the number of carries that occur when two n-place numbers are being added together. Although K has no effect on the total running time of Program A, it does affect the running time of the Program A's counterparts that deal with complement notations, and its analysis is interesting in itself as a significant application of generating functions.

Suppose that u and v are independent random n-place integers, uniformly distributed in the range $0 \le u, v < b^n$. Let p_{nk} be the probability that exactly k carries occur in the addition of u to v, *and* that one of these carries occurs in the most significant position (so that $u + v \ge b^n$). Similarly, let q_{nk} be the probability that exactly k carries occur, but that there is no carry in the most significant position. Then it is not hard to see that

$$\begin{aligned} p_{0k} &= 0, \qquad q_{0k} = \delta_{0k}, \qquad \text{for all } k; \\ p_{(n+1)(k+1)} &= \frac{b+1}{2b} p_{nk} + \frac{b-1}{2b} q_{nk}, \\ q_{(n+1)k} &= \frac{b-1}{2b} p_{nk} + \frac{b+1}{2b} q_{nk}; \end{aligned} \tag{3}$$

this happens because $(b-1)/2b$ is the probability that $u_1 + v_1 \ge b$ and $(b+1)/2b$ is the probability that $u_1 + v_1 + 1 \ge b$, when u_1 and v_1 are independently and uniformly distributed integers in the range $0 \le u_1, v_1 < b$.

To obtain further information about these quantities p_{nk} and q_{nk}, we may set up the generating functions

$$P(z,t) = \sum_{k,n} p_{nk}\, z^k t^n, \qquad Q(z,t) = \sum_{k,n} q_{nk}\, z^k t^n. \tag{4}$$

From (3) we have the basic relations

$$\begin{aligned} P(z,t) &= zt\left(\frac{b+1}{2b} P(z,t) + \frac{b-1}{2b} Q(z,t)\right), \\ Q(z,t) &= 1 + t\left(\frac{b-1}{2b} P(z,t) + \frac{b+1}{2b} Q(z,t)\right). \end{aligned}$$

These two equations are readily solved for $P(z,t)$ and $Q(z,t)$; and if we let

$$G(z,t) = P(z,t) + Q(z,t) = \sum_n G_n(z) t^n,$$

where $G_n(z)$ is the generating function for the total number of carries when n-place numbers are added, we find that

$$G(z,t) = (b - zt)/p(z,t), \quad \text{where } p(z,t) = b - \tfrac{1}{2}(1+b)(1+z)t + zt^2. \tag{5}$$

Note that $G(1,t) = 1/(1-t)$, and this checks with the fact that $G_n(1)$ must equal 1 (it is the sum of all the possible probabilities). Taking partial derivatives

of (5) with respect to z, we find that

$$\frac{\partial G}{\partial z} = \sum_n G_n'(z)t^n = \frac{-t}{p(z,t)} + \frac{t(b-zt)(b+1-2t)}{2p(z,t)^2};$$
$$\frac{\partial^2 G}{\partial z^2} = \sum_n G_n''(z)t^n = \frac{-t^2(b+1-2t)}{p(z,t)^2} + \frac{t^2(b-zt)(b+1-2t)}{p(z,t)^3}.$$

Now let us put $z = 1$ and expand in partial fractions:

$$\sum_n G_n'(1)t^n = \frac{t}{2}\left(\frac{1}{(1-t)^2} - \frac{1}{(b-1)(1-t)} + \frac{1}{(b-1)(b-t)}\right),$$
$$\sum_n G_n''(1)t^n = \frac{t^2}{2}\left(\frac{1}{(1-t)^3} - \frac{1}{(b-1)^2(1-t)} + \frac{1}{(b-1)^2(b-t)} + \frac{1}{(b-1)(b-t)^2}\right).$$

It follows that the average number of carries, i.e., the mean value of K, is

$$G_n'(1) = \frac{1}{2}\left(n - \frac{1}{b-1}\left(1 - \left(\frac{1}{b}\right)^n\right)\right); \tag{6}$$

the variance is

$$G_n''(1) + G_n'(1) - G_n'(1)^2 = \frac{1}{4}\left(n + \frac{2n}{b-1} - \frac{2b+1}{(b-1)^2} + \frac{2b+2}{(b-1)^2}\left(\frac{1}{b}\right)^n - \frac{1}{(b-1)^2}\left(\frac{1}{b}\right)^{2n}\right). \tag{7}$$

So the number of carries is just slightly less than $\frac{1}{2}n$ under these assumptions.

History and bibliography. The early history of the classical algorithms described in this section is left as an interesting project for the reader, and only the history of their implementation on computers will be traced here.

The use of 10^n as an assumed radix when multiplying large numbers on a desk calculator was discussed by D. N. Lehmer and J. P. Ballantine, *AMM* **30** (1923), 67–69.

Double-precision arithmetic on digital computers was first treated by J. von Neumann and H. H. Goldstine in their introductory notes on programming, originally published in 1947 [J. von Neumann, *Collected Works* **5**, 142–151]. Theorems A and B above are due to D. A. Pope and M. L. Stein [*CACM* **3** (1960), 652–654], whose paper also contains a bibliography of earlier work on double-precision routines. Other ways of choosing the trial quotient $\hat{q}$ have been discussed by A. G. Cox and H. A. Luther, *CACM* **4** (1961), 353 [divide by $v_1 + 1$ instead of v_1], and by M. L. Stein, *CACM* **7** (1964), 472–474 [divide by v_1 or

$v_1 + 1$ according to the magnitude of v_2]; E. V. Krishnamurthy [*CACM* **8** (1965), 179–181] showed that examination of the single-precision remainder in the latter method leads to an improvement over Theorem B. Krishnamurthy and Nandi [*CACM* **10** (1967), 809–813] suggested a way to replace the normalization and unnormalization operations of Algorithm D by a calculation of $\hat{q}$ based on several leading digits of the operands. G. E. Collins and D. R. Musser have carried out an interesting analysis of the original Pope and Stein algorithm [*Inf. Proc. Letters* **6** (1977), 151–155].

Several alternative methods for division have also been suggested:

1) "Fourier division" [J. Fourier, *Analyse des équations déterminées* (Paris, 1831), §2.21]. This method, which was often used on desk calculators, essentially obtains each new quotient digit by increasing the precision of the divisor and the dividend at each step. Some rather extensive tests by the author have indicated that such a method is inferior to the divide-and-correct technique above, but there may be some applications in which Fourier division is practical. See D. H. Lehmer, *AMM* **33** (1926), 198–206; J. V. Uspensky, *Theory of Equations* (New York: McGraw-Hill, 1948), 159–164.

2) "Newton's method" for evaluating the reciprocal of a number was extensively used in early computers when there was no single-precision division instruction. The idea is to find some initial approximation x_0 to the number $1/v$, then to let $x_{n+1} = 2x_n - vx_n^2$. This method converges rapidly to $1/v$, since $x_n = (1-\epsilon)/v$ implies that $x_{n+1} = (1-\epsilon^2)/v$. Convergence to third order, i.e., with ϵ replaced by $O(\epsilon^3)$ at each step, can be obtained using the formula

$$\begin{aligned} x_{n+1} &= x_n + x_n(1 - vx_n) + x_n(1 - vx_n)^2 \\ &= x_n\big(1 + (1 - vx_n)(1 + (1 - vx_n))\big), \end{aligned}$$

and similar formulas hold for fourth-order convergence, etc.; see P. Rabinowitz, *CACM* **4** (1961), 98. For calculations on extremely large numbers, Newton's second-order method and subsequent multiplication by u can actually be considerably faster than Algorithm D, if we increase the precision of x_n at each step and if we also use the fast multiplication routines of Section 4.3.3. (See Algorithm 4.3.3D for details.) Some related iterative schemes have been discussed by E. V. Krishnamurthy, *IEEE Trans.* **C–19** (1970), 227–231.

3) Division methods have also been based on the evaluation of

$$\frac{u}{v+\epsilon} = \frac{u}{v}\left(1 - \left(\frac{\epsilon}{v}\right) + \left(\frac{\epsilon}{v}\right)^2 - \left(\frac{\epsilon}{v}\right)^3 + \cdots\right).$$

See H. H. Laughlin, *AMM* **37** (1930), 287–293. We have used this idea in the double-precision case (Eq. 4.2.3–3).

Besides the references just cited, the following early articles concerning multiple-precision arithmetic are of interest: High-precision routines for floating point calculations using ones' complement arithmetic are described by A. H.

Stroud and D. Secrest, *Comp. J.* **6** (1963), 62–66. Extended-precision subroutines for use in FORTRAN programs are described by B. I. Blum, *CACM* **8** (1965), 318–320; and for use in ALGOL by M. Tienari and V. Suokonautio, *BIT* **6** (1966), 332–338. Arithmetic on integers with *unlimited* precision, making use of linked memory allocation techniques, has been elegantly described by G. E. Collins, *CACM* **9** (1966), 578–589. For a much larger repertoire of operations, including logarithms and trigonometric functions, see R. P. Brent, *ACM Trans. Math. Software* **4** (1978), 57–81.

We have restricted our discussion in this section to arithmetic techniques for use in computer programming. There are many algorithms for *hardware* implementation of arithmetic operations that are very interesting, but they appear to be inapplicable to computer programs for high-precision numbers; for example, see G. W. Reitwiesner, "Binary Arithmetic," *Advances in Computers* **1** (New York: Academic Press, 1960), 231–308; O. L. MacSorley, *Proc. IRE* **49** (1961), 67–91; G. Metze, *IRE Trans.* **EC–11** (1962), 761–764; H. L. Garner, "Number Systems and Arithmetic," *Advances in Computers* **6** (New York: Academic Press, 1965), 131–194. The minimum achievable execution time for hardware addition and multiplication operations has been investigated by S. Winograd, *JACM* **12** (1965), 277–285, **14** (1967), 793–802; by R. P. Brent, *IEEE Trans.* **C–19** (1970), 758–759; and by R. W. Floyd, *IEEE Symp. Found. Comp. Sci.* **16** (1975), 3–5.

EXERCISES

1. [*42*] Study the early history of the classical algorithms for arithmetic by looking up the writings of, say, Sun Tsŭ, al-Khwârizmî, al-Uqlîdisî, Fibonacci, and Robert Recorde, and by translating their methods as faithfully as possible into precise algorithmic notation.

2. [*15*] Generalize Algorithm A so that it does "column addition," i.e., obtains the sum of m nonnegative n-place integers. (Assume that $m \leq b$.)

3. [*21*] Write a MIX program for the algorithm of exercise 2, and estimate its running time as a function of m and n.

4. [*M21*] Give a formal proof of the validity of Algorithm A, using the method of "inductive assertions" explained in Section 1.2.1.

5. [*21*] Algorithm A adds the two inputs by going from right to left, but sometimes the data is more readily accessible from left to right. Design an algorithm that produces the same answer as Algorithm A, but that generates the digits of the answer from left to right, going back to change previous values if a carry occurs to make a previous value incorrect. [*Note:* Early Hindu and Arabic manuscripts dealt with addition from left to right in this way, probably because it was customary to work from left to right on an abacus; the right-to-left addition algorithm was a refinement due to al-Uqlîdisî, perhaps because Arabic is written from right to left.]

▸ **6.** [*22*] Design an algorithm that adds from left to right (as in exercise 5), but your algorithm should not store a digit of the answer until this digit cannot possibly be affected by future carries; there is to be no changing of any answer digit once it has been stored. [*Hint:* Keep track of the number of consecutive $(b-1)$'s that have not yet been stored in the answer.] This sort of algorithm would be appropriate, for example, in a situation where the input and output numbers are to be read and written from left to right on magnetic tapes, or if they appear in straight linear lists.

7. [*M26*] Determine the average number of times the algorithm of exercise 5 will find that a carry makes it necessary to go back and change k digits of the partial answer, for $k = 1, 2, \ldots, n$. (Assume that both inputs are independently and uniformly distributed between 0 and $b^n - 1$.)

8. [*M26*] Write a MIX program for the algorithm of exercise 5, and determine its average running time based on the expected number of carries as computed in the text.

▸ **9.** [*21*] Generalize Algorithm A to obtain an algorithm that adds two n-place numbers in a *mixed-radix* number system, with bases $b_0, b_1, \ldots$ (from right to left). Thus the least significant digits lie between 0 and $b_0 - 1$, the next digits lie between 0 and $b_1 - 1$, etc.; cf. Eq. 4.1–9.

10. [*18*] Would Program S work properly if the instructions on lines 06 and 07 were interchanged? If the instructions on lines 05 and 06 were interchanged?

11. [*10*] Design an algorithm that compares two nonnegative n-place integers $u = (u_1 u_2 \ldots u_n)_b$ and $v = (v_1 v_2 \ldots v_n)_b$, to determine whether $u < v$, $u = v$, or $u > v$.

12. [*16*] Algorithm S assumes that we know which of the two input operands is the larger; if this information is not known, we could go ahead and perform the subtraction anyway, and we would find that an extra "borrow" is still present at the end of the algorithm. Design another algorithm that could be used (if there is a "borrow" present at the end of Algorithm S) to complement $(w_1 w_2 \ldots w_n)_b$ and therefore to obtain the absolute value of the difference of u and v.

13. [*21*] Write a MIX program that multiplies $(u_1 u_2 \ldots u_n)_b$ by v, where v is a single-precision number (i.e., $0 \le v < b$), producing the answer $(w_0 w_1 \ldots w_n)_b$. How much running time is required?

▸ **14.** [*M24*] Give a formal proof of the validity of Algorithm M, using the method of "inductive assertions" explained in Section 1.2.1.

15. [*M20*] If we wish to form the product of two n-place fractions, $(.u_1 u_2 \ldots u_n)_b \times (.v_1 v_2 \ldots v_n)_b$, and to obtain only an n-place approximation $(.w_1 w_2 \ldots w_n)_b$ to the result, Algorithm M could be used to obtain a $2n$-place answer that is subsequently rounded to the desired approximation. But this involves about twice as much work as is necessary for reasonable accuracy, since the products $u_i v_j$ for $i + j > n + 2$ contribute very little to the answer.

Give an estimate of the maximum error that can occur, if these products $u_i v_j$ for $i + j > n + 2$ are not computed during the multiplication, but are assumed to be zero.

▸ **16.** [*20*] Design an algorithm that divides a nonnegative n-place integer $(u_1 u_2 \ldots u_n)_b$ by v, where v is a single-precision number (i.e., $0 < v < b$), producing the quotient $(w_1 w_2 \ldots w_n)_b$ and remainder r.

17. [*M20*] In the notation of Fig. 6, assume that $v_1 \ge \lfloor b/2 \rfloor$; show that if $u_0 = v_1$, we must have $q = b - 1$ or $b - 2$.

18. [*M20*] In the notation of Fig. 6, show that if $q' = \lfloor (u_0 b + u_1)/(v_1 + 1) \rfloor$, then $q' \le q$.

▶ **19.** [*M21*] In the notation of Fig. 6, let $\hat{q}$ be an approximation to q, and let $\hat{r} = u_0 b + u_1 - \hat{q} v_1$. Assume that $v_1 > 0$. Show that if $v_2 \hat{q} > b\hat{r} + u_2$, then $q < \hat{q}$. [*Hint:* Strengthen the proof of Theorem A by examining the influence of v_2.]

20. [*M22*] Using the notation and assumptions of exercise 19, show that if $v_2 \hat{q} \le b\hat{r} + u_2$, then $\hat{q} = q$ or $q = \hat{q} - 1$.

▶ **21.** [*M23*] Show that if $v_1 \ge \lfloor b/2 \rfloor$, and if $v_2 \hat{q} \le b\hat{r} + u_2$ but $\hat{q} \ne q$ in the notation of exercises 19 and 20, then $u \bmod v \ge (1 - 2/b)v$. (The latter event occurs with approximate probability $2/b$, so that when b is the word size of a computer we must have $q_j = \hat{q}$ in Algorithm D except in very rare circumstances.)

▶ **22.** [*24*] Find an example of a four-digit number divided by a three-digit number for which step D6 is necessary in Algorithm D, when the radix b is 10.

23. [*M23*] Given that v and b are integers, and that $1 \le v < b$, prove that we always have $\lfloor b/2 \rfloor \le v\lfloor b/(v+1) \rfloor < (v+1)\lfloor b/(v+1) \rfloor \le b$.

24. [*M20*] Using the law of the distribution of leading digits explained in Section 4.2.4, give an approximate formula for the probability that $d = 1$ in Algorithm D. (When $d = 1$, it is, of course, possible to omit most of the calculation in steps D1 and D8.)

25. [*26*] Write a MIX routine for step D1, which is needed to complete Program D.

26. [*21*] Write a MIX routine for step D8, which is needed to complete Program D.

27. [*M20*] Prove that at the beginning of step D8 in Algorithm D, the unnormalized remainder $(u_{m+1} u_{m+2} \ldots u_{m+n})_b$ is always an exact multiple of d.

28. [*M30*] (A. Svoboda, *Stroje na Zpracování Informací* **9** (1963), 25–32.) Let $v = (v_1 v_2 \ldots v_n)_b$ be any radix b integer, where $v_1 \ne 0$. Perform the following operations:

N1. If $v_1 < b/2$, multiply v by $\lfloor (b+1)/(v_1+1) \rfloor$. Let the result of this step be $(v_0 v_1 v_2 \ldots v_n)_b$.

N2. If $v_0 = 0$, set $v \leftarrow v + (1/b)\lfloor b(b - v_1)/(v_1 + 1) \rfloor v$; let the result of this step be $(v_0 v_1 v_2 \ldots v_n . v_{n+1} \ldots)_b$. Repeat step N2 until $v_0 \ne 0$.

Prove that step N2 will be performed at most three times, and that we must always have $v_0 = 1$, $v_1 = 0$ at the end of the calculations.

[*Note:* If u and v are both multiplied by the above constants, we do not change the value of the quotient u/v, and the divisor has been converted into the form $(10 v_2 \ldots v_n . v_{n+1} v_{n+2} v_{n+3})_b$. This form of the divisor is very convenient because, in the notation of Algorithm D, we may simply take $\hat{q} = u_j$ as a trial divisor at the beginning of step D3, or $\hat{q} = b - 1$ when $(u_{j-1}, u_j) = (1, 0)$.]

29. [*15*] Prove or disprove: At the beginning of step D7 of Algorithm D, we always have $u_j = 0$.

▶ **30.** [*22*] If memory space is limited, it may be desirable to use the same storage locations for both input and output during the performance of some of the algorithms in this section. Is it possible to have $w_1, \ldots, w_n$ stored in the same respective locations as $u_1, \ldots, u_n$ or $v_1, \ldots, v_n$ during Algorithm A or S? Is it possible to have the quotient $q_0, \ldots, q_m$ occupy the same locations as $u_0, \ldots, u_m$ in Algorithm D? Is there any permissible overlap of memory locations between input and output in Algorithm M?

31. [28] Assume that $b = 3$ and that $u = (u_1 \ldots u_{m+n})_3$, $v = (v_1 \ldots v_n)_3$ are integers in *balanced ternary* notation (cf. Section 4.1), $v_1 \neq 0$. Design a long-division algorithm that divides u by v, obtaining a remainder whose absolute value does not exceed $\frac{1}{2}|v|$. Try to find an algorithm that would be efficient if incorporated into the arithmetic circuitry of a balanced ternary computer.

32. [M40] Assume that $b = 2i$ and that u and v are complex numbers expressed in the quater-imaginary number system. Design algorithms that divide u by v, perhaps obtaining a suitable remainder of some sort, and compare their efficiency. [*References:* M. Nadler, *CACM* **4** (1961), 192–193; Z. Pawlak and A. Wakulicz, *Bull. de l'Acad. Polonaise des Sciences*, Classe III, **5** (1957), 233–236 (see also pp. 803–804); and exercise 4.1–15.]

33. [M40] Design an algorithm for taking square roots, analogous to Algorithm D and to the traditional pencil-and-paper method for extracting square roots.

34. [40] Develop a set of computer subroutines for doing the four arithmetic operations on arbitrary integers, putting no constraint on the size of the integers except for the implicit assumption that the total memory capacity of the computer should not be exceeded. (Use linked memory allocation, so that no time is wasted in finding room to put the results.)

35. [40] Develop a set of computer subroutines for "decuple-precision floating point" arithmetic, using excess 0, base b, nine-place floating point number representation, where b is the computer word size, and allowing a full word for the exponent. (Thus each floating point number is represented in 10 words of memory, and all scaling is done by moving full words instead of by shifting within the words.)

36. [M42] Compute the values of the fundamental constants listed in Appendix B to much higher precision than the 40-place values listed there. [*Note:* The first 100,000 digits of the decimal expansion of π were published by D. Shanks and J. W. Wrench, Jr., in *Math. Comp.* **16** (1962), 76–99. One million digits of π were computed by Jean Guilloud and Martine Bouyer of the French Atomic Energy Commission in 1974.]

▶ **37.** [20] (E. Salamin.) Explain how to avoid the normalization and unnormalization steps of Algorithm D, when d is a power of 2 on a binary computer, without changing the sequence of trial quotient digits computed by that algorithm. (How can $\hat{q}$ be computed in step D3 if the normalization of step D1 hasn't been done?)

*4.3.2. Modular Arithmetic

Another interesting alternative is available for doing arithmetic on large integer numbers, based on some simple principles of number theory. The idea is to have several "moduli" $m_1, m_2, \ldots, m_r$ that contain no common factors, and to work indirectly with "residues" $u \bmod m_1, u \bmod m_2, \ldots, u \bmod m_r$ instead of directly with the number u.

For convenience in notation throughout this section, let

$$u_1 = u \bmod m_1, \qquad u_2 = u \bmod m_2, \qquad \ldots, \qquad u_r = u \bmod m_r. \tag{1}$$

It is easy to compute $(u_1, u_2, \ldots, u_r)$ from an integer number u by means of division; and it is important to note that no information is lost in this process,

since we can recompute u from $(u_1, u_2, \ldots, u_r)$ provided that u is not too large. For example, if $0 \le u < v \le 1000$, it is impossible to have $(u \bmod 7, u \bmod 11, u \bmod 13)$ equal to $(v \bmod 7, v \bmod 11, v \bmod 13)$. This is a consequence of the "Chinese remainder theorem" stated below.

We may therefore regard $(u_1, u_2, \ldots, u_r)$ as a new type of internal computer representation, a "modular representation," of the integer u.

The advantages of a modular representation are that addition, subtraction, and multiplication are very simple:

$$(u_1, \ldots, u_r) + (v_1, \ldots, v_r) = ((u_1 + v_1) \bmod m_1, \ldots, (u_r + v_r) \bmod m_r), \quad (2)$$
$$(u_1, \ldots, u_r) - (v_1, \ldots, v_r) = ((u_1 - v_1) \bmod m_1, \ldots, (u_r - v_r) \bmod m_r), \quad (3)$$
$$(u_1, \ldots, u_r) \times (v_1, \ldots, v_r) = ((u_1 \times v_1) \bmod m_1, \ldots, (u_r \times v_r) \bmod m_r). \quad (4)$$

To derive (4), for example, we need to show that

$$uv \bmod m_j = (u \bmod m_j)(v \bmod m_j) \bmod m_j$$

for each modulus m_j. But this is a basic fact of elementary number theory: $x \bmod m_j = y \bmod m_j$ if and only if $x \equiv y$ (modulo m_j); furthermore if $x \equiv x'$ and $y \equiv y'$, then $xy \equiv x'y'$ (modulo m_j); hence $(u \bmod m_j)(v \bmod m_j) \equiv uv$ (modulo m_j).

The disadvantages of a modular representation are that it is comparatively difficult to test whether a number is positive or negative or to test whether or not $(u_1, \ldots, u_r)$ is greater than $(v_1, \ldots, v_r)$. It is also difficult to test whether or not overflow has occurred as the result of an addition, subtraction, or multiplication, and it is even more difficult to perform division. When these operations are required frequently in conjunction with addition, subtraction, and multiplication, the use of modular arithmetic can be justified only if fast means of conversion into and out of the modular representation are available. Therefore conversion between modular and positional notation is one of the principal topics of interest to us in this section.

The processes of addition, subtraction, and multiplication using (2), (3), and (4) are called residue arithmetic or *modular arithmetic*. The range of numbers that can be handled by modular arithmetic is equal to $m = m_1 m_2 \ldots m_r$, the product of the moduli. Therefore we see that the amount of time required to add, subtract, or multiply n-digit numbers using modular arithmetic is essentially proportional to n (not counting the time to convert in and out of modular representation). This is no advantage at all when addition and subtraction are considered, but it can be a considerable advantage with respect to multiplication since the conventional method of the preceding section requires an execution time proportional to n^2.

Moreover, on a computer that allows many operations to take place simultaneously, modular arithmetic can be a significant advantage even for addition and subtraction; the operations with respect to different moduli can all be done at the same time, so we obtain a substantial increase in speed. The same kind of

decrease in execution time could not be achieved by the conventional techniques discussed in the previous section, since carry propagation must be considered. Perhaps some day highly parallel computers will make simultaneous operations commonplace, so that modular arithmetic will be of significant importance in "real-time" calculations when a quick answer to a single problem requiring high precision is needed. (With highly parallel computers, it is often preferable to run k *separate* programs simultaneously, instead of running a *single* program k times as fast, since the latter alternative is more complicated but does not utilize the machine any more efficiently. "Real-time" calculations are exceptions that make the inherent parallelism of modular arithmetic more significant.)

Now let us examine the basic fact that underlies the modular representation of numbers:

Theorem C (*Chinese Remainder Theorem*). *Let m_1, m_2, ..., m_r be positive integers that are relatively prime in pairs, i.e.,*

$$\gcd(m_j, m_k) = 1 \qquad \text{when } j \neq k. \tag{5}$$

Let $m = m_1 m_2 \ldots m_r$, and let a, u_1, u_2, ..., u_r be integers. Then there is exactly one integer u that satisfies the conditions

$$a \leq u < a + m, \qquad \text{and} \qquad u \equiv u_j \text{ (modulo } m_j) \text{ for } 1 \leq j \leq r. \tag{6}$$

Proof. If $u \equiv v$ (modulo m_j) for $1 \leq j \leq r$, then $u - v$ is a multiple of m_j for all j, so (5) implies that $u - v$ is a multiple of $m = m_1 m_2 \ldots m_r$. This argument shows that there is *at most* one solution of (6). To complete the proof we must now show the existence of *at least* one solution, and this can be done in two simple ways:

METHOD 1 ("Nonconstructive" proof). As u runs through the m distinct values $a \leq u < a + m$, the r-tuples $(u \bmod m_1, \ldots, u \bmod m_r)$ must also run through m distinct values, since (6) has at most one solution. But there are exactly $m_1 m_2 \ldots m_r$ possible r-tuples $(v_1, \ldots, v_r)$ such that $0 \leq v_j < m_j$. Therefore each r-tuple must occur exactly once, and there must be some value of u for which $(u \bmod m_1, \ldots, u \bmod m_r) = (u_1, \ldots, u_r)$.

METHOD 2 ("Constructive" proof). We can find numbers M_j for $1 \leq j \leq r$ such that

$$M_j \equiv 1 \text{ (modulo } m_j) \qquad \text{and} \qquad M_j \equiv 0 \text{ (modulo } m_k) \text{ for } k \neq j. \tag{7}$$

This follows because (5) implies that m_j and m/m_j are relatively prime, so we may take

$$M_j = (m/m_j)^{\varphi(m_j)} \tag{8}$$

by Euler's theorem (exercise 1.2.4–28). Now the number

$$u = a + \big((u_1 M_1 + u_2 M_2 + \cdots + u_r M_r - a) \bmod m\big) \tag{9}$$

satisfies all the conditions of (6). ∎

A very special case of this theorem was stated by the Chinese mathematician Sun Tsŭ, who gave a rule called tái-yen ("great generalization"). The date of his writing is very uncertain; it is thought to be between 280 and 473 A.D. [See Joseph Needham, *Science and Civilization in China* **3** (Cambridge University Press, 1959), 33–34, 119–120, for an interesting discussion.] Theorem C was apparently first stated and proved in its proper generality by Chhin Chiu Shao in his *Shu Shu Chiu Chang* (1247). Numerous early contributions to this theory have been summarized by L. E. Dickson in his *History of the Theory of Numbers* **2** (New York: Chelsea, 1952), 57–64.

As a consequence of Theorem C, we may use modular representation for numbers in any consecutive interval of $m = m_1 m_2 \dots m_r$ integers. For example, we could take $a = 0$ in (6), and work only with nonnegative integers u less than m. On the other hand, when addition and subtraction are being done, as well as multiplication, it is usually most convenient to assume that all the moduli $m_1, m_2, \dots, m_r$ are odd numbers, so that $m = m_1 m_2 \dots m_r$ is odd, and to work with integers in the range

$$-\frac{m}{2} < u < \frac{m}{2}, \tag{10}$$

which is completely symmetrical about zero.

To perform the basic operations listed in (2), (3), and (4), we need to compute $(u_j + v_j) \bmod m_j$, $(u_j - v_j) \bmod m_j$, and $u_j v_j \bmod m_j$, when $0 \le u_j, v_j < m_j$. If m_j is a single-precision number, it is most convenient to form $u_j v_j \bmod m_j$ by doing a multiplication and then a division operation. For addition and subtraction, the situation is a little simpler, since no division is necessary; the following formulas may conveniently be used:

$$(u_j + v_j) \bmod m_j = \begin{cases} u_j + v_j, & \text{if } u_j + v_j < m_j; \\ u_j + v_j - m_j, & \text{if } u_j + v_j \ge m_j. \end{cases} \tag{11}$$

$$(u_j - v_j) \bmod m_j = \begin{cases} u_j - v_j, & \text{if } u_j - v_j \ge 0; \\ u_j - v_j + m_j, & \text{if } u_j - v_j < 0. \end{cases} \tag{12}$$

(Cf. Section 3.2.1.1.) In this case, since we want m to be as large as possible, it is easiest to let m_1 be the largest odd number that fits in a computer word, to let m_2 be the largest odd number $< m_1$ that is relatively prime to m_1, to let m_3 be the largest odd number $< m_2$ that is relatively prime to both m_1 and m_2, and so on until enough m_j's have been found to give the desired range m. Efficient ways to determine whether or not two integers are relatively prime are discussed in Section 4.5.2.

As a simple example, suppose that we have a decimal computer whose words hold only two digits, so that the word size is 100. Then the procedure described in the previous paragraph would give

$$m_1 = 99, \quad m_2 = 97, \quad m_3 = 95, \quad m_4 = 91, \quad m_5 = 89, \quad m_6 = 83, \tag{13}$$

and so on.

On binary computers it is sometimes desirable to choose the m_j in a different way, by selecting

$$m_j = 2^{e_j} - 1. \tag{14}$$

In other words, each modulus is one less than a power of 2. Such a choice of m_j often makes the basic arithmetic operations simpler, because it is relatively easy to work modulo $2^{e_j} - 1$, as in ones' complement arithmetic. When the moduli are chosen according to this strategy, it is helpful to relax the condition $0 \le u_j < m_j$ slightly, so that we require only

$$0 \le u_j < 2^{e_j}, \qquad u_j \equiv u \text{ (modulo } 2^{e_j} - 1). \tag{15}$$

Thus, the value $u_j = m_j = 2^{e_j} - 1$ is allowed as an optional alternative to $u_j = 0$, since this does not affect the validity of Theorem C, and it means we are allowing u_j to be any e_j-bit binary number. Under this assumption, the operations of addition and multiplication modulo m_j become the following:

$$u_j \oplus v_j = \begin{cases} u_j + v_j, & \text{if } u_j + v_j < 2^{e_j}; \\ ((u_j + v_j) \bmod 2^{e_j}) + 1, & \text{if } u_j + v_j \ge 2^{e_j}. \end{cases} \tag{16}$$

$$u_j \otimes v_j = (u_j v_j \bmod 2^{e_j}) \oplus \lfloor u_j v_j / 2^{e_j} \rfloor. \tag{17}$$

(Here $\oplus$ and $\otimes$ refer to the operations done on the individual components of $(u_1, \ldots, u_r)$ and $(v_1, \ldots, v_r)$ when adding or multiplying, respectively, using the convention (15).) Equation (12) may be used for subtraction. These operations can be performed efficiently even when m_j is larger than the computer's word size, since it is a simple matter to compute the remainder of a positive number modulo a power of 2, or to divide a number by a power of 2. In (17) we have the sum of the "upper half" and the "lower half" of the product, as discussed in exercise 3.2.1.1–8.

If moduli of the form $2^{e_j} - 1$ are to be used, we must know under what conditions the number $2^e - 1$ is relatively prime to the number $2^f - 1$. Fortunately, there is a very simple rule,

$$\gcd(2^e - 1, 2^f - 1) = 2^{\gcd(e,f)} - 1, \tag{18}$$

which states in particular that $2^e - 1$ *and* $2^f - 1$ *are relatively prime if and only if* e *and* f *are relatively prime.* Equation (18) follows from Euclid's algorithm and the identity

$$(2^e - 1) \bmod (2^f - 1) = 2^{e \bmod f} - 1. \tag{19}$$

(See exercise 6.) Thus we could choose for example $m_1 = 2^{35} - 1$, $m_2 = 2^{34} - 1$, $m_3 = 2^{33} - 1$, $m_4 = 2^{31} - 1$, $m_5 = 2^{29} - 1$, if we had a computer with word size 2^{35}; this would permit efficient addition, subtraction, and multiplication of integers in a range of size $m_1 m_2 m_3 m_4 m_5 > 2^{161}$.

As we have already observed, the operations of conversion to and from modular representation are very important. If we are given a number u, its modular representation $(u_1, \ldots, u_r)$ may be obtained by simply dividing u by $m_1, \ldots, m_r$ and saving the remainders. A possibly more attractive procedure, if $u = (v_m v_{m-1} \ldots v_0)_b$, is to evaluate the polynomial

$$(\ldots(v_m b + v_{m-1})b + \cdots)b + v_0$$

using modular arithmetic. When $b = 2$ and when the modulus m_j has the special form $2^{e_j} - 1$, both of these methods reduce to quite a simple procedure: Consider the binary representation of u with blocks of e_j bits grouped together,

$$u = a_t A^t + a_{t-1}A^{t-1} + \cdots + a_1 A + a_0, \tag{20}$$

where $A = 2^{e_j}$ and $0 \le a_k < 2^{e_j}$ for $0 \le k \le t$. Then

$$u \equiv a_t + a_{t-1} + \cdots + a_1 + a_0 \text{ (modulo } 2^{e_j} - 1), \tag{21}$$

since $A \equiv 1$, so we obtain u_j by adding the e_j-bit numbers $a_t \oplus \cdots \oplus a_1 \oplus a_0$, using (16). This process is similar to the familiar device of "casting out nines" that determines $u \bmod 9$ when u is expressed in the decimal system.

Conversion back from modular form to positional notation is somewhat more difficult. It is interesting in this regard to make a few side remarks about the way computers make us change our viewpoint towards mathematical proofs: Theorem C tells us that the conversion from $(u_1, \ldots, u_r)$ to u is possible, and two proofs are given. The first proof we considered is a classical one that relies only on very simple concepts, namely the facts that

i) any number that is a multiple of m_1, of m_2, ..., and of m_r, must be a multiple of $m_1 m_2 \ldots m_r$ when the m_j's are pairwise relatively prime; and

ii) if m things are put into m boxes with no two things in the same box, then there must be one in each box.

By traditional notions of mathematical aesthetics, this is no doubt the nicest proof of Theorem C; but from a computational standpoint it is completely worthless. It amounts to saying, "Try $u = a$, $a + 1$, ... until you find a value for which $u \equiv u_1$ (modulo m_1), ..., $u \equiv u_r$ (modulo m_r)."

The second proof of Theorem C is more explicit; it shows how to compute r new constants $M_1, \ldots, M_r$, and to get the solution in terms of these constants by formula (9). This proof uses more complicated concepts (for example, Euler's theorem), but it is much more satisfactory from a computational standpoint, since the constants $M_1, \ldots, M_r$ need to be determined only once. On the other hand, the determination of M_j by Eq. (8) is certainly not trivial, since the evaluation of Euler's φ-function requires, in general, the factorization of m_j into prime powers. Furthermore, M_j is likely to be a terribly large number, even if we compute only the quantity $M_j \bmod m$ (which will work just as well as M_j in (9)).

Since $M_j \bmod m$ is uniquely determined if (7) is to be satisfied (because of the Chinese remainder theorem), we can see that, in any event, Eq. (9) requires a lot of high-precision calculation, and such calculation is just what we wished to avoid by modular arithmetic in the first place.

So we need an even *better* proof of Theorem C if we are going to have a really usable method of conversion from $(u_1, \ldots, u_r)$ to u. Such a method was suggested by H. L. Garner in 1958; it can be carried out using $\binom{r}{2}$ constants c_{ij} for $1 \le i < j \le r$, where

$$c_{ij}\, m_i \equiv 1 \quad (\text{modulo } m_j). \tag{22}$$

These constants c_{ij} are readily computed using Euclid's algorithm, since for any given i and j Algorithm 4.5.2X will determine a and b such that $am_i + bm_j = \gcd(m_i, m_j) = 1$, and we may take $c_{ij} = a$. When the moduli have the special form $2^{e_j} - 1$, a simple method of determining c_{ij} is given in exercise 6.

Once the c_{ij} have been determined satisfying (22), we can set

$$\begin{aligned}
v_1 &\leftarrow u_1 \bmod m_1,\\
v_2 &\leftarrow (u_2 - v_1)\, c_{12} \bmod m_2,\\
v_3 &\leftarrow \big((u_3 - v_1)\, c_{13} - v_2\big)\, c_{23} \bmod m_3,\\
&\;\;\vdots\\
v_r &\leftarrow \big(\ldots((u_r - v_1)\, c_{1r} - v_2)\, c_{2r} - \cdots - v_{r-1}\big)\, c_{(r-1)r} \bmod m_r.
\end{aligned} \tag{23}$$

Then

$$u = v_r m_{r-1} \ldots m_2 m_1 + \cdots + v_3 m_2 m_1 + v_2 m_1 + v_1 \tag{24}$$

is a number satisfying the conditions

$$0 \le u < m, \qquad u \equiv u_j \ (\text{modulo } m_j) \quad \text{for } 1 \le j \le r. \tag{25}$$

(See exercise 8; another way of rewriting (23) that does not involve as many auxiliary constants is given in exercise 7.) Equation (24) is a *mixed-radix representation* of u, which may be converted to binary or decimal notation using the methods of Section 4.4. If $0 \le u < m$ is not the desired range, an appropriate multiple of m can be added or subtracted after the conversion process.

The advantage of the computation shown in (23) is that the calculation of v_j can be done using only arithmetic mod m_j, which is already built into the modular arithmetic algorithms. Furthermore, (23) allows parallel computation: We can start with $(v_1, \ldots, v_r) \leftarrow (u_1 \bmod m_1, \ldots, u_r \bmod m_r)$, then at time j for $1 \le j < r$ we simultaneously set $v_k \leftarrow (v_k - v_j)\, c_{jk} \bmod m_k$ for $j < k \le r$. An alternative way to compute the mixed-radix representation, allowing similar possibilities for parallelism, has been discussed by A. S. Fraenkel, *Proc. ACM Nat. Conf.* **19** (Philadelphia, 1965), E1.4.

It is important to observe that the mixed-radix representation (24) is sufficient to compare the magnitudes of two modular numbers. For if we know that

$0 \le u < m$ and $0 \le u' < m$, then we can tell if $u < u'$ by first doing the conversion to $(v_1, \ldots, v_r)$ and $(v'_1, \ldots, v'_r)$, then testing if $v_r < v'_r$, or if $v_r = v'_r$ and $v_{r-1} < v'_{r-1}$, etc. It is not necessary to convert all the way to binary or decimal notation if we only want to know whether $(u_1, \ldots, u_r)$ is less than $(u'_1, \ldots, u'_r)$.

The operation of comparing two numbers, or of deciding if a modular number is negative, is intuitively very simple, so we would expect to have a much easier method for making this test than the conversion to mixed-radix form. But the following theorem shows that there is little hope of finding a substantially better method, since the range of a modular number depends essentially on all bits of all the residues $(u_1, \ldots, u_r)$:

Theorem S (Nicholas Szabó, 1961). *In terms of the notation above, assume that* $m_1 < \sqrt{m}$, *and let* L *be any value in the range*

$$m_1 \le L \le m - m_1. \tag{26}$$

Let g *be any function such that the set* $\{g(0), g(1), \ldots, g(m_1 - 1)\}$ *contains fewer than* m_1 *values. Then there are numbers* u *and* v *such that*

$$g(u \bmod m_1) = g(v \bmod m_1), \qquad u \bmod m_j = v \bmod m_j \quad \text{for } 2 \le j \le r; \tag{27}$$

$$0 \le u < L \le v < m. \tag{28}$$

Proof. By hypothesis, there must exist numbers $u \neq v$ satisfying (27), since g must take on the same value for two different residues. Let (u, v) be a pair of values with $0 \le u < v < m$ satisfying (27), for which u is a minimum. Since $u' = u - m_1$ and $v' = v - m_1$ also satisfy (27), we must have $u' < 0$ by the minimality of u. Hence $u < m_1 \le L$; and if (28) does not hold, we must have $v < L$. But $v > u$, and $v - u$ is a multiple of $m_2 \ldots m_r = m/m_1$, so $v \ge v - u \ge m/m_1 > m_1$. Therefore, if (28) does not hold for (u, v), it will be satisfied for the pair $(u'', v'') = (v - m_1, u + m - m_1)$. ∎

Of course, a similar result can be proved for any m_j in place of m_1; and we could also replace (28) by the condition "$a \le u < a + L \le v < a + m$" with only minor changes in the proof. Therefore Theorem S shows that many simple functions cannot be used to determine the range of a modular number.

Let us now reiterate the main points of the discussion in this section: Modular arithmetic can be a significant advantage for applications in which the predominant calculations involve exact multiplication (or raising to a power) of large integers, combined with addition and subtraction, but where there is very little need to divide or compare numbers, *or to test whether intermediate results "overflow" out of range.* (It is important not to forget the latter restriction; methods are available to test for overflow, as in exercise 12, but they are in general so complicated that they nullify the advantages of modular arithmetic.) Several applications of modular computations have been discussed by H. Takahasi and Y. Ishibashi, *Information Proc. in Japan* **1** (1961), 28–42.

An example of such an application is the exact solution of linear equations with rational coefficients. For various reasons it is desirable in this case to assume that the moduli $m_1, m_2, \ldots, m_r$ are all large prime numbers; the linear equations can be solved independently modulo each m_j. A detailed discussion of this procedure has been given by I. Borosh and A. S. Fraenkel [*Math. Comp.* **20** (1966), 107–112]. By means of their method, the nine independent solutions of a system of 111 linear equations in 120 unknowns were obtained exactly in less than one hour's running time on a CDC 1604 computer. The same procedure is worthwhile also for solving simultaneous linear equations with floating point coefficients, when the matrix of coefficients is ill-conditioned. The modular technique (treating the given floating point coefficients as exact rational numbers) gives a method for obtaining the *true* answers in less time than conventional methods can produce reliable *approximate* answers! [See M. T. McClellan, *JACM* **20** (1973), 563–588, for further developments of this approach; and see also E. H. Bareiss, *J. Inst. Math. and Appl.* **10** (1972), 68–104, for a discussion of its limitations.]

The published literature concerning modular arithmetic is mostly oriented towards hardware design, since the carry-free properties of modular arithmetic make it attractive from the standpoint of high-speed operation. The idea was first published by A. Svoboda and M. Valach in the Czechoslovakian journal *Stroje na Zpracování Informací* **3** (1955), 247–295; then independently by H. L. Garner [*IRE Trans.* **EC–8** (1959), 140–147]. The use of moduli of the form $2^{e_j} - 1$ was suggested by A. S. Fraenkel [*JACM* **8** (1961), 87–96], and several advantages of such moduli were demonstrated by A. Schönhage [*Computing* **1** (1966), 182–196]. See the book *Residue Arithmetic and its Applications to Computer Technology* by N. S. Szabó and R. I. Tanaka (New York: McGraw-Hill, 1967), for additional information and a comprehensive bibliography of the subject. A Russian book published in 1968 by I. Ĭa. Akushskiĭ and D. I. Ĭuditskiĭ includes a chapter about complex moduli [cf. *Rev. Romaine des Math.* **15** (1970), 159–160].

Further discussion of modular arithmetic can be found in Section 4.3.3B.

EXERCISES

1. [*20*] Find all integers u that satisfy all of the following conditions: $u \bmod 7 = 1$, $u \bmod 11 = 6$, $u \bmod 13 = 5$, $0 \le u < 1000$.

2. [*M20*] Would Theorem C still be true if we allowed a, u_1, u_2, ..., u_r and u to be arbitrary real numbers (not just integers)?

▶ **3.** [*M26*] (*Generalized Chinese Remainder Theorem.*) Let $m_1, m_2, \ldots, m_r$ be positive integers. Let m be the least common multiple of $m_1, m_2, \ldots, m_r$, and let a, $u_1, u_2, \ldots, u_r$ be any integers. Prove that there is exactly one integer u that satisfies the conditions

$$a \le u < a + m, \qquad u \equiv u_j \text{ (modulo } m_j), \qquad 1 \le j \le r,$$

provided that

$$u_i \equiv u_j \pmod{\gcd(m_i, m_j)}, \qquad 1 \le i < j \le r;$$

and there is no such integer u when the latter condition fails to hold.

4. [*20*] Continue the process shown in (13); what would m_7, m_8, m_9, ... be?

▶ **5.** [*M23*] Suppose that the method of (13) is continued until no more m_j can be chosen; does this method give the largest attainable value $m_1 m_2 \ldots m_r$ such that the m_j are odd positive integers less than 100 that are relatively prime in pairs?

6. [*M22*] Let e, f, g be nonnegative integers. (a) Show that $2^e \equiv 2^f \pmod{2^g - 1}$ if and only if $e \equiv f \pmod{g}$. (b) Given that $e \bmod f = d$ and $ce \bmod f = 1$, prove that

$$\left((1 + 2^d + \cdots + 2^{(c-1)d}) \cdot (2^e - 1)\right) \bmod (2^f - 1) = 1.$$

(Thus, we have a comparatively simple formula for the inverse of $2^e - 1$, modulo $2^f - 1$, as required in (22).)

▶ **7.** [*M21*] Show that (23) can be rewritten as follows:

$$\begin{aligned}
v_1 &\leftarrow u_1 \bmod m_1,\\
v_2 &\leftarrow (u_2 - v_1)\, c_{12} \bmod m_2,\\
v_3 &\leftarrow (u_3 - (v_1 + m_1 v_2))\, c_{13} c_{23} \bmod m_3,\\
&\vdots\\
v_r &\leftarrow (u_r - (v_1 + m_1(v_2 + m_2(v_3 + \cdots + m_{r-2} v_{r-1}) \ldots)))\, c_{1r} \ldots c_{(r-1)r} \bmod m_r.
\end{aligned}$$

If the formulas are rewritten in this way, we see that only $r - 1$ constants $C_j = c_{1j} \ldots c_{(j-1)j} \bmod m_j$ are needed instead of $r(r-1)/2$ constants c_{ij} as in (23). Discuss the relative merits of this version of the formula as compared to (23), from the standpoint of computer calculation.

8. [*M21*] Prove that the number u defined by (23) and (24) satisfies (25).

9. [*M20*] Show how to go from the values $v_1, \ldots, v_r$ of the mixed-radix notation (24) back to the original residues $u_1, \ldots, u_r$, using only arithmetic mod m_j to compute the value of u_j.

10. [*M25*] An integer u that lies in the symmetrical range (10) might be represented by finding the numbers $u_1, \ldots, u_r$ such that $u \equiv u_j \pmod{m_j}$ and $-m_j/2 < u_j < m_j/2$, instead of insisting that $0 \le u_j < m_j$ as in the text. Discuss the modular arithmetic procedures that would be appropriate in connection with such a symmetrical representation (including the conversion process, (23)).

11. [*M23*] Assume that all the m_j are odd, and that $u = (u_1, \ldots, u_r)$ is known to be even, where $0 \le u < m$. Find a reasonably fast method to compute $u/2$ using modular arithmetic.

12. [*M10*] Prove that, if $0 \le u, v < m$, the modular addition of u and v causes overflow (i.e., is outside the range allowed by the modular representation) if and only if the sum is less than u. (Thus the overflow detection problem is equivalent to the comparison problem.)

▸ **13.** [*M25*] (*Automorphic numbers.*) An n-place decimal number $x > 1$ is called an "automorph" by recreational mathematicians if the last n digits of x^2 are equal to x. For example, 9376 is a 4-place automorph, since $9376^2 = 87909376$. [See *Scientific American* **218** (January 1968), 125.]

a) Prove that an n-place number $x > 1$ is an automorph if and only if $x \bmod 5^n = 0$ or 1 and $x \bmod 2^n = 1$ or 0, respectively. (Thus, if $m_1 = 2^n$ and $m_2 = 5^n$, the only two n-place automorphs are the numbers M_1 and M_2 in (7).)

b) Prove that if x is an n-place automorph, then $(3x^2 - 2x^3) \bmod 10^{2n}$ is a $2n$-place automorph.

c) Given that $cx \equiv 1$ (modulo y), find a simple formula for a number c' depending on c and x but not on y, such that $c'x^2 \equiv 1$ (modulo y^2).

*4.3.3. How Fast Can We Multiply?

The conventional method for multiplication in positional number systems, Algorithm 4.3.1M, requires approximately cmn operations to multiply an m-digit number by an n-digit number, where c is a constant. In this section, let us assume for convenience that $m = n$, and let us consider the following question: *Does every general computer algorithm for multiplying two n-digit numbers require an execution time proportional to n^2, as n increases?*

(In this question, a "general" algorithm means one that accepts, as input, the number n and two arbitrary n-digit numbers in positional notation, and whose output is their product in positional form. Certainly if we were allowed to choose a different algorithm for each value of n, the question would be of no interest, since multiplication could be done for any specific value of n by a "table-lookup" operation in some huge table. The term "computer algorithm" is meant to imply an algorithm that is suitable for implementation on a digital computer such as MIX, and the execution time is to be the time it takes to perform the algorithm on such a computer.)

A. Digital methods. The answer to the above question is, rather surprisingly, "No," and, in fact, it is not very difficult to see why. For convenience, let us assume throughout this section that we are working with integers expressed in binary notation. If we have two $2n$-bit numbers $u = (u_{2n-1} \ldots u_1 u_0)_2$ and $v = (v_{2n-1} \ldots v_1 v_0)_2$, we can write

$$u = 2^n U_1 + U_0, \qquad v = 2^n V_1 + V_0, \tag{1}$$

where $U_1 = (u_{2n-1} \ldots u_n)_2$ is the "most significant half" of the number u and $U_0 = (u_{n-1} \ldots u_0)_2$ is the "least significant half"; similarly $V_1 = (v_{2n-1} \ldots v_n)_2$ and $V_0 = (v_{n-1} \ldots v_0)_2$. Now we have

$$uv = (2^{2n} + 2^n)U_1V_1 + 2^n(U_1 - U_0)(V_0 - V_1) + (2^n + 1)U_0V_0. \tag{2}$$

This formula reduces the problem of multiplying $2n$-bit numbers to three multiplications of n-bit numbers, namely U_1V_1, $(U_1 - U_0)(V_0 - V_1)$, and U_0V_0, plus some simple shifting and adding operations.

Formula (2) can be used for double-precision multiplication when we want a quadruple-precision result, and it will be just a little faster than the traditional method on many machines. But the main advantage of (2) is that we can use it to define a recursive process for multiplication that is significantly faster than the familiar order-n^2 method when n is large: If $T(n)$ is the time required to perform multiplication of n-bit numbers, we have

$$T(2n) \le 3T(n) + cn \tag{3}$$

for some constant c, since the right-hand side of (2) uses just three multiplications plus some additions and shifts. Relation (3) implies by induction that

$$T(2^k) \le c(3^k - 2^k), \qquad k \ge 1, \tag{4}$$

if we choose c to be large enough so that this inequality is valid when $k = 1$; therefore we have

$$\begin{aligned} T(n) \le T(2^{\lceil \lg n \rceil}) &\le c(3^{\lceil \lg n \rceil} - 2^{\lceil \lg n \rceil}) \\ &< 3c \cdot 3^{\lg n} = 3cn^{\lg 3}. \end{aligned} \tag{5}$$

Relation (5) shows that the running time for multiplication can be reduced from order n^2 to order $n^{\lg 3} \approx n^{1.585}$, so the recursive method is much faster than the traditional method when n is large.

(A similar but more complicated method for doing multiplication with running time of order $n^{\lg 3}$ was apparently first suggested by A. Karatsuba in *Doklady Akad. Nauk SSSR* **145** (1962), 293–294 [English translation in *Soviet Physics–Doklady* **7** (1963), 595–596]. Curiously, this idea does not seem to have been discovered before 1962; none of the "calculating prodigies" who have become famous for their ability to multiply large numbers mentally have been reported to use any such method, although formula (2) adapted to decimal notation would seem to lead to a reasonably easy way to multiply eight-digit numbers in one's head.)

The running time can be reduced still further, in the limit as n approaches infinity, if we observe that the method just used is essentially the special case $r = 1$ of a more general method that yields

$$T\big((r+1)n\big) \le (2r+1)T(n) + cn \tag{6}$$

for any fixed r. This more general method can be obtained as follows: Let

$$u = (u_{(r+1)n-1} \ldots u_1 u_0)_2 \qquad \text{and} \qquad v = (v_{(r+1)n-1} \ldots v_1 v_0)_2$$

be broken into $r+1$ pieces,

$$u = U_r 2^{rn} + \cdots + U_1 2^n + U_0, \qquad v = V_r 2^{rn} + \cdots + V_1 2^n + V_0, \tag{7}$$

where each U_j and each V_j is an n-bit number. Consider the polynomials

$$U(x) = U_r x^r + \cdots + U_1 x + U_0, \qquad V(x) = V_r x^r + \cdots + V_1 x + V_0, \tag{8}$$

and let

$$W(x) = U(x)V(x) = W_{2r} x^{2r} + \cdots + W_1 x + W_0. \tag{9}$$

Since $u = U(2^n)$ and $v = V(2^n)$, we have $uv = W(2^n)$, so we can easily compute uv if we know the coefficients of $W(x)$. The problem is to find a good way to compute the coefficients of $W(x)$ by using only $2r+1$ multiplications of n-bit numbers plus some further operations that involve only an execution time proportional to n. This can be done by computing

$$U(0)V(0) = W(0), \quad U(1)V(1) = W(1), \quad \ldots, \quad U(2r)V(2r) = W(2r). \tag{10}$$

The coefficients of a polynomial of degree $2r$ can be written as a linear combination of the values of that polynomial at $2r+1$ distinct points; computing such a linear combination requires an execution time at most proportional to n. (Actually, the products $U(j)V(j)$ are not strictly products of n-bit numbers, but they are products of at most $(n+t)$-bit numbers, where t is a fixed value depending on r. It is easy to design a multiplication routine for $(n+t)$-bit numbers that requires only $T(n)+c_1 n$ operations, where $T(n)$ is the number of operations needed for n-bit multiplications, since two products of t-bit by n-bit numbers can be done in $c_2 n$ operations when t is fixed.) Therefore we obtain a method of multiplication satisfying (6).

Relation (6) implies that $T(n) \le c_3 n^{\log_{r+1}(2r+1)} < c_3 n^{1+\log_{r+1} 2}$, if we argue as in the derivation of (5), so we have now proved the following result:

Theorem A. *Given $\epsilon > 0$, there exists a multiplication algorithm such that the number of elementary operations $T(n)$ needed to multiply two n-bit numbers satisfies*

$$T(n) < c(\epsilon) n^{1+\epsilon}, \tag{11}$$

for some constant $c(\epsilon)$ independent of n. ∎

This theorem is still not the result we are after. It is unsatisfactory for practical purposes in that the method becomes much more complicated as $\epsilon \to 0$ (and therefore as $r \to \infty$), causing $c(\epsilon)$ to grow so rapidly that extremely huge values of n are needed before we have any significant improvement over (5). And it is unsatisfactory for theoretical purposes because it does not make use of the full power of the polynomial method on which it is based. We can obtain a better result if we let r *vary* with n, choosing larger and larger values of r as n increases. This idea is due to A. L. Toom [*Doklady Akad. Nauk SSSR* **150** (1963), 496–498, English translation in *Soviet Mathematics* **3** (1963), 714–716], who used it to show that computer circuitry for multiplication of n-bit numbers can be constructed involving a fairly small number of components as n grows. S. A. Cook [*On the minimum computation time of functions* (Thesis, Harvard

University, 1966), 51–77] later showed how Toom's method can be adapted to fast computer programs.

Before we discuss the Toom–Cook algorithm any further, let us study a small example of the transition from $U(x)$ and $V(x)$ to the coefficients of $W(x)$. This example will not demonstrate the efficiency of the method, since the numbers are too small, but it points out some useful simplifications that we can make in the general case. Suppose that we want to multiply $u = 1234$ times $v = 2341$; in binary notation this is $u = (0100\ 1101\ 0010)_2$ times $v = (1001\ 0010\ 0101)_2$. Let $r = 2$; the polynomials $U(x)$, $V(x)$ in (8) are

$$U(x) = 4x^2 + 13x + 2, \qquad V(x) = 9x^2 + 2x + 5.$$

Hence we find, for $W(x) = U(x)V(x)$,

$$\begin{array}{lllll} U(0) = 2, & U(1) = 19, & U(2) = 44, & U(3) = 77, & U(4) = 118; \\ V(0) = 5, & V(1) = 16, & V(2) = 45, & V(3) = 92, & V(4) = 157; \\ W(0) = 10, & W(1) = 304, & W(2) = 1980, & W(3) = 7084, & W(4) = 18526. \end{array} \tag{12}$$

Our job now is to compute the five coefficients of $W(x)$ from the latter five values.

There is an attractive little algorithm that can be used to compute the coefficients of a polynomial $W(x) = W_{m-1}x^{m-1} + \cdots + W_1x + W_0$ when the values $W(0), W(1), \ldots, W(m-1)$ are given: Let us first write

$$W(x) = \theta_{m-1}\,x^{\underline{m-1}} + \theta_{m-2}\,x^{\underline{m-2}} + \cdots + \theta_1 x^{\underline{1}} + \theta_0, \tag{13}$$

where $x^{\underline{k}} = x(x-1)\ldots(x-k+1)$, and where the coefficients θ_j are unknown. The falling factorial powers have the important property that

$$W(x+1) - W(x) = (m-1)\theta_{m-1}\,x^{\underline{m-2}} + (m-2)\theta_{m-2}\,x^{\underline{m-3}} + \cdots + \theta_1;$$

hence by induction we find that, for all $k \geq 0$,

$$\frac{1}{k!}\left(W(x+k) - \binom{k}{1}W(x+k-1) + \binom{k}{2}W(x+k-2) - \cdots + (-1)^k W(x)\right)$$
$$= \binom{m-1}{k}\theta_{m-1}\,x^{\underline{m-1-k}} + \binom{m-2}{k}\theta_{m-2}\,x^{\underline{m-2-k}} + \cdots + \binom{k}{k}\theta_k. \tag{14}$$

Denoting the left-hand side of (14) by $(1/k!)\,\Delta^k W(x)$, we see that

$$\frac{1}{k!}\Delta^k W(x) = \frac{1}{k}\left(\frac{1}{(k-1)!}\Delta^{k-1}W(x+1) - \frac{1}{(k-1)!}\Delta^{k-1}W(x)\right)$$

and $(1/k!)\,\Delta^k W(0) = \theta_k$. So the coefficients θ_j can be evaluated using a very simple method, illustrated here for the polynomial $W(x)$ in (12):

$$\begin{array}{lllll} 10 & & & & \\ & 294 & & & \\ 304 & & 1382/2 = 691 & & \\ & 1676 & & 1023/3 = 341 & \\ 1980 & & 3428/2 = 1714 & & 144/4 = 36 \\ & 5104 & & 1455/3 = 485 & \\ 7084 & & 6338/2 = 3169 & & \\ & 11442 & & & \\ 18526 & & & & \end{array} \tag{15}$$

The leftmost column of this tableau is a listing of the given values of $W(0)$, $W(1)$, $\ldots$, $W(4)$; the kth succeeding column is obtained by computing the difference between successive values of the preceding column and dividing by k. The coefficients θ_j appear at the top of the columns, so that $\theta_0 = 10$, $\theta_1 = 294$, $\ldots$, $\theta_4 = 36$, and we have

$$\begin{aligned} W(x) &= 36x^{\underline{4}} + 341x^{\underline{3}} + 691x^{\underline{2}} + 294x^{\underline{1}} + 10 \\ &= \big(((36(x-3)+341)(x-2)+691)(x-1)+294\big)x + 10. \end{aligned} \tag{16}$$

In general, we can write

$$W(x) = \big(\ldots((\theta_{m-1}(x-m+2)+\theta_{m-2})(x-m+3)+\theta_{m-3})(x-m+4) + \cdots + \theta_1\big)x + \theta_0,$$

and this formula shows how the coefficients $W_{m-1}, \ldots, W_1, W_0$ can be obtained from the θ's:

36	341			
	$-3\cdot 36$			
36	233	691		
	$-2\cdot 36$	$-2\cdot 233$		
36	161	225	294	
	$-1\cdot 36$	$-1\cdot 161$	$-1\cdot 225$	
36	125	64	69	10

(17)

Here the numbers below the horizontal lines successively show the coefficients of the polynomials

$$\theta_{m-1}, \qquad \theta_{m-1}(x+m+2)+\theta_{m-2}, \qquad \big(\theta_{m-1}(x-m+2)+\theta_{m-2}\big)(x-m+3)+\theta_{m-3}, \qquad \text{etc.}$$

From this tableau we have

$$W(x) = 36x^4 + 125x^3 + 64x^2 + 69x + 10,$$

so the answer to our original problem is $1234 \cdot 2341 = W(16)$, where $W(16)$ is obtained by adding and shifting. A generalization of this method for obtaining coefficients is discussed in Section 4.6.4.

The basic Stirling number identity,

$$x^n = \left\{ {n \atop n} \right\} x^{\underline{n}} + \cdots + \left\{ {n \atop 1} \right\} x^{\underline{1}} + \left\{ {n \atop 0} \right\},$$

Eq. 1.2.6–41, shows that if the coefficients of $W(x)$ are nonnegative, so are the numbers θ_j, and in such a case *all of the intermediate results in the above computation are nonnegative.* This further simplifies the Toom–Cook multiplication algorithm, which we will now consider in detail.

Algorithm C (*High-precision multiplication of binary numbers*). Given a positive integer n and two nonnegative n-bit integers u and v, this algorithm forms their $2n$-bit product, w. Four auxiliary stacks are used to hold the long numbers that are manipulated during the procedure:

Stacks U, V:	Temporary storage of $U(j)$ and $V(j)$ in step C4.
Stack C:	Numbers to be multiplied, and control codes.
Stack W:	Storage of $W(j)$.

These stacks may contain either binary numbers or special control symbols called code-1, code-2, and code-3. The algorithm also constructs an auxiliary table of numbers q_k, r_k; this table is maintained in such a manner that it may be stored as a linear list, where a single pointer that traverses the list (moving back and forth) may be used to access the current table entry of interest.

(Stacks C and W are used to control the recursive mechanism of this multiplication algorithm in a reasonably straightforward manner that is a special case of general procedures discussed in Chapter 8.)

C1. [Compute q, r tables.] Set stacks U, V, C, and W empty. Set

$$k \leftarrow 1, \quad q_0 \leftarrow q_1 \leftarrow 16, \quad r_0 \leftarrow r_1 \leftarrow 4, \quad Q \leftarrow 4, \quad R \leftarrow 2.$$

Now if $q_{k-1} + q_k < n$, set

$$k \leftarrow k+1, \quad Q \leftarrow Q + R, \quad R \leftarrow \lfloor \sqrt{Q} \rfloor, \quad q_k \leftarrow 2^Q, \quad r_k \leftarrow 2^R,$$

and repeat this operation until $q_{k-1} + q_k \geq n$. (*Note:* The calculation of $R \leftarrow \lfloor \sqrt{Q} \rfloor$ does not require a square root to be taken, since we may simply set $R \leftarrow R+1$ if $(R+1)^2 \leq Q$ and leave R unchanged if $(R+1)^2 > Q$; see exercise 2. In this step we build the sequences

k	$=$	0	1	2	3	4	5	6	$\ldots$
q_k	$=$	2^4	2^4	2^6	2^8	2^{10}	2^{13}	2^{16}	$\ldots$
r_k	$=$	2^2	2^2	2^2	2^2	2^3	2^3	2^4	$\ldots$

The multiplication of 70000-bit numbers would cause this step to terminate with $k = 6$, since $70000 < 2^{13} + 2^{16}$.)

C2. [Put u, v on stack.] Put code-1 on stack C, then place u and v onto stack C as numbers of exactly $q_{k-1} + q_k$ bits each.

C3. [Check recursion level.] Decrease k by 1. If $k = 0$, the top of stack C now contains two 32-bit numbers, u and v; remove them, set $w \leftarrow uv$ using a built-in routine for multiplying 32-bit numbers, and go to step C10. If $k > 0$, set $r \leftarrow r_k$, $q \leftarrow q_k$, $p \leftarrow q_{k-1} + q_k$, and go on to step C4.

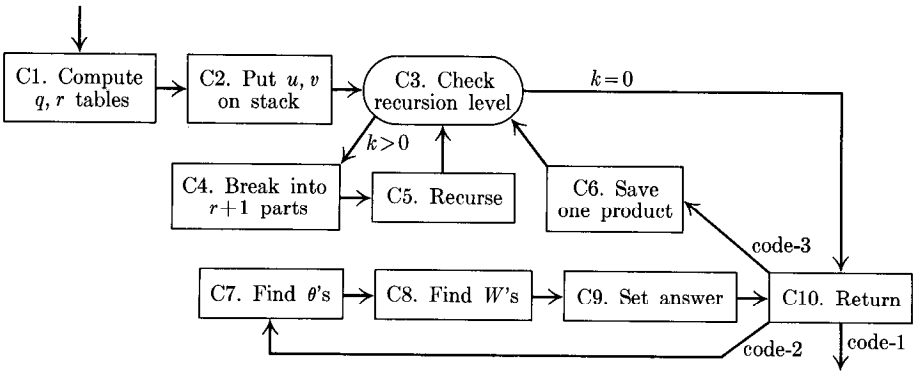

Fig. 8. Toom–Cook algorithm for high-precision multiplication.

C4. [Break into $r+1$ parts.] Let the number at the top of stack C be regarded as a list of $r+1$ numbers with q bits each, $(U_r \ldots U_1 U_0)_{2^q}$. (The top of stack C now contains an $(r+1)q = (q_k + q_{k+1})$-bit number.) For $j = 0$, $1, \ldots, 2r$, compute the p-bit numbers

$$\big(\ldots(U_r j + U_{r-1})j + \cdots + U_1\big)j + U_0 = U(j)$$

and successively put these values onto stack U. (The bottom of stack U now contains $U(0)$, then comes $U(1)$, etc., with $U(2r)$ on top. Note that

$$U(j) \le U(2r) < 2^q\big((2r)^r + (2r)^{r-1} + \cdots + 1\big) < 2^{q+1}(2r)^r \le 2^p,$$

by exercise 3.) Then remove $U_r \ldots U_1 U_0$ from stack C.

Now the top of stack C contains another list of $r+1$ q-bit numbers, $V_r \ldots V_1 V_0$, and the p-bit numbers

$$\big(\ldots(V_r j + V_{r-1})j + \cdots + V_1\big)j + V_0 = V(j)$$

should be put onto stack V in the same way. After this has been done, remove $V_r \ldots V_1 V_0$ from stack C.

C5. [Recurse.] Successively put the following items onto stack C, at the same time emptying stacks U and V:

$$\text{code-2, } V(2r), U(2r), \text{ code-3, } V(2r-1), U(2r-1), \ldots,$$
$$\text{code-3, } V(1), U(1), \text{ code-3, } V(0), U(0).$$

Go back to step C3.

C6. [Save one product.] (At this point the multiplication algorithm has set w to one of the products $W(j) = U(j)V(j)$.) Put w onto stack W. (This number w contains $2(q_k + q_{k-1})$ bits.) Go back to step C3.

C7. [Find θ's.] Set $r \leftarrow r_k$, $q \leftarrow q_k$, $p \leftarrow q_{k-1} + q_k$. (At this point stack W contains a sequence of numbers ending with $W(0)$, $W(1)$, $\ldots$, $W(2r)$ from bottom to top, where each $W(j)$ is a $2p$-bit number.)

Now for $j = 1, 2, 3, \ldots, 2r$, perform the following loop: For $t = 2r$, $2r-1$, $2r-2$, $\ldots$, j, set $W(t) \leftarrow \big(W(t) - W(t-1)\big)/j$. (Here j must increase and t must decrease. The quantity $\big(W(t) - W(t-1)\big)/j$ will always be a nonnegative integer that fits in $2p$ bits; cf. (15).)

C8. [Find W's.] For $j = 2r-1, 2r-2, \ldots, 1$, perform the following loop: For $t = j, j+1, \ldots, 2r-1$, set $W(t) \leftarrow W(t) - jW(t+1)$. (Here j must decrease and t must increase. The result of this operation will again be a nonnegative $2p$-bit integer; cf. (17).)

C9. [Set answer.] Set w to the $2(q_k + q_{k+1})$-bit integer

$$\big(\ldots(W(2r)2^q + W(2r-1))2^q + \cdots + W(1)\big)2^q + W(0).$$

Remove $W(2r)$, $\ldots$, $W(0)$ from stack W.

C10. [Return.] Set $k \leftarrow k+1$. Remove the top of stack C. If it is code-3, go to step C6. If it is code-2, put w onto stack W and go to step C7. And if it is code-1, terminate the algorithm (w is the answer). ∎

Let us now estimate the running time, $T(n)$, for Algorithm C, in terms of some things we shall call "cycles," i.e., elementary machine operations. Step C1 takes $O(q_k)$ cycles, even if we represent the number q_k internally as a long string of q_k bits followed by some delimiter, since $q_k + q_{k-1} + \cdots + q_0$ will be $O(q_k)$. Step C2 obviously takes $O(q_k)$ cycles.

Now let t_k denote the amount of computation required to get from step C3 to step C10 for a particular value of k (after k has been decreased at the beginning of step C3). Step C3 requires $O(q)$ cycles at most. Step C4 involves r multiplications of p-bit numbers by $(\lg 2r)$-bit numbers, and r additions of p-bit numbers, all repeated $4r+2$ times. Thus we need a total of $O(r^2 q \log r)$ cycles. Step C5 requires moving $4r+2$ p-bit numbers, so it involves $O(rq)$ cycles. Step C6 requires $O(q)$ cycles, and it is done $2r+1$ times per iteration. The recursion involved when the algorithm essentially invokes itself (by returning to step C3) requires t_{k-1} cycles, $2r+1$ times. Step C7 requires $O(r^2)$ subtractions of p-bit numbers and divisions of $2p$-bit by $(\lg 2r)$-bit numbers, so it requires $O(r^2 q \log r)$ cycles. Similarly, step C8 requires $O(r^2 q \log r)$ cycles. Step C9 involves $O(rq)$ cycles, and C10 takes hardly any time at all.

Summing up, we have $T(n) = O(q_k) + O(q_k) + t_{k-1}$, where (if $q = q_k$ and $r = r_k$) the main contribution to the running time satisfies

$$\begin{aligned} t_k &= O(q) + O(r^2 q \log r) + O(rq) + (2r+1)O(q) + O(r^2 q \log r) \\ &\qquad + O(r^2 q \log r) + O(rq) + O(q) + (2r+1)t_{k-1} \\ &= O(r^2 q \log r) + (2r+1)t_{k-1}. \end{aligned}$$

Thus there is a constant c such that

$$t_k \le cr_k^2 q_k \lg r_k + (2r_k + 1)t_{k-1}.$$

To complete the estimation of t_k we can prove by brute force that

$$t_k \le Cq_{k+1}2^{2.5\sqrt{\lg q_{k+1}}} \tag{18}$$

for some constant C. Let us choose $C > 20c$, and let us also take C large enough so that (18) is valid for $k \le k_0$, where k_0 will be specified below. Then when $k > k_0$, let $Q_k = \lg q_k$, $R_k = \lg r_k$; we have by induction

$$t_k \le cq_k r_k^2 \lg r_k + (2r_k + 1)Cq_k 2^{2.5\sqrt{Q_k}} = Cq_{k+1}2^{2.5\sqrt{\lg q_{k+1}}}(\eta_1 + \eta_2),$$

where

$$\eta_1 = \frac{c}{C}R_k 2^{R_k - 2.5\sqrt{Q_{k+1}}} < \frac{1}{20}R_k 2^{-R_k} < 0.05,$$

$$\eta_2 = \left(2 + \frac{1}{r_k}\right)2^{2.5(\sqrt{Q_k} - \sqrt{Q_{k+1}})} \to 2^{-1/4} < 0.85,$$

since

$$\sqrt{Q_{k+1}} - \sqrt{Q_k} = \sqrt{Q_k + \lfloor\sqrt{Q_k}\rfloor} - \sqrt{Q_k} \to \tfrac{1}{2}$$

as $k \to \infty$. It follows that we can find k_0 such that $\eta_2 < 0.95$ for all $k > k_0$, and this completes the proof of (18) by induction.

Finally, therefore, we may compute $T(n)$. Since $n > q_{k-1} + q_{k-2}$, we have $q_{k-1} < n$; hence

$$r_{k-1} = 2^{\lfloor\sqrt{\lg q_{k-1}}\rfloor} < 2^{\sqrt{\lg n}}, \qquad \text{and} \qquad q_k = r_{k-1}q_{k-1} < n2^{\sqrt{\lg n}}.$$

Thus

$$t_{k-1} \le Cq_k 2^{2.5\sqrt{\lg q_k}} < Cn2^{\sqrt{\lg n} + 2.5(\sqrt{\lg n} + 1)},$$

and, since $T(n) = O(q_k) + t_{k-1}$, we have finally derived the following theorem:

Theorem C. *There is a constant c_0 such that the execution time of Algorithm C is less than $c_0 n 2^{3.5\sqrt{\lg n}}$ cycles.* ∎

Since $n2^{3.5\sqrt{\lg n}} = n^{1+3.5/\sqrt{\lg n}}$, this result is noticeably stronger than Theorem A. By adding a few complications to the algorithm, pushing the ideas to their apparent limits (see exercise 5), we can improve the estimated execution time to

$$T(n) = O(n2^{\sqrt{2\lg n}}\log n). \tag{19}$$

B. A modular method. There is another way to multiply large numbers very rapidly, based on the ideas of modular arithmetic as presented in Section 4.3.2. It is very hard to believe at first that this method can be of advantage, since a multiplication algorithm based on modular arithmetic must include the choice of moduli and the conversion of numbers into and out of modular representation, besides the actual multiplication operation itself. In spite of these formidable difficulties, A. Schönhage discovered that all of these operations can be carried out quite rapidly.

In order to understand the essential mechanism of Schönhage's method, we shall look at a special case. Consider the sequence defined by the rules

$$q_0 = 1, \qquad q_{k+1} = 3q_k - 1, \tag{20}$$

so that $q_k = 3^k - 3^{k-1} - \cdots - 1 = \frac{1}{2}(3^k + 1)$. We will study a procedure that multiplies $(18q_k + 8)$-bit numbers, in terms of a method for multiplying $(18q_{k-1} + 8)$-bit numbers. Thus, if we know how to multiply numbers having $(18q_0 + 8) = 26$ bits, the procedure to be described will show us how to multiply numbers of $(18q_1 + 8) = 44$ bits, then 98 bits, then 260 bits, etc., eventually increasing the number of bits by almost a factor of 3 at each step.

Let $p_k = 18q_k + 8$. When multiplying p_k-bit numbers, the idea is to use the six moduli

$$\begin{aligned} m_1 &= 2^{6q_k-1} - 1, \quad & m_2 &= 2^{6q_k+1} - 1, \quad & m_3 &= 2^{6q_k+2} - 1, \\ m_4 &= 2^{6q_k+3} - 1, \quad & m_5 &= 2^{6q_k+5} - 1, \quad & m_6 &= 2^{6q_k+7} - 1. \end{aligned} \tag{21}$$

These moduli are relatively prime, by Eq. 4.3.2–18, since the exponents

$$6q_k - 1, \quad 6q_k + 1, \quad 6q_k + 2, \quad 6q_k + 3, \quad 6q_k + 5, \quad 6q_k + 7 \tag{22}$$

are always relatively prime (see exercise 6). The six moduli in (21) are capable of representing numbers up to $m = m_1m_2m_3m_4m_5m_6 > 2^{36q_k+16} = 2^{2p_k}$, so there is no chance of overflow in the multiplication of p_k-bit numbers u and v. Thus we may use the following method, when $k > 0$:

a) Compute $u_1 = u \bmod m_1$, ..., $u_6 = u \bmod m_6$; and $v_1 = v \bmod m_1$, ..., $v_6 = v \bmod m_6$.

b) Multiply u_1 by v_1, u_2 by v_2, ..., u_6 by v_6. These are numbers of at most $6q_k + 7 = 18q_{k-1} + 1 < p_{k-1}$ bits, so the multiplications can be performed by using the assumed p_{k-1}-bit multiplication procedure.

c) Compute $w_1 = u_1v_1 \bmod m_1$, $w_2 = u_2v_2 \bmod m_2$, ..., $w_6 = u_6v_6 \bmod m_6$.

d) Compute w such that $0 \le w < m$, $w \bmod m_1 = w_1$, ..., $w \bmod m_6 = w_6$.

Let t_k be the amount of time needed for this process. It is not hard to see that operation (a) takes $O(p_k)$ cycles, since the determination of $u \bmod (2^e - 1)$ is quite simple (like "casting out nines"), as shown in Section 4.3.2. Similarly, operation (c) takes $O(p_k)$ cycles. Operation (b) requires essentially $6t_{k-1}$ cycles.

This leaves us with operation (d), which seems to be quite a difficult computation; but Schönhage has found an ingenious way to perform step (d) in $O(p_k \log p_k)$ cycles, and this is the crux of the method. As a consequence, we have

$$t_k = 6t_{k-1} + O(p_k \log p_k).$$

Since $p_k = 3^{k+2} + 17$, we can show that the time for n-bit multiplication is

$$T(n) = O(N^{\log_3 6}) = O(N^{1.63}). \tag{23}$$

(See exercise 7.)

Although the modular method is more complicated than the $O(n^{\lg 3})$ procedure discussed at the beginning of this section, Eq. (23) shows that it does, in fact, lead to an execution time substantially better than $O(n^2)$ for the multiplication of n-bit numbers. Thus we can improve on the classical method by using either of two completely different approaches.

Let us now analyze operation (d) above. Assume that we are given a set of positive integers $e_1 < e_2 < \cdots < e_r$, relatively prime in pairs; let

$$m_1 = 2^{e_1} - 1, \qquad m_2 = 2^{e_2} - 1, \qquad \ldots, \qquad m_r = 2^{e_r} - 1. \tag{24}$$

We are also given numbers $w_1, \ldots, w_r$ such that $0 \le w_j \le m_j$. Our job is *to determine the binary representation of the number w that satisfies the conditions*

$$\begin{aligned} 0 \le w < m_1 m_2 \ldots m_r, \\ w \equiv w_1 \text{ (modulo } m_1), \qquad \ldots, \qquad w \equiv w_r \text{ (modulo } m_r). \end{aligned} \tag{25}$$

The method is based on (23) and (24) of Section 4.3.2. First we compute

$$w'_j = \big(\ldots((w_j - w'_1)c_{1j} - w'_2)c_{2j} - \cdots - w'_{j-1}\big)c_{(j-1)j} \bmod m_j, \tag{26}$$

for $j = 2, \ldots, r$, where $w'_1 = w_1 \bmod m_1$; then we compute

$$w = \big(\ldots(w'_r m_{r-1} + w'_{r-1})m_{r-2} + \cdots + w'_2\big)m_1 + w'_1. \tag{27}$$

Here c_{ij} is a number such that $c_{ij}m_i \equiv 1$ (modulo m_j); these numbers c_{ij} are not given, they must be determined from the e_j's.

The calculation of (26) for all j involves $\binom{r}{2}$ additions modulo m_j, each of which takes $O(e_r)$ cycles, plus $\binom{r}{2}$ multiplications by c_{ij}, modulo m_j. The calculation of w by formula (27) involves r additions and r multiplications by m_j; it is easy to multiply by m_j, since this is just adding, shifting, and subtracting, so it is clear that the evaluation of Eq. (27) takes $O(r^2 e_r)$ cycles. We will soon see that each of the multiplications by c_{ij}, modulo m_j, requires only $O(e_r \log e_r)$ cycles, and therefore *it is possible to complete the entire job of conversion in* $O(r^2 e_r \log e_r)$ *cycles.*

The above observations leave us with the following problem to solve: Given positive integers $e < f$ and a nonnegative integer $u < 2^f$, compute the value of $(cu) \bmod (2^f - 1)$, where c is the number such that $(2^e - 1)c \equiv 1$ (modulo $2^f - 1$); and the computation must be done in $O(f \log f)$ cycles. The result of exercise 4.3.2–6 gives a formula for c that suggests a suitable procedure. First we find the least positive integer b such that

$$be \equiv 1 \text{ (modulo } f). \tag{28}$$

This can be done using Euclid's algorithm in $O((\log f)^3)$ cycles, since Euclid's algorithm applied to e and f requires $O(\log f)$ iterations, and each iteration requires $O((\log f)^2)$ cycles; alternatively, we could be very sloppy here without violating the total time constraint, by simply trying $b = 1$, 2, etc., until (28) is satisfied, since such a process would take $O(f \log f)$ cycles in all. Once b has been found, exercise 4.3.2–6 tells us that

$$c = c[b] = \Bigg(\sum_{0 \le j < b} 2^{je} \Bigg) \bmod (2^f - 1). \tag{29}$$

A brute-force multiplication of $(cu) \bmod (2^f - 1)$ would not be good enough to solve the problem, since we do not know how to multiply general f-bit numbers in $O(f \log f)$ cycles. But the special form of c provides a clue: The binary representation of c is composed of bits in a regular pattern, and Eq. (29) shows that the number $c[2b]$ can be obtained in a simple way from $c[b]$. This suggests that we can rapidly multiply a number u by $c[b]$ if we build $c[b]u$ up in $\lg b$ steps in a suitably clever manner, such as the following: Let the binary notation for b be

$$b = (b_s \ldots b_2 b_1 b_0)_2;$$

we may calculate the sequences a_k, d_k, u_k, v_k defined by the rules

$$\begin{aligned} a_0 &= e, & a_k &= 2a_{k-1} \bmod f; \\ d_0 &= b_0 e, & d_k &= (d_{k-1} + b_k a_k) \bmod f; \\ u_0 &= u, & u_k &= (u_{k-1} + 2^{a_{k-1}} u_{k-1}) \bmod (2^f - 1); \\ v_0 &= b_0 u, & v_k &= (v_{k-1} + b_k 2^{d_{k-1}} u_k) \bmod (2^f - 1). \end{aligned} \tag{30}$$

It is easy to prove by induction on k that

$$\begin{aligned} a_k &= (2^k e) \bmod f; & u_k &= (c[2^k]u) \bmod (2^f - 1); \\ d_k &= \big((b_k \ldots b_1 b_0)_2\, e\big) \bmod f; & v_k &= \big(c[(b_k \ldots b_1 b_0)_2]u\big) \bmod (2^f - 1). \end{aligned} \tag{31}$$

Hence the desired result, $(c[b]u) \bmod (2^f - 1)$, is v_s. The calculation of a_k, d_k, u_k, v_k from a_{k-1}, d_{k-1}, u_{k-1}, v_{k-1} takes $O(\log f) + O(\log f) + O(f) + O(f) = O(f)$ cycles, and therefore the entire calculation can be done in $s\,O(f) = O(f \log f)$ cycles as desired.

The reader will find it instructive to study the ingenious method represented by (30) and (31) very carefully. Similar techniques are discussed in Section 4.6.3.

Schönhage's paper [*Computing* **1** (1966), 182–196] shows that these ideas can be extended to the multiplication of n-bit numbers using $r \approx 2^{\sqrt{2 \lg n}}$ moduli, obtaining a method analogous to Algorithm C. We shall not dwell on the details here, since Algorithm C is always superior; in fact, an even better method is next on our agenda.

C. Use of discrete Fourier transforms. The critical problem in high-precision multiplication is the determination of "convolution products" such as

$$u_r v_0 + u_{r-1} v_1 + \cdots + u_0 v_r,$$

and there is an intimate relation between convolutions and an important mathematical concept called "Fourier transformation." If $\omega = \exp(2\pi i/K)$ is a Kth root of unity, the one-dimensional Fourier transform of the sequence of complex numbers $(u_0, u_1, \ldots, u_{K-1})$ is defined to be the sequence $(\hat{u}_0, \hat{u}_1, \ldots, \hat{u}_{K-1})$, where

$$\hat{u}_s = \sum_{0 \le t < K} \omega^{st} u_t, \qquad 0 \le s < K. \tag{32}$$

Letting $(\hat{v}_0, \hat{v}_1, \ldots, \hat{v}_{K-1})$ be defined in the same way, as the Fourier transform of $(v_0, v_1, \ldots, v_{K-1})$, it is not difficult to see that $(\hat{u}_0 \hat{v}_0, \hat{u}_1 \hat{v}_1, \ldots, \hat{u}_{K-1} \hat{v}_{K-1})$ is the transform of $(w_0, w_1, \ldots, w_{K-1})$, where

$$\begin{aligned} w_r &= u_r v_0 + u_{r-1} v_1 + \cdots + u_0 v_r + u_{K-1} v_{r+1} + \cdots + u_{r+1} v_{K-1} \\ &= \sum_{i+j \equiv r \,(\text{modulo } K)} u_i v_j. \end{aligned}$$

When $K \ge 2n - 1$ and $u_n = u_{n+1} = \cdots = u_{K-1} = v_n = v_{n+1} = \cdots = v_{K-1} = 0$, the w's are just what we need for multiplication, since the terms $u_{K-1} v_{r+1} + \cdots + u_{r+1} v_{K-1}$ vanish when $0 \le r \le 2n-2$. In other words, *the transform of a convolution product is the ordinary product of the transforms.* This idea is actually a special case of Toom's use of polynomials (cf. (10)), with x replaced by roots of unity.

If K is a power of 2, the discrete Fourier transform (32) can be obtained quite rapidly when the computations are arranged in a certain way, and so can the inverse transform (determining the w's from the $\hat{w}$'s). This property of Fourier transforms was exploited by V. Strassen in 1968, who discovered how to multiply large numbers faster than was possible under all previously known schemes. He and A. Schönhage later refined the method and published improved procedures in *Computing* **7** (1971), 281–292. In order to understand their approach to the problem, let us first take a look at the mechanism of fast Fourier transforms.

Given a sequence of $K = 2^k$ complex numbers $(u_0, \ldots, u_{K-1})$, and given the complex number

$$\omega = \exp(2\pi i/K),$$

the sequence $(\hat{u}_0, \ldots, \hat{u}_{K-1})$ defined in (32) can be calculated rapidly by carrying out the following scheme. (In these formulas the parameters s_j and t_j are either 0 or 1, so that each "pass" represents 2^k computations.)

Pass 0. Let $A^{[0]}(t_{k-1},\ldots,t_0) = u_t$, where $t = (t_{k-1}\ldots t_0)_2$.

Pass 1. Set $A^{[1]}(s_{k-1},t_{k-2},\ldots,t_0) \leftarrow$
$$A^{[0]}(0,t_{k-2},\ldots,t_0) + \omega^{(s_{k-1}0\ldots0)_2}\cdot A^{[0]}(1,t_{k-2},\ldots,t_0).$$

Pass 2. Set $A^{[2]}(s_{k-1},s_{k-2},t_{k-3},\ldots,t_0) \leftarrow$
$$A^{[1]}(s_{k-1},0,t_{k-3},\ldots,t_0) + \omega^{(s_{k-2}s_{k-1}0\ldots0)_2}\cdot A^{[1]}(s_{k-1},1,t_{k-3},\ldots,t_0).$$

...

Pass k. Set $A^{[k]}(s_{k-1},\ldots,s_1,s_0) \leftarrow$
$$A^{[k-1]}(s_{k-1},\ldots,s_1,0) + \omega^{(s_0s_1\ldots s_{k-1})_2}\cdot A^{[k-1]}(s_{k-1},\ldots,s_1,1).$$

It is fairly easy to prove by induction that we have

$$A^{[j]}(s_{k-1},\ldots,s_{k-j},t_{k-j-1},\ldots,t_0) = \sum_{0\le t_{k-1},\ldots,t_{k-j}\le 1} \omega^{(s_0s_1\ldots s_{k-1})_2\cdot(t_{k-1}\ldots t_{k-j}0\ldots0)_2}\,u_t, \tag{33}$$

so that

$$A^{[k]}(s_{k-1},\ldots,s_1,s_0) = \hat{u}_s, \qquad \text{where } s = (s_0s_1\ldots s_{k-1})_2. \tag{34}$$

(Note the reversed order of the binary digits in s. For further discussion of transforms such as this, see Section 4.6.4.)

To get the inverse Fourier transform $(u_0,\ldots,u_{K-1})$ from the values of $(\hat{u}_0,\ldots,\hat{u}_{K-1})$, we may note that the "double transform" is

$$\hat{\hat{u}}_r = \sum_{0\le s<K}\omega^{rs}\hat{u}_s = \sum_{0\le s,t<K}\omega^{rs}\omega^{st}u_t = \sum_{0\le t<K}u_t\left(\sum_{0\le s<K}\omega^{s(t+r)}\right) = Ku_{(-r)\bmod K},$$

since the geometric series $\sum_{0\le s<K}\omega^{sj}$ sums to zero unless j is a multiple of K. Therefore the inverse transform can be computed in the same way as the transform itself, except that the final results must be divided by K and shuffled slightly.

Applying this to the problem of integer multiplication, suppose we wish to compute the product of two n-bit integers u and v. As in Algorithm C we shall work with groups of bits; let

$$2n \le 2^k l < 4n, \qquad K = 2^k, \qquad L = 2^l, \tag{35}$$

and write

$$u = (U_{K-1}\ldots U_1U_0)_L, \qquad v = (V_{K-1}\ldots V_1V_0)_L, \tag{36}$$

regarding u and v as K-place numbers in radix L so that each digit U_j or V_j is an l-bit integer. Actually the leading digits U_j and V_j are zero for all $j \ge K/2$,

because $2^{k-1}l \geq n$. We will select appropriate values for k and l later; at the moment our goal is to see what happens in general, so that we can choose k and l intelligently when all the facts are before us.

The next step of the multiplication procedure is to compute the Fourier transforms $(\hat{u}_0, \ldots, \hat{u}_{K-1})$ and $(\hat{v}_0, \ldots, \hat{v}_{K-1})$ of the sequences $(u_0, \ldots, u_{K-1})$ and $(v_0, \ldots, v_{K-1})$, where we define

$$u_t = U_t/2^{k+l}, \qquad v_t = V_t/2^{k+l}. \tag{37}$$

This scaling is done for convenience so that the absolute values $|u_t|$ and $|v_t|$ are less than 2^{-k}, ensuring that $|\hat{u}_s|$ and $|\hat{v}_s|$ will be less than 1 for all s.

An obvious problem arises here, since the complex number ω can't be represented exactly in binary notation. How are we going to compute a reliable Fourier transform? By a stroke of good luck, it turns out that everything will work properly if we do the calculations with only a modest amount of precision. For the moment let us bypass this question and assume that infinite-precision calculations are being performed; we shall analyze later how much accuracy is actually needed.

Once the $\hat{u}_s$ and $\hat{v}_s$ have been found, we let $\hat{w}_s = \hat{u}_s\hat{v}_s$ for $0 \leq s < K$ and determine the inverse Fourier transform $(w_0, \ldots, w_{K-1})$. As explained above, we now have

$$w_r = \sum_{i+j=r} u_i v_j = \sum_{i+j=r} U_i V_j / 2^{2k+2l},$$

so the integers $W_r = 2^{2k+2l} w_r$ are the coefficients in the desired product

$$u \cdot v = W_{K-2} L^{K-2} + \cdots + W_1 L + W_0. \tag{38}$$

Since $0 \leq W_r < (r+1)L^2 < KL^2$, each W_r has at most $k + 2l$ bits, so it will not be difficult to compute the binary representation when the W's are known unless k is large compared to l.

Let us try to estimate how much time this method takes, if m-bit fixed point arithmetic is used in calculating the Fourier transforms. Exercise 10 shows that all of the quantities $A^{[j]}$ during all the passes of the transform calculations will be less than 1 in magnitude because of the scaling (37), hence it suffices to deal with m-bit fractions $(.a_{-1} \ldots a_{-m})_2$ for the real and imaginary parts of all the intermediate quantities. Simplifications are possible because the inputs u_t and v_t are real-valued; only K real values instead of $2K$ need to be carried in each step (see exercise 4.6.4–14). We will ignore such refinements in order to keep complications to a minimum.

The first job is to compute ω and its powers. For simplicity we shall make a table of the values $\omega^0, \ldots, \omega^{K-1}$. Let

$$\omega_r = \exp(2\pi i/2^r),$$

so that $\omega_1 = -1$, $\omega_2 = i$, $\omega_3 = (1+i)/\sqrt{2}$, $\ldots$, $\omega_k = \omega$. If $\omega_r = x_r + iy_r$, we have

$$\omega_{r+1} = \sqrt{\frac{1+x_r}{2}} + i\sqrt{\frac{1-x_r}{2}}. \tag{39}$$

The calculation of $\omega_1, \omega_2, \ldots, \omega_k$ takes negligible time compared with the other computations we need, so we can use any straightforward algorithm for square roots. Once the ω_r have been calculated we can compute all of the powers ω^j by starting with $\omega^0 = 1$ and using the following idea for $j > 0$: If $j = 2^{K-r} \cdot q$ where q is odd, and if $j_0 = 2^{K-r} \cdot (q-1)$, we have

$$\omega^j = \omega^{j_0} \cdot \omega_r. \tag{40}$$

This method of calculation keeps errors from propagating, since each ω^j is a product of at most k of the ω_r's. The total time to calculate all the ω^j is $O(KM)$, where M is the time to do an m-bit complex multiplication; this is less time than the subsequent steps will require, so we can ignore it.

Each of the three Fourier transformations comprises k passes, each of which involves K operations of the form $a \leftarrow b + \omega^j c$, so the total time to calculate the Fourier transforms is

$$O(kKM) = O(Mnk/l).$$

Finally, the work involved in computing the binary digits of $u \cdot v$ using (38) is $O(K(k+l)) = O(n + nk/l)$. Summing over all operations, we find that the total time to multiply n-bit numbers u and v will be $O(n) + O(Mnk/l)$.

Now let's see how large the intermediate precision m needs to be, so that we know how large M needs to be. For simplicity we shall be content with safe estimates of the accuracy, instead of finding the best possible bounds. It will be convenient to compute all the ω^j so that our approximations $(\omega^j)'$ will satisfy $|(\omega^j)'| \le 1$; this condition is easy to guarantee if we truncate towards zero instead of rounding. The operations we need to perform with m-bit fixed point complex arithmetic are all obtained by replacing an exact computation of the form $a \leftarrow b + \omega^j c$ by the approximate computation

$$a' \leftarrow \text{truncate}\big(b' + (\omega^j)' c'\big), \tag{41}$$

where b', $(\omega^j)'$, and c' are previously computed approximations; all of these complex numbers and their approximations are bounded by 1 in absolute value. If $|b' - b| \le \delta_1$, $|(\omega^j)' - \omega^j| \le \delta_2$, and $|c' - c| \le \delta_3$, it is not difficult to see that we will have $|a' - a| < \delta + \delta_1 + \delta_2 + \delta_3$, where

$$\delta = |2^{-m} + 2^{-m} i| = 2^{1/2-m},$$

because we have $\big|(\omega^j)'c' - \omega^j c\big| = \big|\big((\omega^j)' - \omega^j\big)c' + \omega^j(c' - c)\big| \le \delta_2 + \delta_3$, and δ is the maximum truncation error. The approximations $(\omega^j)'$ are obtained by starting with approximate values ω_r' to the numbers defined in (39), and we may assume that $|\omega_r' - \omega_r| \le \delta$. Each multiplication (40) has the form of (41) with $b' = 0$, so an additional error of at most 2δ is made per multiplication, and we have $\big|(\omega^j)' - \omega^j\big| \le (2k-1)\delta$ for all j.

If we have errors of at most ϵ before any pass of the fast Fourier transform, the operations of that pass therefore have the form (41) where $\delta_1 = \delta_3 = \epsilon$ and $\delta_2 = (2k-1)\delta$, and the errors after the pass will be at most $2\epsilon + 2k\delta$. There is no error in "Pass 0," so we find by induction on j that the maximum error after "Pass j" is bounded by $(2^j - 1)\cdot 2k\delta$, and the computed values of $\hat{u}_s$ will satisfy $|(\hat{u}_s)' - \hat{u}_s| < (2^k - 1)\cdot 2k\delta$. A similar formula will hold for $(\hat{v}_s)'$; and we will have

$$|(\hat{w}_s)' - \hat{w}_s| < 2(2^k - 1)\cdot 2k\delta + \delta.$$

During the inverse transformation there is an additional accumulation of errors, but the division by $K = 2^k$ ameliorates most of this; by the same argument we find that the computed values w_r' will satisfy

$$|w_r' - w_r| < 4k2^k\delta.$$

We need enough precision to make $2^{2k+2l}w_r'$ round to the correct integer W_r, hence we need

$$2^{2k+2l+2+\lg k+k+1/2-m} \le \frac{1}{2},$$

i.e., $m \ge 3k + 2l + \lg k + 7/2$. This will hold if we simply require that

$$k \ge 7 \qquad \text{and} \qquad m \ge 4k + 2l. \tag{42}$$

Relations (35) and (42) can be used to determine parameters k, l, m so that multiplication takes $O(n) + O(Mnk/l)$ units of time, where M is the time to multiply m-bit fractions.

If we are using MIX, for example, suppose we want to multiply binary numbers having $n = 2^{13} = 8192$ bits each. We can choose $k = 11$, $l = 8$, $m = 60$, so that the necessary m-bit operations are nothing more than double precision arithmetic. The running time M needed to do fixed point m-bit complex multiplication will therefore be comparatively small. With triple-precision operations we can go up for example to $k = l = 15$, $n \le 15\cdot 2^{14}$, which takes us way beyond MIX's memory capacity.

Further study of the choice of k, l, and m leads in fact to a rather surprising conclusion: ***For all practical purposes we can assume that M is constant, and the Schönhage–Strassen multiplication technique will have a running time linearly proportional to n.*** The reason is that we can choose $k = l$ and $m = 6k$; this choice of k is always less than $\lg n$, so we will never need to use more than sextuple precision unless n is larger than the word size of our computer. (In particular, n would have to be larger than the capacity of an index register, so we probably couldn't fit the numbers u and v in main memory.)

The practical problem of fast multiplication is therefore solved, except for improvements in the constant factor. In fact, the all-integer convolution algorithm of exercise 4.6.4–59 is probably a better choice for practical high-precision multiplication, even though it has a slightly worse asymptotic behavior. Our interest in multiplying large numbers is partly theoretical, however, because it

is interesting to explore the ultimate limits of computational complexity. So let's forget practical considerations and suppose that n is extremely huge, perhaps much larger than the number of atoms in the universe. We can let m be approximately $6 \lg n$, and use the same algorithm recursively to do the m-bit multiplications. The running time will satisfy $T(n) = O\big(nT(\log n)\big)$; hence

$$T(n) \le C\, n(C \lg n)(C \lg\lg n)(C \lg\lg\lg n) \ldots,$$

where the product continues until reaching a factor with $\lg \ldots \lg n \le 1$.

Schönhage and Strassen showed how to improve this theoretical upper bound to $O(n \log n \log\log n)$ in their paper, by using *integer* numbers ω to carry out fast Fourier transforms on integers, modulo numbers of the form $2^e + 1$. This upper bound applies to Turing machines, i.e., to computers with bounded memory and a finite number of arbitrarily long tapes.

If we allow ourselves a more powerful computer, with random access to any number of words of bounded size, Schönhage has pointed out that the upper bound drops to $O(n \log n)$. For we can choose $k = l$ and $m = 6k$, and we have time to build a complete multiplication table of all possible products xy for $0 \le x, y < 2^{\lceil m/12 \rceil}$. (The number of such products is 2^k or 2^{k+1}, and we can compute each table entry by addition from one of its predecessors in $O(k)$ steps, hence $O(k2^k) = O(n)$ steps will suffice for the calculation.) In this case M is the time needed to do 12-place arithmetic in radix $2^{\lceil m/12 \rceil}$, and it follows that $M = O(k) = O(\log n)$ because 1-place multiplication can be done by table lookup.

Schönhage discovered in 1979 that a *pointer machine* can carry out n-bit multiplication in $O(n)$ steps; see exercise 12. Such devices (which are also called "storage modification machines" and "linking automata") seem to provide the best models of computation when $n \to \infty$, as discussed at the end of Section 2.6. So we can conclude that multiplication in $O(n)$ steps is possible for theoretical purposes as well as in practice.

D. Division. Now that we have efficient routines for multiplication, let's consider the inverse problem. It turns out that division can be performed just as fast as multiplication, except for a constant factor.

To divide an n-bit number u by an n-bit number v, we may first find an n-bit approximation to $1/v$, then multiply by u to get an approximation $\hat{q}$ to u/v; finally, we can make the slight correction necessary to $\hat{q}$ to ensure that $0 \le u - qv < v$ by using another multiplication. From this reasoning, we see that it suffices to have an efficient algorithm for approximating the reciprocal of an n-bit number. The following algorithm does this, using "Newton's method" as explained at the end of Section 4.3.1.

Algorithm R (*High-precision reciprocal*). Let v have the binary representation $v = (0.v_1v_2v_3\ldots)_2$, where $v_1 = 1$. This algorithm computes an approximation z to $1/v$, such that

$$|z - 1/v| \le 2^{-n}. \tag{43}$$

R1. [Initial approximation.] Set $z \leftarrow \frac{1}{4}\lfloor 32/(4v_1 + 2v_2 + v_3)\rfloor$ and $k \leftarrow 0$.

R2. [Newtonian iteration.] (At this point we have a number z of the binary form $(xx.xx\ldots x)_2$ with $2^k + 1$ places after the radix point, and $z \le 2$.) Calculate $z^2 = (xxx.xx\ldots x)_2$ exactly, using a high-speed multiplication routine. Then calculate $V_k z^2$ exactly, where $V_k = (0.v_1 v_2 \ldots v_{2^{k+1}+3})_2$. Then set $z \leftarrow 2z - V_k z^2 + r$, where $0 \le r < 2^{-2^{k+1}-1}$ is added if necessary to "round up" z so that it is a multiple of $2^{-2^{k+1}-1}$. Finally, set $k \leftarrow k+1$.

R3. [Test for end.] If $2^k < n$, go back to step R2; otherwise the algorithm terminates. ∎

This algorithm is based on a suggestion by S. A. Cook. A similar technique has been used in computer hardware [see Anderson, Earle, Goldschmidt, and Powers, *IBM J. Res. Dev.* **11** (1967), 48–52]. Of course, it is necessary to check the accuracy of Algorithm R quite carefully, because it comes very close to being inaccurate. We will prove by induction that

$$z \le 2 \qquad \text{and} \qquad |z - 1/v| \le 2^{-2^k} \tag{44}$$

at the beginning and end of step R2.

For this purpose, let $\delta_k = 1/v - z_k$, where z_k is the value of z after k iterations of step R2. To start the induction on k, we have

$$\delta_0 = 1/v - 8/v' + (32/v' - \lfloor 32/v'\rfloor)/4 = \eta_1 + \eta_2,$$

where $v' = (v_1 v_2 v_3)_2$ and $\eta_1 = (v' - 8v)/vv'$, so that we have $-\frac{1}{2} < \eta_1 \le 0$ and $0 \le \eta_2 < \frac{1}{4}$. Hence $|\delta_0| < \frac{1}{2}$. Now suppose that (44) has been verified for k; then

$$\begin{aligned}\delta_{k+1} = 1/v - z_{k+1} &= 1/v - z_k - z_k(1 - z_k V_k) - r \\ &= \delta_k - z_k(1 - z_k v) - z_k^2(v - V_k) - r \\ &= \delta_k - (1/v - \delta_k)v\delta_k - z_k^2(v - V_k) - r \\ &= v\delta_k^2 - z_k^2(v - V_k) - r.\end{aligned}$$

Now

$$0 \le v\delta_k^2 < \delta_k^2 \le (2^{-2^k})^2 = 2^{-2^{k+1}},$$

and

$$0 \le z^2(v - V_k) + r < 4(2^{-2^{k+1}-3}) + 2^{-2^{k+1}-1} = 2^{-2^{k+1}},$$

so $|\delta_{k+1}| \le 2^{-2^{k+1}}$. We must still verify the first inequality of (44); to show that $z_{k+1} \le 2$, there are three cases: (a) $V_k = \frac{1}{2}$; then $z_{k+1} = 2$. (b) $V_k \ne \frac{1}{2} = V_{k-1}$; then $z_k = 2$, so $2z_k - z_k^2 V_k \le 2 - 2^{-2^{k+1}-1}$. (c) $V_{k-1} \ne \frac{1}{2}$; then $z_{k+1} = 1/v - \delta_{k+1} < 2 - 2^{-2^{k+1}} \le 2$, since $k > 0$.

The running time of Algorithm R is bounded by

$$2T(4n) + 2T(2n) + 2T(n) + 2T(\tfrac{1}{2}n) + \cdots + O(n)$$

steps, where $T(n)$ is an upper bound on the time needed to do a multiplication of n-bit numbers. If $T(n)$ has the form $nf(n)$ for some monotonically nondecreasing function $f(n)$, we have

$$T(4n) + T(2n) + T(n) + \cdots < T(8n),$$

so division can be done with a speed comparable to that of multiplication except for a constant factor.

R. P. Brent has shown that functions such as $\log x$, $\exp x$, and $\arctan x$ can be evaluated to n significant bits in $O(M(n)\log n)$ steps, if it takes $M(n)$ units of time to multiply n-bit numbers [*JACM* **23** (1976), 242–251].

E. An even faster multiplication method. It is natural to wonder if multiplication of n-bit numbers can be accomplished in just n steps. We have come from order n^2 down to order n, so perhaps we can squeeze the time down to the absolute minimum. In fact, it is actually possible to output the answer as fast as we input the digits, if we leave the domain of conventional computer programming and allow ourselves to build a computer that has an unlimited number of components all acting at once.

A *linear iterative array* of automata is a set of devices M_1, M_2, M_3, ... that can each be in a finite set of "states" at each step of a computation. The machines M_2, M_3, ... all have *identical* circuitry, and their state at time $t+1$ is a function of their own state at time t as well as the states of their left and right neighbors at time t. The first machine M_1 is slightly different: its state at time $t+1$ is a function of its own state and that of M_2, at time t, and also of the *input* at time t. The *output* of a linear iterative array is a function defined on the states of M_1.

Let $u = (u_{n-1}\ldots u_1u_0)_2$, $v = (v_{n-1}\ldots v_1v_0)_2$, and $q = (q_{n-1}\ldots q_1q_0)_2$ be binary numbers, and let $uv+q = w = (w_{2n-1}\ldots w_1w_0)_2$. It is a remarkable fact that a linear iterative array can be constructed, independent of n, that will output w_0, w_1, w_2, ... at times 1, 2, 3, ..., if it is given the inputs (u_0, v_0, q_0), (u_1, v_1, q_1), (u_2, v_2, q_2), ... at times 0, 1, 2, ...

We can state this phenomenon in the language of computer hardware, by saying that it is possible to design a single "integrated circuit module" with the following property: If we wire together sufficiently many of these devices in a straight line, with each module communicating only with its left and right neighbors, the resulting circuitry will produce the $2n$-bit product of n-bit numbers in exactly $2n$ clock pulses.

Here is the basic idea behind this construction: At time 0, machine M_1 senses (u_0, v_0, q_0) and it therefore is able to output $(u_0v_0 + q_0) \bmod 2$ at time 1. Then it sees (u_1, v_1, q_1) and it can output $(u_0v_1 + u_1v_0 + q_1 + k_1) \bmod 2$, where k_1 is the "carry" left over from the previous step, at time 2. Next it sees (u_2, v_2, q_2) and outputs $(u_0v_2 + u_1v_1 + u_2v_0 + q_2 + k_2) \bmod 2$; furthermore, its state holds the values of u_2 and v_2 so that machine M_2 will be able to sense these values at time 3, and M_2 will be able to compute u_2v_2 for the benefit of M_1 at time 4. Machine M_1 essentially arranges to start M_2 multiplying the sequence (u_2, v_2),

Table 1

MULTIPLICATION IN A LINEAR ITERATIVE ARRAY

Time	Input		Module M_1					Module M_2					Module M_3				
	u_j / v_j	q_j	c	x_0 / y_0	x_1 / y_1	x / y	z_2 / z_1 / z_0	c	x_0 / y_0	x_1 / y_1	x / y	z_2 / z_1 / z_0	c	x_0 / y_0	x_1 / y_1	x / y	z_2 / z_1 / z_0
0	1 / 1	1	0	0 / 0	0 / 0	0 / 0	0 / 0 / 0	0	0 / 0	0 / 0	0 / 0	0 / 0 / 0	0	0 / 0	0 / 0	0 / 0	0 / 0 / 0
1	1 / 1	1	1	1 / 1	0 / 0	0 / 0	0 / 1 / 0	0	0 / 0	0 / 0	0 / 0	0 / 0 / 0	0	0 / 0	0 / 0	0 / 0	0 / 0 / 0
2	1 / 1	0	2	1 / 1	1 / 1	0 / 0	1 / 0 / 0	0	0 / 0	0 / 0	0 / 0	0 / 0 / 0	0	0 / 0	0 / 0	0 / 0	0 / 0 / 0

11	0 / 0	0	3	1 / 1	1 / 1	0 / 0	0 / 0 / 0	3	1 / 1	0 / 0	0 / 0	0 / 0 / 0	3	1 / 1	0 / 0	0 / 0	0 / 0 / 0

(u_3, v_3), ..., and M_2 will ultimately give M_3 the job of multiplying (u_4, v_4), (u_5, v_5), etc. Fortunately, things just work out so that no time is lost. The reader will find it interesting to deduce further details from the formal description that follows.

Each automaton has 2^{11} states

$$(c, x_0, y_0, x_1, y_1, x, y, z_2, z_1, z_0),$$

where $0 \le c < 4$ and each of the x's, y's, and z's is either 0 or 1. Initially, all devices are in state $(0,0,0,0,0,0,0,0,0,0)$. Suppose that a machine M_j, for $j > 1$, is in state $(c, x_0, y_0, x_1, y_1, x, y, z_2, z_1, z_0)$ at time t, and its left neighbor M_{j-1} is in state $(c^l, x_0^l, y_0^l, x_1^l, y_1^l, x^l, y^l, z_2^l, z_1^l, z_0^l)$ while its right neighbor M_{j+1} is in state $(c^r, x_0^r, y_0^r, x_1^r, y_1^r, x^r, y^r, z_2^r, z_1^r, z_0^r)$ at that time. Then machine M_j will go into state $(c', x_0', y_0', x_1', y_1', x', y', z_2', z_1', z_0')$ at time $t+1$, where

$$\begin{aligned}
c' &= \min(c+1, 3) && \text{if } c^l = 3, && 0 && \text{otherwise;}\\
(x_0', y_0') &= (x^l, y^l) && \text{if } c = 0, && (x_0, y_0) && \text{otherwise;}\\
(x_1', y_1') &= (x^l, y^l) && \text{if } c = 1, && (x_1, y_1) && \text{otherwise;}\\
(x', y') &= (x^l, y^l) && \text{if } c \ge 2, && (x, y) && \text{otherwise;}
\end{aligned} \tag{45}$$

and $(z_2' z_1' z_0')_2$ is the binary notation for

$$z_0^r + z_1 + z_2^l + \begin{cases} x^l y^l, & \text{if } c = 0;\\ x_0 y^l + x^l y_0, & \text{if } c = 1;\\ x_0 y^l + x_1 y_1 + x^l y_0, & \text{if } c = 2;\\ x_0 y^l + x_1 y + x y_1 + x^l y_0, & \text{if } c = 3. \end{cases} \tag{46}$$

The leftmost machine M_1 behaves in almost the same way as the others; it acts exactly as if there were a machine to its left in state $(3,0,0,0,0,u,v,q,0,0)$ when it is receiving the inputs (u, v, q). The output of the array is the z_0 component of M_1.

Table 1 shows an example of this array acting on the inputs

$$u = v = (\ldots 00010111)_2, \qquad q = (\ldots 00001011)_2.$$

The output sequence appears in the lower right portion of the states of M_1:

$$0, 0, 1, 1, 1, 0, 0, 0, 0, 1, 0, \ldots,$$

representing the number $(\ldots 01000011100)_2$ from right to left.

This construction is based on a similar one first published by A. J. Atrubin, *IEEE Trans.* **EC–14** (1965), 394–399.

S. Winograd [*JACM* **14** (1967), 793–802] has investigated the minimum multiplication time achievable in a logical circuit when n is given and when the inputs are available all at once in coded form. See also C. S. Wallace, *IEEE Trans.* **EC–13** (1964), 14–17; A. C. Yao, to appear.

EXERCISES

1. [*22*] The idea expressed in (2) can be generalized to the decimal system, if the radix 2 is replaced by 10. Using this generalization, calculate 2718 times 4742 (reducing this product of four-digit numbers to three products of two-digit numbers, and reducing each of the latter to products of one-digit numbers).

2. [*M22*] Prove that, in step C1 of Algorithm C, the value of R either stays the same or increases by one when we set $R \leftarrow \lfloor\sqrt{Q}\rfloor$. (Therefore, as observed in that step, we need not calculate a square root.)

3. [*M23*] Prove that the sequences q_k, r_k defined in Algorithm C satisfy the inequality $2^{q_k+1}(2r_k)^{r_k} \le 2^{q_{k-1}+q_k}$, when $k > 0$.

▶ **4.** [*28*] (K. Baker.) Show that it is advantageous to evaluate the polynomial $W(x)$ at the points $x = -r, \ldots, 0, \ldots, r$ instead of at the nonnegative points $x = 0, 1, \ldots, 2r$ as in Algorithm C. The polynomial $U(x)$ can be written

$$U(x) = U_e(x^2) + xU_o(x^2),$$

and similarly $V(x)$ and $W(x)$ can be expanded in this way; show how to exploit this idea, obtaining faster calculations in steps C7 and C8.

▶ **5.** [*35*] Show that if in step C1 of Algorithm C we set $R \leftarrow \lceil\sqrt{2Q}\,\rceil + 1$ instead of $R \leftarrow \lfloor\sqrt{Q}\rfloor$, with suitable initial values of q_0, q_1, r_0, and r_1, then (19) can be improved to $t_k \le q_{k+1}2^{\sqrt{2\lg q_{k+1}}}(\lg q_{k+1})$.

6. [*M23*] Prove that the six numbers in (22) are relatively prime in pairs.

7. [*M23*] Prove (23).

▶ **8.** [*25*] Prove that it takes only $O(K \log K)$ arithmetic operations to evaluate the discrete Fourier transform (32), even when K is not a power of 2. [*Hint:* Rewrite (32) in the form

$$\hat{u}_s = \omega^{-s^2/2} \sum_{0 \le t < K} \omega^{(s+t)^2/2}\omega^{-t^2/2}u_t$$

and express this sum as a convolution product.]

9. [*M15*] Suppose the Fourier transformation method of the text is applied with all occurrences of ω replaced by ω^q, where q is some fixed integer. Find a simple relation between the numbers $(\tilde{u}_0, \tilde{u}_1, \ldots, \tilde{u}_{K-1})$ obtained by this general procedure and the numbers $(\hat{u}_0, \hat{u}_1, \ldots, \hat{u}_{K-1})$ obtained when $q = 1$.

10. [*M26*] The scaling in (37) makes it clear that all the complex numbers $A^{[j]}$ computed by pass j of the transformation subroutine will be less than 2^{j-k} in absolute value, during the calculations of $\hat{u}_s$ and $\hat{v}_s$ in the Schönhage–Strassen multiplication algorithm. Show that all of the $A^{[j]}$ will be less than 1 in absolute value during the *third* Fourier transformation (the calculation of w_r).

▶ **11.** [*M26*] If n is fixed, how many of the automata in the linear iterative array (45), (46) are needed to compute the product of n-bit numbers? (Note that the automaton M_j is influenced only by the component z_0^r of the machine on its right, so we may remove all automata whose z_0 component is always zero whenever the inputs are n-bit numbers.)

▶ **12.** [*30*] (A. Schönhage.) The purpose of this exercise is to prove that a simple form of pointer machine can multiply n-bit numbers in $O(n)$ steps. The machine has no built-in facilities for arithmetic; all it does is work with nodes and pointers. Each node has the same finite number of link fields, and there are finitely many link registers. The only operations this machine can do are:

i) read one bit of input and jump if that bit is 0;
ii) output 0 or 1;
iii) load a register with the contents of another register or with the contents of a link field in a node pointed to by a register;
iv) store the contents of a register into a link field in a node pointed to by a register;
v) jump if two registers are equal;
vi) create a new node and make a register point to it;
vii) halt.

Implement the Fourier-transform multiplication method efficiently on such a machine. [*Hints:* First show that if N is any positive integer, it is possible to create N nodes representing the integers $\{0, 1, \ldots, N-1\}$, where the node representing p has pointers to the nodes representing $p+1$, $\lfloor p/2 \rfloor$, and $2p$. These nodes can be created in $O(N)$ steps. Show that arithmetic with radix N can now be simulated without difficulty: for example, it takes $O(\log N)$ steps to find the node for $(p+q) \bmod N$ and to determine if $p+q \geq N$, given pointers to p and q; and multiplication can be simulated in $O(\log N)^2$ steps. Now consider the algorithm in the text, with $k = l$ and $m = 6k$ and $N = 2^{\lceil m/13 \rceil}$, so that all quantities in the fixed point arithmetic calculations are 13-place integers with radix N. Finally, show that each pass of the fast Fourier transformations can be done in $O(K + (N \log N)^2) = O(K)$ steps, using the following idea: Each of the K necessary assignments can be "compiled" into a bounded list of instructions for a simulated MIX-like computer whose word size is N, and instructions for K such machines acting in parallel can be simulated in $O(K + (N \log N)^2)$ steps if they are first sorted so that all identical instructions are performed together. (Two instructions are identical if they have the same operation code, the same register contents, and the same memory operand contents.) Note that $N^2 = O(n^{12/13})$, so $(N \log N)^2 = O(K)$.]

13. [*M25*] (A. Schönhage.) What is a good upper bound on the time needed to multiply an m-bit number by an n-bit number, when both m and n are very large but n is much larger than m, based on the results proved in this section for $m = n$?

14. [*M42*] Write a program for Algorithm C, incorporating the improvements of exercise 4. Compare it with a program for Algorithm 4.3.1M and with a program based on (2), to see how large n must be before Algorithm C is an improvement.

15. [*M49*] (S. A. Cook.) A multiplication algorithm is said to be *on line* if the $(k+1)$st input bits of the operands, from right to left, are not read until the kth output bit has been produced. What are the fastest possible on-line multiplication algorithms achievable on various species of automata?

(The best upper bound known is $O(n(\log n)^2 \log\log n)$, due to M. J. Fischer and L. J. Stockmeyer [*J. Comp. and Syst. Sci.* **9** (1974), 317–331]; their construction works on multitape Turing machines, hence also on pointer machines. The best lower bound known is of order $n \log n / \log\log n$, due to M. S. Paterson, M. J. Fischer, and A. R. Meyer [*SIAM/AMS Proceedings* **7** (1974), 97–111]; this applies to multitape Turing machines but not to pointer machines.)

4.4. RADIX CONVERSION

IF OUR ANCESTORS had invented arithmetic by counting with their two fists or their eight fingers, instead of their ten "digits," we would never have to worry about writing binary-decimal conversion routines. (And we would perhaps never have learned as much about number systems.) In this section, we shall discuss the conversion of numbers from positional notation with one radix into positional notation with another radix; this process is, of course, most important on binary computers when converting decimal input data into binary form, and converting binary answers into decimal form.

A. The four basic methods. Binary-decimal conversion is one of the most machine-dependent operations of all, since computer designers keep inventing different ways to provide for it in the hardware. Therefore we shall discuss only the general principles involved, from which a programmer can select the procedure that is best suited to his machine.

We shall assume that only nonnegative numbers enter into the conversion, since the manipulation of signs is easily accounted for.

Let us assume that we are converting from radix b to radix B. (The methods can also be generalized to mixed-radix notations, as shown in exercises 1 and 2.) Most radix-conversion routines are based on multiplication and division, using one of the following four schemes:

1) Conversion of integers (radix point at the right).

• Method (1a) *Division by B* (using radix-b arithmetic). Given an integer number u, we can obtain its radix-B representation $(U_M \dots U_1 U_0)_B$ as follows:

$$\begin{aligned} U_0 &= u \bmod B \\ U_1 &= \lfloor u/B \rfloor \bmod B \\ U_2 &= \lfloor \lfloor u/B \rfloor / B \rfloor \bmod B \\ &\dots \end{aligned}$$

etc., stopping when $\lfloor \dots \lfloor \lfloor u/B \rfloor / B \rfloor \dots / B \rfloor = 0$.

• Method (1b) *Multiplication by b* (using radix-B arithmetic). If u has the radix-b representation $(u_m \dots u_1 u_0)_b$, we can use radix-B arithmetic to evaluate the polynomial $u_m b^m + \cdots + u_1 b + u_0 = u$ in the form

$$\big((\dots(u_m b + u_{m-1})b + \cdots)b + u_1\big)b + u_0.$$

2) Conversion of fractions (radix point at the left). Note that it is often impossible to express a terminating radix-b fraction $(0.u_{-1}u_{-2}\dots u_{-m})_b$ *exactly* as a terminating radix-B fraction $(0.U_{-1}U_{-2}\dots U_{-M})_B$. For example, the fraction $\frac{1}{10}$ has the infinite binary representation $(0.0001100110011\dots)_2$. Therefore methods of rounding the result to M places are sometimes necessary.

• Method (2a) *Multiplication by B* (using radix-b arithmetic). Given a fractional number u, we can obtain the digits of its radix-B representation $(.U_{-1}U_{-2}\ldots)_B$ as follows:

$$U_{-1} = \lfloor uB \rfloor$$
$$U_{-2} = \lfloor \{uB\}B \rfloor$$
$$U_{-3} = \lfloor \{\{uB\}B\}B \rfloor$$
$$\ldots$$

where $\{x\}$ denotes $x \bmod 1 = x - \lfloor x \rfloor$. If it is desired to round the result to M places, the computation can be stopped after U_{-M} has been calculated, and U_{-M} should be increased by unity if $\{\ldots\{\{uB\}B\}\ldots B\}$ is greater than $\frac{1}{2}$. (Note, however, that this may cause carries to propagate, and these carries must be incorporated into the answer using radix-B arithmetic. It would be simpler to add the constant $\frac{1}{2}B^{-M}$ to the original number u before the calculation begins, but this may lead to a terribly incorrect answer when $\frac{1}{2}B^{-M}$ cannot be represented exactly as a radix-b number inside the computer. Note further that it is possible for the answer to round up to $(1.00\ldots0)_B$, if $b^m \geq 2B^M$.)

Exercise 3 shows how to extend this method so that M is *variable*, just large enough to represent the original number to a specified accuracy; in this case the problem of carries does not occur.

• Method (2b) *Division by b* (using radix-B arithmetic). If u has the radix-b representation $(0.u_{-1}u_{-2}\ldots u_{-m})_b$, we can use radix-$B$ arithmetic to evaluate $u_{-1}b^{-1} + u_{-2}b^{-2} + \cdots + u_{-m}b^{-m}$ in the form

$$((\ldots(u_{-m}/b + u_{1-m})/b + \cdots + u_{-2})/b + u_{-1})/b.$$

Care should be taken to control errors that might occur due to truncation or rounding in the division by b; these are often negligible, but not always.

To summarize, Methods (1a), (1b), (2a), and (2b) give us two choices for a conversion process, depending on whether our number is an integer or a fraction. And it is certainly possible to convert between integers and fractions by multiplying or dividing by an appropriate power of b or B; therefore there are at least four methods to choose from when trying to do a conversion.

B. Single-precision conversion. To illustrate these four methods, let us assume that MIX is a binary computer, and suppose that we want to convert a binary integer u to a decimal integer. Thus $b = 2$ and $B = 10$. Method (1a) could be programmed as follows:

```
    ENT1  0            Set j ← 0.
    LDX   U
    ENTA  0            Set rAX ← u.
1H  DIV   =10=         (rA, rX) ← (⌊rAX/10⌋, rAX mod 10).
    STX   ANSWER,1     U_j ← rX.                          (1)
    INC1  1            j ← j + 1.
    SRAX  5            rAX ← rA.
    JXP   1B           Repeat until result is zero.  ∎
```

This requires $18M + 4$ cycles to obtain M digits.

The above method uses division by 10; Method (2a) uses *multiplication* by 10, so it might be a little faster. In order to use Method (2a), we must deal with fractions, and this leads to an interesting situation. Let w be the word size of the computer, and assume that $u < 10^n < w$. With a single division we can find q and r, where

$$wu = 10^n q + r, \qquad 0 \le r < 10^n. \tag{2}$$

Now if we apply Method (2a) to the fraction $(q+1)/w$, we will obtain the digits of u from left to right, in n steps, since

$$\left\lfloor 10^n \frac{q+1}{w} \right\rfloor = \left\lfloor u + \frac{10^n - r}{w} \right\rfloor = u. \tag{3}$$

(This idea is due to P. A. Samet, *Software—Practice and Experience* **1** (1971), 93–96.)

Here is the corresponding MIX program:

```
      JOV   OFLO          Ensure overflow is off.
      LDA   U
      LDX   =10^n=        rAX ← wu + 10^n.
      DIV   =10^n=        rA ← q + 1, rX ← r.
      JOV   ERROR         Jump if u ≥ 10^n.
      ENT1  n-1           Set j ← n − 1.                          (4)
2H    MUL   =10=          Now imagine radix point at left, rA = x.
      STA   ANSWER,1      Set U_j ← ⌊10x⌋.
      SLAX  5             x ← {10x}.
      DEC1  1             j ← j − 1.
      J1NN  2B            Repeat for n > j ≥ 0.  ∎
```

This slightly longer routine requires $16n + 19$ cycles, so it is a little faster than program (1) if $n = M \ge 8$; when leading zeros are present, (1) will be faster.

Program (4) as it stands cannot be used to convert integers $u \ge 10^m$ when $10^m < w < 10^{m+1}$, since we would need to take $n = m + 1$. In this case we can obtain the leading digit of u by computing $\lfloor u/10^m \rfloor$; then $u \bmod 10^m$ can be converted as above with $n = m$.

The fact that the answer digits are obtained from left to right may be an advantage in some applications (e.g., when typing out the answer one digit at a time). Thus we see that a fractional method can be used for conversion of integers, although the use of inexact division makes a little bit of numerical analysis necessary.

A modification of Method (1a) can be used to avoid division by 10, by replacing it with two multiplications. It is worth mentioning this modification here, because radix conversion is often done by small "satellite" computers that have no division capability. If we let x be an approximation to $\frac{1}{10}$, so that $\frac{1}{10} < x < \frac{1}{10} + 1/w$, it is easy to prove (see exercise 7) that $\lfloor ux \rfloor = \lfloor u/10 \rfloor$ or $\lfloor u/10 \rfloor + 1$, so long as $0 \le u < w$. Therefore, if we compute $u - 10\lfloor ux \rfloor$, we

will be able to determine the value of $\lfloor u/10 \rfloor$:

$$\lfloor u/10 \rfloor = \begin{cases} \lfloor ux \rfloor, & \text{if } u - 10\lfloor ux \rfloor \geq 0; \\ \lfloor ux \rfloor - 1, & \text{if } u - 10\lfloor ux \rfloor < 0. \end{cases} \tag{5}$$

This procedure simultaneously determines $u \bmod 10$. A MIX program for conversion using this idea appears in exercise 8; it requires about 33 cycles per digit.

The procedure represented by (5) can be used effectively even if the computer has no built-in multiplication instruction, since multiplication by 10 consists of two shifts and one addition ($10 = 2^3 + 2$). Even the task of multiplication by $\frac{1}{10}$ can be done by judiciously combining a few shifting and adding operations, as explained in exercise 9.

Another way to convert from binary to decimal is to use Method (1b), but to do this we need to simulate doubling in a *decimal* number system. This idea is generally most suitable for incorporation into computer hardware; however, it is possible to program the doubling process for decimal numbers, using binary addition, binary shifting, and binary extraction ("logical AND" on each bit in the register), as shown in the following table.

Table 1

DOUBLING A BINARY-CODED DECIMAL NUMBER

Operation	*General form*	*Example*
1. Given number	$u_1u_2u_3u_4\ u_5u_6u_7u_8\ u_9u_{10}u_{11}u_{12}$	0011 0110 1001 = 3 6 9
2. Add 3 to each digit	$v_1v_2v_3v_4\ v_5v_6v_7v_8\ v_9v_{10}v_{11}v_{12}$	0110 1001 1100
3. Shift left one	$v_1\ v_2v_3v_4v_5\ v_6v_7v_8v_9\ v_{10}v_{11}v_{12}\ 0$	0 1101 0011 1000
4. Extract low bit	$v_1\ 0\ 0\ 0\ v_5\ 0\ 0\ 0\ v_9\ 0\ 0\ 0\ 0$	0 0001 0001 0000
5. Shift right two	$0\ v_1\ 0\ 0\ 0\ v_5\ 0\ 0\ 0\ v_9\ 0\ 0$	0000 0100 0100
6. Shift right one and add	$0\ v_1v_1\ 0\ 0\ v_5v_5\ 0\ 0\ v_9\ v_9\ 0$	0000 0110 0110
7. Add result of step 3	$*\ *\ *\ *\ *\ *\ *\ *\ *\ *\ *\ 0$	0 1101 1001 1110
8. Subtract 6 from each	$y_1\ y_2y_3y_4y_5\ y_6y_7y_8y_9\ y_{10}y_{11}y_{12}\ 0$	0 0111 0011 1000 = 7 3 8

This method changes each individual digit d into $\big((d+3)\times 2+0\big)-6 = 2d$ when $0 \leq d \leq 4$, and into $\big((d+3)\times 2+6\big)-6 = (2d-10)+2^4$ when $5 \leq d \leq q$; and that is just what is needed to double decimal numbers encoded with 4 bits per digit.

Another related idea is to keep a table of the powers of two in decimal form, and to add the appropriate powers together by simulating decimal addition. A survey of bit-manipulation techniques appears in Section 7.1.

Finally, even Method (2b) can be used for the conversion of binary integers to decimal integers. We can find q as in (2), and then we can simulate the decimal division of $q+1$ by w, using a "halving" process (exercise 10) that is similar to the doubling process just described, retaining only the first n digits to the right of the radix point in the answer. In this situation, Method (2b) does not seem to offer advantages over the other three methods already discussed, but we have confirmed the remark made earlier that at least four distinct methods are available for converting integers from one radix to another.

Now let us consider decimal-to-binary conversion (so that $b = 10$, $B = 2$). Method (1a) simulates a decimal division by 2; this is feasible (see exercise 10), but it is primarily suitable for incorporation in hardware instead of programs.

Method (1b) is the most practical method for decimal-to-binary conversion in the great majority of cases. Here it is in MIX code, assuming that there are at least two digits in the number $(u_m \ldots u_1 u_0)_{10}$ being converted:

```
    ENT1 M-1          Set j ← m − 1.
    LDA  INPUT+M      Set U ← u_m.
1H  MUL  =10=
    SLAX 5                                        (6)
    ADD  INPUT,1      U ← 10U + u_j.
    DEC1 1
    J1NN 1B           Repeat for m > j ≥ 0. ∎
```

Note again that adding and shifting may be substituted for the multiplication by 10.

A trickier but perhaps faster method, which uses about $\lg m$ multiplications, extractions, and additions instead of m multiplications and additions, is described in exercise 19.

For the conversion of decimal fractions $(0.u_{-1}u_{-2}\ldots u_{-m})_{10}$ to binary form, we can use Method (2b); or, more commonly, we can convert the integer $(u_{-1}u_{-2}\ldots u_{-m})_{10}$ by Method (1b) and then divide by 10^m.

C. Hand calculation. It is occasionally necessary for computer programmers to convert numbers by hand, and since this is a subject not yet taught in elementary schools, it may be worthwhile to examine it briefly here. There are very simple pencil-and-paper methods for converting between decimal and octal notations, and these methods are easily learned, so they ought to be more widely known.

Converting octal integers to decimal. The simplest conversion is from octal to decimal; this technique was apparently first published by Walter Soden, *Math. Comp.* **7** (1953), 273–274. To do the conversion, write down the given octal number; then at the kth step, double the k leading digits using decimal arithmetic, and subtract this from the $k+1$ leading digits using decimal arithmetic. The process terminates in $n-1$ steps if the given number has n digits. It is a good idea to insert a radix point to show which digits are being doubled, as shown in the following example, in order to prevent embarrassing mistakes.

Example 1. Convert $(5325121)_8$ to decimal.

```
   5.3 2 5 1 2 1
— 1 0
   4 3.2 5 1 2 1
—    8 6
   3 4 6.5 1 2 1
—    6 9 2
   2 7 7 3.1 2 1
—    5 5 4 6
   2 2 1 8 5.2 1
—    4 4 3 7 0
   1 7 7 4 8 2.1
—    3 5 4 9 6 4
   1 4 1 9 8 5 7
```

Answer: $(14198757)_{10}$.

A reasonably good check on the computations may be had by "casting out nines": The sum of the digits of the decimal number must be congruent modulo 9 to the alternating sum and difference of the digits of the octal number, with the rightmost digit of the latter given a plus sign. In the above example, we have $1+4+1+9+8+5+7=35$, and $1-2+1-5+2-3+5=-1$; the difference is 36 (a multiple of 9). If this test fails, it can be applied to the $k+1$ leading digits after the kth step, and the error can be located using a "binary search" procedure; i.e., we start by checking the middle result, then use the same procedure on the first or second half of the calculation, depending on whether the middle result is incorrect or correct.

The "casting-out-nines" process is only about 89 percent reliable, because there is one chance in nine that two *random* integers will differ by a multiple of nine. An even better check is to convert the answer back to octal by using an inverse method, which we shall now consider.

Converting decimal integers to octal. A similar procedure can be used for the opposite conversion: Write down the given decimal number; then at the kth step, double the k leading digits using *octal* arithmetic, and *add* these to the $k+1$ leading digits using *octal* arithmetic. The process terminates in $n-1$ steps if the given number has n digits. (See Example 2 on the following page.)

The two procedures just given are essentially Method (1b) of the general radix-conversion procedures. Doubling and subtracting in decimal notation is like multiplying by $10-2=8$; doubling and adding in octal notation is like multiplying by $8+2=10$. There is a similar method for hexadecimal/decimal conversions, but it is a little more difficult since it involves multiplication by 6 instead of by 2.

To keep these two methods straight in our minds, it is not hard to remember that we must subtract to go from octal to decimal, since the decimal representation of a number is smaller; similarly we must add to go from decimal to

Example 2. Convert $(1419857)_{10}$ to octal.

```
  1.4 1 9 8 5 7
+   2
  1 6.1 9 8 5 7
+   3 4
  2 1 5.9 8 5 7
+   4 3 2
  2 6 1 3.8 5 7
+   5 4 2 6
  3 3 5 6 6.5 7
+   6 7 3 5 4
  4 2 5 2 4 1.7
+ 1 0 5 2 5 0 2
  5 3 2 5 1 2 1
```

(Note that the nonoctal digits 8 and 9 enter into this octal computation.) The answer can be checked as discussed above. This method was published by Charles P. Rozier, *IEEE Trans.* **CE–11** (1962), 708–709.

Answer: $(5325121)_8$.

octal. The computations are performed using the radix of the *answer*, not the radix of the given number, otherwise we couldn't get the desired answer.

Converting fractions. No equally fast method of converting fractions manually is known; the best way seems to be Method (2a), with doubling and adding or subtracting to simplify the multiplications by 10 or by 8. In this case, we reverse the addition-subtraction criterion, adding when we convert to decimal and subtracting when we convert to octal; we also use the radix of the given input number, *not* the radix of the answer, in this computation (see Examples 3 and 4). The process is about twice as hard as the above method for integers.

Example 3. Convert $(.14159)_{10}$ to octal.

```
.1 4 1 5 9
  2 8 3 1 8−
1.1 3 2 7 2
    2 6 5 4 4−
  1.0 6 1 7 6
      1 2 3 5 2−
    0.4 9 4 0 8
        9 8 8 1 6−
      3.9 5 2 4 6
          1 9 0 5 2 8−
        7.6 2 1 1 2
            1 2 4 2 2 4−
          4.9 6 8 9 6
```

Answer: $(.110374\ldots)_8$.

Example 4. Convert $(.110374)_8$ to decimal.

```
.1 1 0 3 7 4
  2 2 0 7 7 0+
1.3 2 4 7 3 0
    6 5 1 6 6 0+
  4.1 2 1 1 6 0
      2 4 2 3 4 0+
    1.4 5 4 1 4 0
        1 1 3 0 3 0 0+
      5.6 7 1 7 0 0
          1 5 6 3 6 0 0+
        8.5 0 2 6 0 0
            1 2 0 5 4 0 0+
          6.2 3 3 4 0 0
```

Answer: $(.141586\ldots)_{10}$.

D. Floating point conversion. When floating point values are to be converted, it is necessary to deal with both the exponent and the fraction parts simultaneously, since conversion of the exponent will affect the fraction part. Given the number $f \cdot 2^e$ to be converted to decimal, we may express 2^e in the form $F \cdot 10^E$ (usually by means of auxiliary tables), and then convert Ff to decimal. Alternatively, we can multiply e by $\log_{10} 2$ and round this to the nearest integer E; then divide $f \cdot 2^e$ by 10^E and convert the result. Conversely, given the number $F \cdot 10^E$ to be converted to binary, we may convert F and then multiply it by the floating point number 10^E (again by using auxiliary tables). Obvious techniques can be used to reduce the maximum size of the auxiliary tables by using several multiplications and/or divisions, although this can cause rounding errors to propagate.

E. Multiple-precision conversion. When converting extremely long numbers, it is most convenient to start by converting blocks of digits, which can be handled by single-precision techniques, and then to combine these blocks by using simple multiple-precision techniques. For example, suppose that 10^n is the highest power of 10 less than the computer word size. Then

a) To convert a multiple-precision *integer* from binary to decimal, divide it repeatedly by 10^n (thus converting from binary to radix 10^n by Method (1a)). Single-precision operations will give the n decimal digits for each place of the radix-10^n representation.

b) To convert a multiple-precision *fraction* from binary to decimal, proceed similarly, multiplying by 10^n (i.e., using Method (2a) with $B = 10^n$).

c) To convert a multiple-precision integer from decimal to binary, convert blocks of n digits first; then use Method (1b) to convert from radix 10^n to binary.

d) To convert a multiple-precision fraction from decimal to binary, convert first to radix 10^n as in (c), then use Method (2b).

F. History and Bibliography. Radix-conversion techniques implicitly originated in ancient problems dealing with weights, measures, and currencies, where mixed-radix systems were generally involved; auxiliary tables were usually prepared to help make the conversions. During the seventeenth century, when sexagesimal fractions were being supplanted by decimal fractions, it was necessary to convert between the two systems in order to use existing books of astronomical tables; a systematic method to transform fractions from radix 60 to radix 10 and vice versa was given in the 1667 edition of William Oughtred's *Clavis Mathematicæ*, Chapter 6, Section 18. (This material was not present in the original 1631 edition of Oughtred's book.) Conversion rules had already been given by al-Kashî of Persia in his *Key to Arithmetic* (c. 1414), where Methods (1a), (1b), and (2a) are clearly explained [*Istoriko-Mat. Issled.* **7** (1954), 126–135], but his work was unknown in Europe. The 18th century American mathematician Hugh Jones used the words "octavation" and "decimation" to describe octal/decimal conversions, but his methods were not as clever as his terminology. A. M. Legendre [*Théorie des nombres* (Paris: 1798), 229] noted that positive integers may be conveniently converted to binary form if they are repeatedly divided by 64.

In 1946, H. H. Goldstine and J. von Neumann gave prominent consideration to radix conversion in their classic memoir, "Planning and coding problems for an electronic computing instrument," because it was necessary to justify the use of binary arithmetic; see John von Neumann, *Collected Works* **5** (New York: Macmillan, 1963), 127–142. Another early discussion of radix conversion on binary computers was published by F. Koons and S. Lubkin, *Math. Comp.* **3** (1949), 427–431, who suggested a rather unusual method. The first discussion of floating point conversion was given somewhat later by F. L. Bauer and K. Samelson [*Zeit. für angewandte Math. und Physik* **4** (1953), 312–316].

The following articles may be useful for further reference: A note by G. T. Lake [*CACM* **5** (1962), 468–469] mentions some hardware techniques for conversion and gives clear examples. A. H. Stroud and D. Secrest [*Comp. J.* **6** (1963), 62–66] have discussed conversion of multiple-precision floating point numbers. The conversion of *unnormalized* floating point numbers, preserving the amount of "significance" implied by the representation, has been discussed by H. Kanner [*JACM* **12** (1965), 242–246] and by N. Metropolis and R. L. Ashenhurst [*Math. Comp.* **19** (1965), 435–441]. See also K. Sikdar, *Sankhyā* (B) **30** (1968), 315–334, and the references cited in his paper.

EXERCISES

▶ **1.** [*25*] Generalize Method (1b) so that it works with arbitrary mixed-radix notations, converting

$$a_m b_{m-1} \ldots b_1 b_0 + \cdots + a_1 b_0 + a_0 \quad \text{into} \quad A_M B_{M-1} \ldots B_1 B_0 + \cdots + A_1 B_0 + A_0,$$

where $0 \le a_j < b_j$ and $0 \le A_J < B_J$ for $0 \le j < m$ and $0 \le J < M$.

Give an example of your generalization by manually converting the quantity "3 days, 9 hours, 12 minutes, and 37 seconds" into long tons, hundredweights, stones, pounds, and ounces. (Let one second equal one ounce. The British system of weights has 1 stone = 14 pounds, 1 hundredweight = 8 stone, 1 long ton = 20 hundredweight.) In other words, let $b_0 = 60$, $b_1 = 60$, $b_2 = 24$, $m = 3$, $B_0 = 16$, $B_1 = 14$, $B_2 = 8$, $B_3 = 20$, $M = 4$; the problem is to find $A_4, \ldots, A_0$ in the proper ranges such that $3b_2b_1b_0 + 2b_1b_0 + 12b_0 + 37 = A_4B_3B_2B_1B_0 + A_3B_2B_1B_0 + A_2B_1B_0 + A_1B_0 + A_0$, using a systematic method that generalizes Method (1b). (All arithmetic is to be done in a mixed-radix system.)

2. [*25*] Generalize Method (1a) so that it works with mixed-radix notations, as in exercise 1, and give an example of your generalization by manually solving the same conversion problem stated in exercise 1.

▶ **3.** [*25*] (D. Taranto.) When fractions are being converted, there is no obvious way to decide how many digits to give in the answer. Design a simple generalization of Method (2a) that, given two positive radix-b fractions u and ϵ between 0 and 1, converts u to a rounded radix-B equivalent U that has just enough places M to the right of the radix point to ensure that $|U - u| < \epsilon$. (In particular if u is a multiple of b^{-m} and $\epsilon = b^{-m}/2$, the value of U will have just enough digits so that u can be recomputed exactly, given U and m. Note that M might be zero; for example, if $\epsilon \le \frac{1}{2}$ and $u > 1 - \epsilon$, the proper answer is $U = 1$.)

4. [*M21*] (a) Prove that every real number with a terminating *binary* representation also has a terminating *decimal* representation. (b) Find a simple condition on the positive integers b and B that is satisfied if and only if every real number that has a terminating radix-b representation also has a terminating radix-B representation.

5. [*M20*] Show that program (4) would still work if the instruction "LDX =10^n=" were replaced by "LDX =c=" for certain other constants c.

6. [*30*] Discuss using Methods (1a), (1b), (2a), and (2b) when b or B is -2.

7. [*M18*] Given that $0 < \alpha \le x \le \alpha + 1/w$ and $0 \le u \le w$, prove that $\lfloor ux \rfloor$ is equal to either $\lfloor \alpha u \rfloor$ or $\lfloor \alpha u \rfloor + 1$. Furthermore $\lfloor ux \rfloor = \lfloor \alpha u \rfloor$ exactly, if $u < \alpha w$ and α^{-1} is an integer.

8. [*24*] Write a MIX program analogous to (1) that uses (5) and includes no division instructions.

9. [*M27*] Let u be an integer, $0 \le u < 2^{34}$. Assume that the following sequence of operations (equivalent to addition and binary "shift-right" instructions) is performed:

$$v \leftarrow \lfloor \tfrac{1}{2}u \rfloor, \quad v \leftarrow v + \lfloor \tfrac{1}{2}v \rfloor, \quad v \leftarrow v + \lfloor 2^{-4}v \rfloor,$$
$$v \leftarrow v + \lfloor 2^{-8}v \rfloor, \quad v \leftarrow v + \lfloor 2^{-16}v \rfloor, \quad v \leftarrow \lfloor \tfrac{1}{8}v \rfloor.$$

Prove that $v = \lfloor u/10 \rfloor$ or $\lfloor u/10 \rfloor - 1$.

10. [*22*] The text shows how a binary-coded decimal number can be doubled by using various shifting, extracting, and addition operations on a binary computer. Give an analogous method that computes *half* of a binary-coded decimal number (throwing away the remainder if the number is odd).

11. [*16*] Convert $(57721)_8$ to decimal.

▶ **12.** [*22*] Invent a rapid pencil-and-paper method for converting integers from ternary notation to decimal, and illustrate your method by converting $(1212011210210)_3$ into decimal. How would you go from decimal to ternary?

▶ **13.** [*25*] Assume that locations U + 1, U + 2, ..., U + m contain a multiple-precision fraction $(.u_{-1}u_{-2}\ldots u_{-m})_b$, where b is the word size of MIX. Write a MIX routine that converts this fraction to decimal notation, truncating it to 180 decimal digits. The answer should be printed on two lines, with the digits grouped into 20 blocks of nine each separated by blanks. (Use the CHAR instruction.)

▶ **14.** [*M27*] (A. Schönhage.) The text's method of converting multiple-precision integers requires an execution time of order n^2 to convert an n-place integer, when n is large. Show that it is possible to convert n-digit decimal integers into binary notation in $O(M(n)\log n)$ steps, where $M(n)$ is an upper bound on the number of steps needed to multiply n-bit binary numbers that satisfies the "smoothness condition" $M(2n) \ge 2M(n)$.

15. [*M47*] Can the upper bound on the time to convert large integers, given in exercise 14, be substantially lowered? (Cf. exercise 4.3.3–12.)

16. [*41*] Construct a fast linear iterative array for radix conversion from decimal to binary (cf. Section 4.3.3).

17. [*M40*] Design "ideal" floating point conversion subroutines, taking p-digit decimal numbers into P-digit binary numbers and vice versa, in both cases producing a true rounded result in the sense of Section 4.2.2.

18. [*HM34*] (David W. Matula.) Let $\text{round}_b(u, p)$ be the function of b, u, and p that represents the best p-digit base b floating point approximation to u, in the sense of Section 4.2.2. Under the assumption that $\log_B b$ is irrational and that the range of exponents is unlimited, prove that

$$u = \text{round}_b(\text{round}_B(u, P), p)$$

holds for all p-digit base b floating point numbers u if and only if $B^{P-1} \geq b^p$. (In other words, an "ideal" input conversion of u into an independent base B, followed by an "ideal" output conversion of this result, will always yield u again if and only if the intermediate precision P is suitably large, as specified by the formula above.)

19. [*M23*] Let the decimal number $u = (u_7 \ldots u_1 u_0)_{10}$ be represented as the binary-coded decimal number $U = (u_7 \ldots u_1 u_0)_{16}$. Find appropriate constants c_i and masks m_i so that the operation $U \leftarrow U - c_i(U \wedge m_i)$, repeated for $i = 1, 2, 3$, will convert U to the binary representation of u, where "$\wedge$" denotes extraction (i.e., "logical AND" on individual bits).

4.5. RATIONAL ARITHMETIC

IT IS OFTEN important to know that the answer to some numerical problem is exactly $\frac{1}{3}$, not a floating point number that gets printed as "0.333333574". If arithmetic is done on fractions instead of on approximations to fractions, many computations can be done entirely *without any accumulated rounding errors.* This results in a comfortable feeling of security that is often lacking when floating point calculations have been made, and it means that the accuracy of the calculation cannot be improved upon.

4.5.1. Fractions

When fractional arithmetic is desired, the numbers can be represented as pairs of integers, (u/u'), where u and u' are relatively prime to each other and $u' > 0$. The number zero is represented as $(0/1)$. In this form, $(u/u') = (v/v')$ if and only if $u = v$ and $u' = v'$.

Multiplication of fractions is, of course, easy; to form $(u/u') \times (v/v') = (w/w')$, we can simply compute uv and $u'v'$. The two products uv and $u'v'$ might not be relatively prime, but if $d = \gcd(uv, u'v')$, the desired answer is $w = uv/d$, $w' = u'v'/d$. (See exercise 2.) Efficient algorithms to compute the greatest common divisor are discussed in Section 4.5.2.

Another way to perform the multiplication is to find $d_1 = \gcd(u, v')$ and $d_2 = \gcd(u', v)$; then the answer is $w = (u/d_1)(v/d_2)$, $w' = (u'/d_2)(v'/d_1)$. (See exercise 3.) This method requires two gcd calculations, but it is not really slower than the former method; the gcd process involves a number of iterations that is essentially proportional to the logarithm of its inputs, so the total number of iterations needed to evaluate both d_1 and d_2 is essentially the same as the number of iterations during the single calculation of d. Furthermore, each iteration in the evaluation of d_1 and d_2 is potentially faster, because comparatively small numbers are being examined. If u, u', v, and v' are single-precision quantities, this method has the advantage that no double-precision numbers appear in the calculation unless it is impossible to represent both of the answers w and w' in single-precision form.

Division may be done in a similar manner; see exercise 4.

Addition and subtraction are slightly more complicated. The obvious procedure is to set $(u/u') \pm (v/v') = \big((uv' \pm u'v)/u'v'\big)$ and then to reduce this fraction to lowest terms by calculating $d = \gcd(uv' \pm u'v, u'v')$ as in the first multiplication method. But again it is possible to avoid working with such large numbers, if we start by calculating $d_1 = \gcd(u', v')$. If $d_1 = 1$, then the desired numerator and denominator are $w = uv' \pm u'v$ and $w' = u'v'$. (According to Theorem 4.5.2D, d_1 will be 1 about 61 percent of the time, if the denominators u' and v' are randomly distributed, so it is wise to single this case out separately.) If $d_1 > 1$, then let $t = u(v'/d_1) \pm v(u'/d_1)$ and calculate $d_2 = \gcd(t, d_1)$; finally the answer is $w = t/d_2$, $w' = (u'/d_1)(v'/d_2)$. (Exercise 6 proves that these values of w and w' are relatively prime to each other.) If single-precision

numbers are being used, this method requires only single-precision operations, except that t may be a double-precision number or slightly larger (see exercise 7); since $\gcd(t, d_1) = \gcd(t \bmod d_1, d_1)$, the calculation of d_2 does not require double precision.

For example, to compute $(7/66) + (17/12)$, we form $d_1 = \gcd(66, 12) = 6$; then $t = 7 \cdot 2 + 17 \cdot 11 = 201$, and $d_2 = \gcd(201, 6) = 3$, so the answer is

$$\frac{201}{3} \Big/ \frac{66}{6}\,\frac{12}{3} = 67/44.$$

To help check out subroutines for rational arithmetic, inversion of matrices with known inverses (e.g., Cauchy matrices, exercise 1.2.3–41) is suggested.

Experience with fractional calculations shows that in many cases the numbers grow to be quite large. So if u and u' are intended to be single-precision numbers for each fraction (u/u'), it is important to include tests for overflow in each of the addition, subtraction, multiplication, and division subroutines. For numerical problems in which perfect accuracy is important, a set of subroutines for fractional arithmetic with *arbitrary* precision allowed in numerator and denominator is very useful.

The methods of this section extend also to other number fields besides the rational numbers; for example, we could do arithmetic on quantities of the form $(u + u'\sqrt{5}\,)/u''$, where u, u', u'' are integers, $\gcd(u, u', u'') = 1$, and $u'' > 0$; or on quantities of the form $(u + u'\sqrt[3]{2} + u''\sqrt[3]{4}\,)/u'''$, etc.

Instead of insisting on exact calculations with fractions, it is interesting to consider also "fixed slash" and "floating slash" numbers, which are analogous to floating point numbers but based on rational fractions instead of radix-oriented fractions. In a binary fixed-slash scheme, the numerator and denominator of a representable fraction each consist of at most p bits, for some given p. In a floating-slash scheme, the *sum* of numerator bits plus denominator bits must be a total of at most q, for some given q, and another field of the representation is used to indicate how many of these q bits belong to the numerator. To do arithmetic on such numbers, we define $x \oplus y = \text{round}(x + y)$, $x \ominus y = \text{round}(x - y)$, etc., where $\text{round}(x) = x$ if x is representable, otherwise it is one of the two representable numbers that surround x.

It may seem at first that the best definition of $\text{round}(x)$ would be to choose the representable number that is closest to x, by analogy with the way we round in floating point arithmetic. But experience has shown that it is best to bias our rounding towards "simple" numbers, since numbers with small numerator and denominator occur much more often than complicated fractions do. We want more numbers to round to $\frac{1}{2}$ than to $\frac{127}{255}$. The rounding rule that turns out to be most successful in practice is called "mediant rounding": If (u/u') and (v/v') are adjacent representable numbers, so that whenever $u/u' \le x \le v/v'$ we must have $\text{round}(x)$ equal to (u/u') or (v/v'), the mediant rounding rule says that

$$\text{round}(x) = \frac{u}{u'} \text{ for } x < \frac{u+v}{u'+v'}, \quad \text{round}(x) = \frac{v}{v'} \text{ for } x > \frac{u+v}{u'+v'}. \qquad (1)$$

If $x = (u + v)/(u' + v')$ exactly, we let round(x) be the neighboring fraction with the smallest denominator (or, if $u' = v'$, with the smallest numerator).

For example, suppose we are doing fixed slash arithmetic with $p = 8$, so that the representable numbers (u/u') have $-128 < u < 128$ and $0 \le v < 256$ and $\gcd(u, u') = 1$. This isn't much precision, but it is enough to give us a feel for slash arithmetic. The numbers adjacent to $0 = (0/1)$ are $(-1/255)$ and $(1/255)$; according to the mediant rounding rule, we will therefore have round$(x) = 0$ if and only if $|x| \le 1/256$. Suppose we have a calculation that would take the overall form $\frac{22}{7} = \frac{314}{159} + \frac{1300}{1113}$ if we were working in exact rational arithmetic, but the intermediate quantities have had to be rounded to representable numbers. In this case $\frac{314}{159}$ would round to $(79/40)$ and $\frac{1300}{1113}$ would round to $(7/6)$. The sum $\frac{79}{40} + \frac{7}{6} = \frac{377}{120}$ rounds to $(22/7)$, so we have obtained the correct answer even though three roundings were required. This example was not specially contrived; when the answer to a problem is a simple fraction, slash arithmetic tends to make the intermediate rounding errors cancel out.

Exact representation of fractions within a computer was first discussed in the literature by P. Henrici, *JACM* **3** (1956), 6–9. Fixed and floating slash arithmetic was proposed by David W. Matula, in *Applications of Number Theory to Numerical Analysis*, ed. by S. K. Zaremba (New York: Academic Press, 1972), 486–489. Further developments of the idea are discussed by Matula and Kornerup in *Proc. IEEE Symp. Computer Arith.* **4** (1978), 29–47; *Lecture Notes in Comp. Sci.* **72** (1979), 383–397; *Computing*, Suppl. **2** (1980), 85–111.

EXERCISES

1. [*15*] Suggest a reasonable computational method for comparing two fractions, to test whether or not $(u/u') < (v/v')$.

2. [*M15*] Prove that if $d = \gcd(u, v)$ then u/d and v/d are relatively prime.

3. [*M20*] Prove that if u and u' are relatively prime, and if v and v' are relatively prime, then $\gcd(uv, u'v') = \gcd(u, v')\gcd(u', v)$.

4. [*11*] Design a division algorithm for fractions, analogous to the second multiplication method of the text. (Note that the sign of v must be considered.)

5. [*10*] Compute $(17/120) + (-27/70)$ by the method recommended in the text.

▶ **6.** [*M23*] Show that if u, u' are relatively prime and if v, v' are relatively prime, then $\gcd(uv' + vu', u'v') = d_1 d_2$, where $d_1 = \gcd(u', v')$ and $d_2 = \gcd(d_1, u(v'/d_1) + v(u'/d_1))$. (Hence if $d_1 = 1$, then $uv' + vu'$ is relatively prime to $u'v'$.)

7. [*M22*] How large can the absolute value of the quantity t become, in the addition-subtraction method recommended in the text, if the numerators and denominators of the inputs are less than N in absolute value?

▶ **8.** [*22*] Discuss using $(1/0)$ and $(-1/0)$ as representations for ∞ and $-\infty$, and/or as representations of overflow.

9. [*M23*] If $1 \le u', v' < 2^n$, show that $\lfloor 2^{2n} u/u' \rfloor = \lfloor 2^{2n} v/v' \rfloor$ implies $u/u' = v/v'$.

10. [*41*] Extend the subroutines suggested in exercise 4.3.1–34 so that they deal with "arbitrary" rational numbers.

11. [*M23*] Consider fractions of the form $(u+u'\sqrt{5})/u''$, where u, u', u'' are integers, $\gcd(u, u', u'') = 1$, and $u'' > 0$. Explain how to divide two such fractions and to obtain a quotient having the same form.

12. [*20*] (Matula and Kornerup.) Discuss the representation of floating slash numbers in a 32-bit word.

13. [*M23*] Explain how to compute the exact number of pairs of integers (u, u') such that $1 \le u \le M$ and $N_1 < u' \le N_2$ and $\gcd(u, u') = 1$. (This can be used to determine how many numbers are representable in slash arithmetic. According to Theorem 4.5.2D, the number will be approximately $(6/\pi^2)M(N_2 - N_1)$.)

14. [*42*] Modify one of the compilers at your installation so that it will replace all floating point calculations by floating slash calculations. Experiment with the use of slash arithmetic by running existing programs that were written by programmers who actually had floating point arithmetic in mind. (When special subroutines like square root or logarithm are called, your system should automatically convert slash numbers to floating point form before the subroutine is invoked, then back to slash form again afterwards. There should be a new option to print slash numbers in a fractional format; however, if you make no changes to a user's source program, you probably will have to print slash numbers in decimal notation, in order to keep from messing up any column alignments.) Are the results better or worse, when floating slash numbers are substituted?

4.5.2. The Greatest Common Divisor

If u and v are integers, not both zero, we say that their *greatest common divisor*, $\gcd(u, v)$, is the largest integer that evenly divides both u and v. This definition makes sense, because if $u \neq 0$ then no integer greater than $|u|$ can evenly divide u, but the integer 1 does divide both u and v; hence there must be a largest integer that divides them both. When u and v are both zero, every integer evenly divides zero, so the above definition does not apply; it is convenient to set

$$\gcd(0, 0) = 0. \tag{1}$$

The definitions just given obviously imply that

$$\gcd(u, v) = \gcd(v, u), \tag{2}$$

$$\gcd(u, v) = \gcd(-u, v), \tag{3}$$

$$\gcd(u, 0) = |u|. \tag{4}$$

In the previous section, we reduced the problem of expressing a rational number in "lowest terms" to the problem of finding the greatest common divisor of its numerator and denominator. Other applications of the greatest common divisor have been mentioned for example in Sections 3.2.1.2, 3.3.3, 4.3.2, 4.3.3. So the concept of $\gcd(u, v)$ is important and worthy of serious study.

The *least common multiple* of two integers u and v, written $\operatorname{lcm}(u, v)$, is a related idea that is also important. It is defined to be the smallest positive integer

that is a multiple of (i.e., evenly divisible by) both u and v; and $\operatorname{lcm}(0,0) = 0$. The classical method for teaching children how to add fractions $u/u' + v/v'$ is to train them to find the "least common denominator," which is $\operatorname{lcm}(u', v')$.

According to the "fundamental theorem of arithmetic" (proved in exercise 1.2.4–21), each positive integer u can be expressed in the form

$$u = 2^{u_2}3^{u_3}5^{u_5}7^{u_7}11^{u_{11}}\ldots = \prod_{p \text{ prime}} p^{u_p}, \tag{5}$$

where the exponents u_2, u_3, ... are uniquely determined nonnegative integers, and where all but a finite number of the exponents are zero. From this canonical factorization of a positive integer, it is easy to discover one way to compute the greatest common divisor of u and v: By (2), (3), and (4), we may assume that u and v are positive integers, and if both of them have been canonically factored into primes we have

$$\gcd(u,v) = \prod_{p \text{ prime}} p^{\min(u_p,v_p)}, \tag{6}$$

$$\operatorname{lcm}(u,v) = \prod_{p \text{ prime}} p^{\max(u_p,v_p)}. \tag{7}$$

Thus, for example, the greatest common divisor of $u = 7000 = 2^3 \cdot 5^3 \cdot 7$ and $v = 4400 = 2^4 \cdot 5^2 \cdot 11$ is $2^{\min(3,4)}\,5^{\min(3,2)}\,7^{\min(1,0)}\,11^{\min(0,1)} = 2^3 \cdot 5^2 = 200$. The least common multiple of the same two numbers is $2^4 \cdot 5^3 \cdot 7 \cdot 11 = 154000$.

From formulas (6) and (7) we can easily prove a number of basic identities concerning the gcd and the lcm:

$$\gcd(u,v)w = \gcd(uw,vw), \qquad \text{if } w \geq 0; \tag{8}$$

$$\operatorname{lcm}(u,v)w = \operatorname{lcm}(uw,vw), \qquad \text{if } w \geq 0; \tag{9}$$

$$u \cdot v = \gcd(u,v) \cdot \operatorname{lcm}(u,v), \qquad \text{if } u,v \geq 0; \tag{10}$$

$$\gcd\big(\operatorname{lcm}(u,v), \operatorname{lcm}(u,w)\big) = \operatorname{lcm}\big(u, \gcd(v,w)\big); \tag{11}$$

$$\operatorname{lcm}\big(\gcd(u,v), \gcd(u,w)\big) = \gcd\big(u, \operatorname{lcm}(v,w)\big). \tag{12}$$

The latter two formulas are "distributive laws" analogous to the familiar identity $uv + uw = u(v + w)$. Equation (10) reduces the calculation of $\gcd(u,v)$ to the calculation of $\operatorname{lcm}(u,v)$, and conversely.

Euclid's algorithm. Although Eq. (6) is useful for theoretical purposes, it is generally no help for calculating a greatest common divisor in practice, because it requires that we first determine the factorization of u and v. There is no known method for finding the prime factors of an integer very rapidly (see Section 4.5.4). But fortunately there is an efficient way to calculate the greatest common divisor of two integers without factoring them, and, in fact, such a method was discovered over 2250 years ago; this is "Euclid's algorithm," which we have already examined in Sections 1.1 and 1.2.1.

Euclid's algorithm is found in Book 7, Propositions 1 and 2 of his *Elements* (*c.* 300 B.C.), but it probably wasn't his own invention. Scholars believe that the method was known up to 200 years earlier, at least in its subtractive form, and it was almost certainly known to Eudoxus (*c.* 375 B.C.); cf. K. von Fritz, *Ann. Math.* (2) **46** (1945), 242–264. We might call it the granddaddy of all algorithms, because it is the oldest nontrivial algorithm that has survived to the present day. (The chief rival for this honor is perhaps the ancient Egyptian method for multiplication, which was based on doubling and adding, and which forms the basis for efficient calculation of nth powers as explained in Section 4.6.3. But the Egyptian manuscripts merely give examples that are not completely systematic, and these examples were certainly not stated systematically; the Egyptian method is therefore not quite deserving of the name "algorithm." Several ancient Babylonian methods, for doing such things as solving special sets of quadratic equations in two variables, are also known. Genuine algorithms are involved in this case, not just special solutions to the equations for certain input parameters; for even though the Babylonians invariably presented each method in conjunction with an example worked with particular input data, they regularly explained the general procedure in the accompanying text. [See D. E. Knuth, *CACM* **15** (1972), 671–677; **19** (1976), 108.] Many of these Babylonian algorithms predate Euclid by 1500 years, and they are the earliest known instances of written procedures for mathematics. But they do not have the stature of Euclid's algorithm, since they do not involve iteration and since they have been superseded by modern algebraic methods.)

In view of the importance of Euclid's algorithm, for historical as well as practical reasons, let us now consider how Euclid himself treated it. Paraphrasing his words into modern terminology, this is essentially what he wrote:

Proposition. *Given two positive integers, find their greatest common divisor.*

Let A, C be the two given positive integers; it is required to find their greatest common divisor. If C divides A, then C is a common divisor of C and A, since it also divides itself. And it clearly is in fact the greatest, since no greater number than C will divide C.

But if C does not divide A, then continually subtract the lesser of the numbers A, C from the greater, until some number is left that divides the previous one. This will eventually happen, for if unity is left, it will divide the previous number.

Now let E be the positive remainder of A divided by C; let F be the positive remainder of C divided by E; and let F be a divisor of E. Since F divides E and E divides $C - F$, F also divides $C - F$; but it also divides itself, so it divides C. And C divides $A - E$; therefore F also divides $A - E$. But it also divides E; therefore it divides A. Hence it is a common divisor of A and C.

I now claim that it is also the greatest. For if F is not the greatest common divisor of A and C, some larger number will divide them both. Let such a number be G.

Now since G divides C while C divides $A-E$, G divides $A-E$. G also divides the whole of A, so it divides the remainder E. But E divides $C - F$; therefore G also divides $C - F$. And G also divides the whole of C, so it divides the remainder F; that is, a greater number divides a smaller one. This is impossible.

Therefore no number greater than F will divide A and C, so F is their greatest common divisor.

Corollary. This argument makes it evident that any number dividing two numbers divides their greatest common divisor. *Q.E.D.*

Note. Euclid's statements have been simplified here in one nontrivial respect: Greek mathematicians did not regard unity as a "divisor" of another positive integer. Two positive integers were either both equal to unity, or they were relatively prime, or they had a greatest common divisor. In fact, unity was not even considered to be a "number," and zero was of course nonexistent. These rather awkward conventions made it necessary for Euclid to duplicate much of his discussion, and he gave two separate propositions that are each essentially like the one appearing here.

In his discussion, Euclid first suggests subtracting the smaller of the two current numbers from the larger, repeatedly, until we get two numbers where one is a multiple of the other. But in the proof he really relies on taking the remainder of one number divided by another; and since he has no simple concept of zero, he cannot speak of the remainder when one number divides the other. It is reasonable to say that he imagines each *division* (not the individual subtractions) as a single step of the algorithm, and hence an "authentic" rendition of his algorithm can be phrased as follows:

Algorithm E (*Original Euclidean algorithm*). Given two integers A and C greater than unity, this algorithm finds their greatest common divisor.

E1. [A divisible by C?] If C divides A, the algorithm terminates with C as the answer.

E2. [Replace A by remainder.] If $A \bmod C$ is equal to unity, the given numbers were relatively prime, so the algorithm terminates. Otherwise replace the pair of values (A, C) by $(C, A \bmod C)$ and return to step E1. ∎

The "proof" Euclid gave, which is quoted above, is especially interesting because it is not really a proof at all! He verifies the result of the algorithm only if step E1 is performed once or thrice. Surely he must have realized that step E1 could take place more than three times, although he made no mention of such a possibility. Not having the notion of a proof by mathematical induction, he could only give a proof for a finite number of cases. (In fact, he often proved only the case $n = 3$ of a theorem that he wanted to establish for general n.) Although Euclid is justly famous for the great advances he made in the art of logical deduction, techniques for giving valid proofs by induction were not discovered until many centuries later, and the crucial ideas for proving the validity of *algorithms* are only now becoming really clear. (See Section 1.2.1 for a complete proof of Euclid's algorithm, together with a short discussion of general proof procedures for algorithms.)

It is worth noting that this algorithm for finding the greatest common divisor was chosen by Euclid to be the very first step in his development of the theory of numbers. The same order of presentation is still in use today in modern

textbooks. Euclid also gave a method (Proposition 34) to find the least common multiple of two integers u and v, namely to divide u by $\gcd(u, v)$ and to multiply the result by v; this is equivalent to Eq. (10).

If we avoid Euclid's bias against the numbers 0 and 1, we can reformulate Algorithm E in the following way.

Algorithm A (*Modern Euclidean algorithm*). Given nonnegative integers u and v, this algorithm finds their greatest common divisor. (*Note:* The greatest common divisor of *arbitrary* integers u and v may be obtained by applying this algorithm to $|u|$ and $|v|$, because of Eqs. (2) and (3).)

A1. [$v = 0$?] If $v = 0$, the algorithm terminates with u as the answer.

A2. [Take $u \bmod v$.] Set $r \leftarrow u \bmod v$, $u \leftarrow v$, $v \leftarrow r$, and return to A1. (The operations of this step decrease the value of v, but they leave $\gcd(u, v)$ unchanged.) ∎

For example, we may calculate $\gcd(40902, 24140)$ as follows:

$$\begin{aligned}\gcd(40902, 24140) &= \gcd(24140, 16762) = \gcd(16762, 7378)\\ &= \gcd(7378, 2006) = \gcd(2006, 1360) = \gcd(1360, 646)\\ &= \gcd(646, 68) = \gcd(68, 34) = \gcd(34, 0) = 34.\end{aligned}$$

A proof that Algorithm A is valid follows readily from Eq. (4) and the fact that

$$\gcd(u, v) = \gcd(v, u - qv), \tag{13}$$

if q is any integer. Equation (13) holds because any common divisor of u and v is a divisor of both v and $u - qv$, and, conversely, any common divisor of v and $u - qv$ must divide both u and v.

The following MIX program illustrates the fact that Algorithm A can easily be implemented on a computer:

Program A (*Euclid's algorithm*). Assume that u and v are single-precision, nonnegative integers, stored respectively in locations U and V; this program puts $\gcd(u, v)$ into rA.

```
    LDX  U     1      rX ← u.
    JMP  2F    1
1H  STX  V     T      v ← rX.
    SRAX 5     T      rAX ← rA.
    DIV  V     T      rX ← rAX mod v.
2H  LDA  V     1+T    rA ← v.
    JXNZ 1B    1+T    Done if rX = 0.   ∎
```

The running time for this program is $19T + 6$ cycles, where T is the number of divisions performed. The discussion in Section 4.5.3 shows that we may take $T = 0.842766 \ln N + 0.06$ as an approximate average value, when u and v are independently and uniformly distributed in the range $1 \le u, v \le N$.

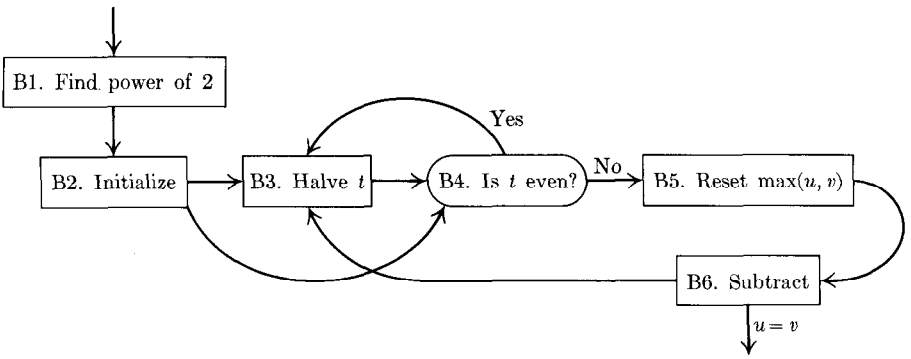

Fig. 9. Binary algorithm for the greatest common divisor.

A binary method. Since Euclid's patriarchal algorithm has been used for so many centuries, it is a rather surprising fact that it may not always be the best method for finding the greatest common divisor after all. A quite different gcd algorithm, which is primarily suited to binary arithmetic, was discovered by J. Stein in 1961 [see *J. Comp. Phys.* **1** (1967), 397–405]. This new algorithm requires no division instruction; it relies solely on the operations of (i) subtraction, (ii) testing whether a number is even or odd, and (iii) shifting the binary representation of an even number to the right (halving).

The binary gcd algorithm is based on four simple facts about positive integers u and v:

a) If u and v are both even, then $\gcd(u, v) = 2\gcd(u/2, v/2)$. [See Eq. (8).]
b) If u is even and v is odd, then $\gcd(u, v) = \gcd(u/2, v)$. [See Eq. (6).]
c) As in Euclid's algorithm, $\gcd(u, v) = \gcd(u - v, v)$. [See Eqs. (13), (2).]
d) If u and v are both odd, then $u - v$ is even, and $|u - v| < \max(u, v)$.

These facts immediately suggest the following algorithm:

Algorithm B (*Binary gcd algorithm*). Given positive integers u and v, this algorithm finds their greatest common divisor.

B1. [Find power of 2.] Set $k \leftarrow 0$, and then repeatedly set $k \leftarrow k + 1$, $u \leftarrow u/2$, $v \leftarrow v/2$, zero or more times until u and v are not both even.

B2. [Initialize.] (Now the original values of u and v have been divided by 2^k, and at least one of their present values is odd.) If u is odd, set $t \leftarrow -v$ and go to B4. Otherwise set $t \leftarrow u$.

B3. [Halve t.] (At this point, t is even, and nonzero.) Set $t \leftarrow t/2$.

B4. [Is t even?] If t is even, go back to B3.

B5. [Reset $\max(u, v)$.] If $t > 0$, set $u \leftarrow t$; otherwise set $v \leftarrow -t$. (The larger of u and v has been replaced by $|t|$, except perhaps during the first time this step is performed.)

B6. [Subtract.] Set $t \leftarrow u - v$. If $t \neq 0$, go back to B3. Otherwise the algorithm terminates with $u \cdot 2^k$ as the output. ∎

As an example of Algorithm B, let us consider $u = 40902$, $v = 24140$, the same numbers we have used to try out Euclid's algorithm. Step B1 sets $k \leftarrow 1$, $u \leftarrow 20451$, $v \leftarrow 12070$. Then t is set to -12070, and replaced by -6035; then v is replaced by 6035, and the computation proceeds as follows:

u	v	t
20451	6035	$+14416, +7208, +3604, +1802, +901;$
901	6035	$-5134, -2567;$
901	2567	$-1666, -833;$
901	833	$+68, +34, +17;$
17	833	$-816, -408, -204, -102, -51;$
17	51	$-34, -17;$
17	17	0.

The answer is $17 \cdot 2^1 = 34$. A few more iterations were necessary here than we needed with Algorithm A, but each iteration was somewhat simpler since no division steps were used.

A MIX program for Algorithm B requires just a little more code than for Algorithm A. In order to make such a program fairly typical of a binary computer's representation of Algorithm B, let us assume that MIX is extended to include the following operators:

• SLB (shift left AX binary). C = 6; F = 6.
The contents of registers A and X are "shifted left" M binary places; that is, $|\mathrm{rAX}| \leftarrow |2^M \mathrm{rAX}| \bmod B^{10}$, where B is the byte size. (As with all MIX shift commands, the signs of rA and rX are not affected.)

• SRB (shift right AX binary). C = 6; F = 7.
The contents of registers A and X are "shifted right" M binary places; that is, $|\mathrm{rAX}| \leftarrow \lfloor |\mathrm{rAX}|/2^M \rfloor$.

• JAE, JAO (jump A even, jump A odd). C = 40; F = 6, 7, respectively.
A JMP occurs if rA is even or odd, respectively.

• JXE, JXO (jump X even, jump X odd). C = 47; F = 6, 7, respectively.
Analogous to JAE, JAO.

Program B (*Binary gcd algorithm*). Assume that u and v are single-precision positive integers, stored respectively in locations U and V; this program uses Algorithm B to put $\gcd(u, v)$ into rA. Register assignments: $t \equiv$ rA, $k \equiv$ rI1.

```

The running time of this program is

$$9A + 2B + 6C + 3D + E + 13$$

units, where $A = k$, $B = 1$ if $t \leftarrow u$ in step B2 (otherwise $B = 0$), C is the number of subtraction steps, D is the number of halvings in step B3, and E is the number of times $t > 0$ in step B5. Calculations discussed later in this section imply that we may take $A = \frac{1}{3}$, $B = \frac{1}{3}$, $C = 0.71n - 0.5$, $D = 1.41n - 2.7$, $E = 0.35n - 0.4$ as average values for these quantities, assuming random inputs u and v in the range $1 \leq u, v < 2^n$. The total running time is therefore about $8.8n + 5$ cycles, compared to about $11.1n + 7$ for Program A under the same assumptions. The worst possible running time for u and v in this range occurs when $A = 0$, $B = 0$, $C = n$, $D = 2n - 2$, $E = 1$; this amounts to $12n + 8$ cycles. (The corresponding value for Program A is $26.8n + 19$.)

Thus the greater speed of the iterations in Program B, due to the simplicity of the operations, compensates for the greater number of iterations required. We have found that the binary algorithm is about 20 percent faster than Euclid's algorithm on the MIX computer. Of course, the situation may be different on other computers, and in any event both programs are quite efficient; but it appears that not even a procedure as venerable as Euclid's algorithm can withstand progress.

V. C. Harris [*Fibonacci Quarterly* 8 (1970), 102–103] has suggested an interesting cross between Euclid's algorithm and the binary algorithm. If u and v are odd, with $u \geq v > 0$, we can always write $u = qv \pm r$ where $0 \leq r < v$ and r is even; if $r \neq 0$ we set $r \leftarrow r/2$ until r is odd, then set $u \leftarrow v$, $v \leftarrow r$ and repeat the process. In subsequent iterations, $q \geq 3$.

Extensions. We can extend the methods used to calculate $\gcd(u, v)$ in order to solve some slightly more difficult problems. For example, assume that we want to compute the greatest common divisor of n integers $u_1, u_2, \ldots, u_n$.

One way to calculate $\gcd(u_1, u_2, \ldots, u_n)$, assuming that the u's are all nonnegative, is to extend Euclid's algorithm in the following way: If all u_j are zero,

the greatest common divisor is taken to be zero; otherwise if only one u_j is nonzero, it is the greatest common divisor; otherwise replace u_k by $u_k \bmod u_j$ for all $k \neq j$, where u_j is the minimum of the nonzero u's.

The algorithm sketched in the preceding paragraph is a natural generalization of Euclid's method, and it can be justified in a similar manner. But there is a simpler method available, based on the easily verified identity

$$\gcd(u_1, u_2, \ldots, u_n) = \gcd\bigl(u_1, \gcd(u_2, \ldots, u_n)\bigr). \tag{14}$$

To calculate $\gcd(u_1, u_2, \ldots, u_n)$, we may therefore proceed as follows:

C1. Set $d \leftarrow u_n$, $j \leftarrow n - 1$.

C2. If $d \neq 1$ and $j > 0$, set $d \leftarrow \gcd(u_j, d)$ and $j \leftarrow j - 1$ and repeat this step. Otherwise $d = \gcd(u_1, \ldots, u_n)$.

This method reduces the calculation of $\gcd(u_1, \ldots, u_n)$ to repeated calculations of the greatest common divisor of two numbers at a time. It makes use of the fact that $\gcd(u_1, \ldots, u_j, 1) = 1$; and this will be helpful, since we will already have $\gcd(u_{n-1}, u_n) = 1$ over 60 percent of the time if u_{n-1} and u_n are chosen at random. In most cases, the value of d will decrease rapidly during the first few stages of the calculation, and this will make the remainder of the computation quite fast. Here Euclid's algorithm has an advantage over Algorithm B, in that its running time is primarily governed by the value of $\min(u, v)$, while the running time for Algorithm B is primarily governed by $\max(u, v)$; it would be reasonable to perform one iteration of Euclid's algorithm, replacing u by $u \bmod v$ if u is much larger than v, and then to continue with Algorithm B.

The assertion that $\gcd(u_{n-1}, u_n)$ will be equal to unity more than 60 percent of the time for random inputs is a consequence of the following well-known result of number theory:

Theorem D (G. Lejeune Dirichlet, *Abhandlungen Königlich Preuß. Akad. Wiss.* (1849), 69–83). *If u and v are integers chosen at random, the probability that $\gcd(u, v) = 1$ is $6/\pi^2 \approx .60793$.*

A precise formulation of this theorem, which carefully defines what is meant by being "chosen at random," appears in exercise 10 with a rigorous proof. Let us content ourselves here with a heuristic argument that shows why the theorem is plausible.

If we assume, without proof, the existence of a well-defined probability p that $\gcd(u, v)$ equals unity, then we can determine the probability that $\gcd(u, v) = d$ for any positive integer d, because $\gcd(u, v) = d$ if and only if u is a multiple of d and v is a multiple of d and $\gcd(u/d, v/d) = 1$. Thus the probability that $\gcd(u, v) = d$ is equal to $1/d$ times $1/d$ times p, namely p/d^2. Now let us sum these probabilities over all possible values of d; we should get

$$1 = \sum_{d \geq 1} p/d^2 = p(1 + \frac{1}{4} + \frac{1}{9} + \frac{1}{16} + \cdots).$$

Since the sum $1 + \frac{1}{4} + \frac{1}{9} + \cdots = H_\infty^{(2)}$ is equal to $\pi^2/6$ (cf. Section 1.2.7), we need $p = 6/\pi^2$ in order to make this equation come out right. ∎

Euclid's algorithm can be extended in another important way: We can calculate integers u' and v' such that

$$uu' + vv' = \gcd(u, v) \tag{15}$$

at the same time $\gcd(u, v)$ is being calculated. This extension of Euclid's algorithm can be described conveniently in vector notation:

Algorithm X (*Extended Euclid's algorithm*). Given nonnegative integers u and v, this algorithm determines a vector (u_1, u_2, u_3) such that $uu_1 + vu_2 = u_3 = \gcd(u, v)$. The computation makes use of auxiliary vectors (v_1, v_2, v_3), (t_1, t_2, t_3); all vectors are manipulated in such a way that the relations

$$ut_1 + vt_2 = t_3, \qquad uu_1 + vu_2 = u_3, \qquad uv_1 + vv_2 = v_3 \tag{16}$$

hold throughout the calculation.

X1. [Initialize.] Set $(u_1, u_2, u_3) \leftarrow (1, 0, u)$, $(v_1, v_2, v_3) \leftarrow (0, 1, v)$.

X2. [Is $v_3 = 0$?] If $v_3 = 0$, the algorithm terminates.

X3. [Divide, subtract.] Set $q \leftarrow \lfloor u_3/v_3 \rfloor$, and then set

$$(t_1, t_2, t_3) \leftarrow (u_1, u_2, u_3) - (v_1, v_2, v_3)q,$$
$$(u_1, u_2, u_3) \leftarrow (v_1, v_2, v_3), \qquad (v_1, v_2, v_3) \leftarrow (t_1, t_2, t_3).$$

Return to step X2. ∎

For example, let $u = 40902$, $v = 24140$. At step X2 we have

q	u_1	u_2	u_3	v_1	v_2	v_3
—	1	0	40902	0	1	24140
1	0	1	24140	1	−1	16762
1	1	−1	16762	−1	2	7378
2	−1	2	7378	3	−5	2006
3	3	−5	2006	−10	17	1360
1	−10	17	1360	13	−22	646
2	13	−22	646	−36	61	68
9	−36	61	68	337	−571	34
2	337	−571	34	−710	1203	0

The solution is therefore $337 \cdot 40902 - 571 \cdot 24140 = 34 = \gcd(40902, 24140)$.

The validity of Algorithm X follows from (16) and the fact that the algorithm is identical to Algorithm A with respect to its manipulation of u_3 and v_3; a detailed proof of Algorithm X is discussed in Section 1.2.1. Gordon H. Bradley has observed that we can avoid a good deal of the calculation in Algorithm X by suppressing u_2, v_2, and t_2; then u_2 can be determined afterwards using the relation $uu_1 + vu_2 = u_3$.

Exercise 14 shows that the values of $|u_1|$, $|u_2|$, $|v_1|$, $|v_2|$ remain bounded by the size of the inputs u and v. Algorithm B, which computes the greatest common divisor using properties of binary notation, can be extended in a similar way; see exercise 35. For some instructive extensions to Algorithm X, see exercises 18 and 19 in Section 4.6.1.

The ideas underlying Euclid's algorithm can also be applied to find a *general solution in integers* of any set of linear equations with integer coefficients. For example, suppose that we want to find all integers w, x, y, z that satisfy the two equations

$$10w + 3x + 3y + 8z = 1, \tag{17}$$

$$6w - 7x \qquad - 5z = 2. \tag{18}$$

We can introduce a new variable

$$\lfloor 10/3 \rfloor w + \lfloor 3/3 \rfloor x + \lfloor 3/3 \rfloor y + \lfloor 8/3 \rfloor z = 3w + x + y + 2z = t_1,$$

and use it to eliminate y; Eq. (17) becomes

$$(10 \bmod 3)w + (3 \bmod 3)x + 3t_1 + (8 \bmod 3)z = w + 3t_1 + 2z = 1, \tag{19}$$

and Eq. (18) remains unchanged. The new equation (19) may be used to eliminate w, and (18) becomes

$$6(1 - 3t_1 - 2z) - 7x - 5z = 2;$$

that is,

$$7x + 18t_1 + 17z = 4. \tag{20}$$

Now as before we introduce a new variable

$$x + 2t_1 + 2z = t_2$$

and eliminate x from (20):

$$7t_2 + 4t_1 + 3z = 4. \tag{21}$$

Another new variable can be introduced in the same fashion, in order to eliminate the variable z, which has the smallest coefficient:

$$2t_2 + t_1 + z = t_3.$$

Eliminating z from (21) yields

$$t_2 + t_1 + 3t_3 = 4, \tag{22}$$

and this equation, finally, can be used to eliminate t_2. We are left with two independent variables, t_1 and t_3; substituting back for the original variables, we obtain the general solution

$$\begin{aligned} w &= 17 - 5t_1 - 14t_3, \\ x &= 20 - 5t_1 - 17t_3, \\ y &= -55 + 19t_1 + 45t_3, \\ z &= -8 + t_1 + 7t_3. \end{aligned} \tag{23}$$

In other words, all integer solutions (w, x, y, z) to the original equations (17), (18) are obtained from (23) by letting t_1 and t_3 independently run through all integers.

The general method that has just been illustrated is based on the following procedure: Find a nonzero coefficient c of smallest absolute value in the system of equations. Suppose that this coefficient appears in an equation having the form

$$cx_0 + c_1x_1 + \cdots + c_kx_k = d; \tag{24}$$

assume for simplicity that $c > 0$. If $c = 1$, use this equation to eliminate the variable x_0 from the other equations remaining in the system; then repeat the procedure on the remaining equations. (If no more equations remain, the computation stops, and a general solution in terms of the variables not yet eliminated has essentially been obtained.) If $c > 1$, then if $c_1 \bmod c = \cdots = c_k \bmod c = 0$ check that $d \bmod c = 0$, otherwise there is no integer solution; then divide both sides of (24) by c and eliminate x_0 as in the case $c = 1$. Finally, if $c > 1$ and not all of $c_1 \bmod c$, ..., $c_k \bmod c$ are zero, then introduce a new variable

$$\lfloor c/c \rfloor x_0 + \lfloor c_1/c \rfloor x_1 + \cdots + \lfloor c_k/c \rfloor x_k = t; \tag{25}$$

eliminate the variable x_0 from the other equations, in favor of t, and replace the original equation (24) by

$$ct + (c_1 \bmod c)x_1 + \cdots + (c_k \bmod c)x_k = d. \tag{26}$$

(Cf. (19) and (21) in the above example.)

This process must terminate, since each step reduces either the number of equations or the size of the smallest nonzero coefficient in the system. A study of the above procedure will reveal its intimate connection with Euclid's algorithm. The method is a comparatively simple means of solving linear equations when the variables are required to take on integer values only. It isn't the best available method for this problem, however; substantial refinements are possible, but beyond the scope of this book.

High-precision calculation. If u and v are very large integers, requiring a multiple-precision representation, the binary method (Algorithm B) is a simple and fairly efficient means of calculating their greatest common divisor, since it involves only subtractions and shifting.

By contrast, Euclid's algorithm seems much less attractive, since step A2 requires a multiple-precision division of u by v. But this difficulty is not really as bad as it seems, since we will prove in Section 4.5.3 that the quotient $\lfloor u/v \rfloor$ is almost always very small; for example, assuming random inputs, the quotient $\lfloor u/v \rfloor$ will be less than 1000 approximately 99.856 percent of the time. Therefore it is almost always possible to find $\lfloor u/v \rfloor$ and $(u \bmod v)$ using single-precision calculations, together with the comparatively simple operation of calculating $u - qv$ where q is a single-precision number. Furthermore, if it does turn out that u is much larger than v (e.g., the initial input data might have this form),

we don't really mind having a large quotient q, since Euclid's algorithm makes a great deal of progress when it replaces u by $u \bmod v$ in such a case.

A significant improvement in the speed of Euclid's algorithm when high-precision numbers are involved can be achieved by using a method due to D. H. Lehmer [*AMM* **45** (1938), 227–233]. Working only with the leading digits of large numbers, it is possible to do most of the calculations with single-precision arithmetic, and to make a substantial reduction in the number of multiple-precision operations involved. We save a lot of time by doing a "virtual" calculation instead of the actual one.

For example, let us consider the pair of eight-digit numbers $u = 27182818$, $v = 10000000$, assuming that we are using a machine with only four-digit words. Let $u' = 2718$, $v' = 1001$, $u'' = 2719$, $v'' = 1000$; then u'/v' and u''/v'' are approximations to u/v, with

$$u'/v' < u/v < u''/v''. \tag{27}$$

The ratio u/v determines the sequence of quotients obtained in Euclid's algorithm. If we carry out Euclid's algorithm simultaneously on the single-precision values (u', v') and (u'', v'') until we get a different quotient, it is not difficult to see that the same sequence of quotients would have appeared to this point if we had worked with the multiple-precision numbers (u, v). Thus, consider what happens when Euclid's algorithm is applied to (u', v') and to (u'', v''):

u'	v'	q'	u''	v''	q''
2718	1001	2	2719	1000	2
1001	716	1	1000	719	1
716	285	2	719	281	2
285	146	1	281	157	1
146	139	1	157	124	1
139	7	19	124	33	3

The first five quotients are the same in both cases, so they must be the true ones. But on the sixth step we find that $q' \neq q''$, so the single-precision calculations are suspended. We have gained the knowledge that the calculation would have proceeded as follows if we had been working with the original multiple-precision numbers:

u	v	q
u_0	v_0	2
v_0	$u_0 - 2v_0$	1
$u_0 - 2v_0$	$-u_0 + 3v_0$	2
$-u_0 + 3v_0$	$3u_0 - 8v_0$	1
$3u_0 - 8v_0$	$-4u_0 + 11v_0$	1
$-4u_0 + 11v_0$	$7u_0 - 19v_0$	?

(28)

(The next quotient lies somewhere between 3 and 19.) No matter how many digits are in u and v, the first five steps of Euclid's algorithm would be the same as (28),

so long as (27) holds. We can therefore avoid the multiple-precision operations of the first five steps, and replace them all by a multiple-precision calculation of $-4u_0 + 11v_0$ and $7u_0 - 19v_0$. In this case we obtain $u = 1268728$, $v = 279726$; the calculation can now proceed in a similar manner with $u' = 1268$, $v' = 280$, $u'' = 1269$, $v'' = 279$, etc. If we had a larger accumulator, more steps could be done by single-precision calculations; our example showed that only five cycles of Euclid's algorithm were combined into one multiple step, but with (say) a word size of 10 digits we could do about twelve cycles at a time. (Results proved in Section 4.5.3 imply that the number of multiple-precision cycles that can be replaced at each iteration is essentially proportional to the number of digits used in the single-precision calculations.)

Lehmer's method can be formulated as follows:

Algorithm L (*Euclid's algorithm for large numbers*). Let u, v be nonnegative integers, with $u \geq v$, represented in multiple precision. This algorithm computes the greatest common divisor of u and v, making use of auxiliary single-precision p-digit variables $\hat{u}$, $\hat{v}$, A, B, C, D, T, q, and auxiliary multiple-precision variables t and w.

L1. [Initialize.] If v is small enough to be represented as a single-precision value, calculate $\gcd(u, v)$ by Algorithm A and terminate the computation. Otherwise, let $\hat{u}$ be the p leading digits of u, and let $\hat{v}$ be the corresponding digits of v; in other words, if radix-b notation is being used, $\hat{u} \leftarrow \lfloor u/b^k \rfloor$ and $\hat{v} \leftarrow \lfloor v/b^k \rfloor$, where k is as small as possible consistent with the condition $\hat{u} < b^p$.

Set $A \leftarrow 1$, $B \leftarrow 0$, $C \leftarrow 0$, $D \leftarrow 1$. (These variables represent the coefficients in (28), where

$$u = Au_0 + Bv_0, \qquad v = Cu_0 + Dv_0, \tag{29}$$

in the equivalent actions of Algorithm A on multiple-precision numbers. We also have

$$u' = \hat{u} + B, \qquad v' = \hat{v} + D, \qquad u'' = \hat{u} + A, \qquad v'' = \hat{v} + C \tag{30}$$

in terms of the notation in the example worked above.)

L2. [Test quotient.] Set $q \leftarrow \lfloor (\hat{u} + A)/(\hat{v} + C) \rfloor$. If $q \neq \lfloor (\hat{u} + B)/(\hat{v} + D) \rfloor$, go to step L4. (This step tests if $q' \neq q''$, in the notation of the above example. Note that single-precision overflow can occur in special circumstances during the computation in this step, but only when $\hat{u} = b^p - 1$ and $A = 1$ or when $\hat{v} = b^p - 1$ and $D = 1$; the conditions

$$\begin{aligned} 0 \leq \hat{u} + A \leq b^p, \qquad & 0 \leq \hat{v} + C < b^p, \\ 0 \leq \hat{u} + B < b^p, \qquad & 0 \leq \hat{v} + D \leq b^p \end{aligned} \tag{31}$$

will always hold, because of (30). It is possible to have $\hat{v} + C = 0$ or $\hat{v} + D = 0$, but not both simultaneously; therefore division by zero in this step is taken to mean "Go directly to L4.")

L3. [Emulate Euclid.] Set $T \leftarrow A - qC$, $A \leftarrow C$, $C \leftarrow T$, $T \leftarrow B - qD$, $B \leftarrow D$, $D \leftarrow T$, $T \leftarrow \hat{u} - q\hat{v}$, $\hat{u} \leftarrow \hat{v}$, $\hat{v} \leftarrow T$, and go back to step L2. (These single-precision calculations are the equivalent of multiple-precision operations, as in (28), under the conventions of (29).)

L4. [Multiprecision step.] If $B = 0$, set $t \leftarrow u \bmod v$, $u \leftarrow v$, $v \leftarrow t$, using multiple-precision division. (This happens only if the single-precision operations cannot simulate any of the multiple-precision ones. It implies that Euclid's algorithm requires a very large quotient, and this is an extremely rare occurrence.) Otherwise, set $t \leftarrow Au$, $t \leftarrow t + Bv$, $w \leftarrow Cu$, $w \leftarrow w + Dv$, $u \leftarrow t$, $v \leftarrow w$ (using straightforward multiple-precision operations). Go back to step L1. ∎

The values of A, B, C, D remain as single-precision numbers throughout this calculation, because of (31).

Algorithm L requires a somewhat more complicated program than Algorithm B, but with large numbers it will be faster on many computers. The binary technique of Algorithm B can, however, be speeded up in a similar way (see exercise 34), to the point where it continues to win. Algorithm L has the advantage that it can readily be extended, as in Algorithm X (see exercise 17); furthermore, it determines the sequence of quotients obtained in Euclid's algorithm, and this yields the regular continued fraction expansion of a real number (see exercise 4.5.3–18).

Analysis of the binary algorithm. Let us conclude this section by studying the running time of Algorithm B, in order to justify the formulas stated earlier.

An exact determination of the behavior of Algorithm B appears to be exceedingly difficult to derive, but we can begin to study it by means of an approximate model of its behavior. Suppose that u and v are odd numbers, with $u > v$ and

$$\lfloor \lg u \rfloor = m, \qquad \lfloor \lg v \rfloor = n. \tag{32}$$

(Thus, u is an $(m+1)$-bit number, and v is an $(n+1)$-bit number.) Algorithm B forms $u - v$ and shifts this quantity right until obtaining an odd number u' that replaces u. Under random conditions, we would expect to have $u' = (u - v)/2$ about one-half of the time, $u' = (u - v)/4$ about one-fourth of the time, $u' = (u - v)/8$ about one-eighth of the time, and so on. We have

$$\lfloor \lg u' \rfloor = m - k - r, \tag{33}$$

where k is the number of places that $u - v$ is shifted right, and where r is $\lfloor \lg u \rfloor - \lfloor \lg(u - v) \rfloor$, the number of bits lost at the left during the subtraction of v from u. Note that $r \leq 1$ when $m \geq n + 2$, and $r \geq 1$ when $m = n$. For simplicity, we will assume that $r = 0$ when $m \neq n$ and that $r = 1$ when $m = n$, although this lower bound tends to make u' seem larger than it usually is.

The approximate model we shall use to study Algorithm B is based solely on the values $m = \lfloor \lg u \rfloor$ and $n = \lfloor \lg v \rfloor$ throughout the course of the algorithm,

not on the actual values of u and v. Let us call this approximation a *lattice-point model*, since we will say that we are "at the point (m, n)" when $\lfloor \lg u \rfloor = m$ and $\lfloor \lg v \rfloor = n$. From point (m, n) the algorithm takes us to (m', n) if $u > v$, or to (m, n') if $u < v$, or terminates if $u = v$. For example, the calculation starting with $u = 20451$ and $v = 6035$ begins at the point $(14, 12)$, then goes to $(9, 12)$, $(9, 11)$, $(9, 9)$, $(4, 9)$, $(4, 5)$, $(4, 4)$, and terminates. In line with the comments of the preceding paragraph, we will make the following assumptions about the probability that we reach a given point just after point (m, n):

Case 1, $m > n$.

Next point	Probability
$(m-1, n)$	$\frac{1}{2}$
$(m-2, n)$	$\frac{1}{4}$
$\ldots$	$\ldots$
$(1, n)$	$(\frac{1}{2})^{m-1}$
$(0, n)$	$(\frac{1}{2})^{m-1}$

Case 2, $m < n$.

Next point	Probability
$(m, n-1)$	$\frac{1}{2}$
$(m, n-2)$	$\frac{1}{4}$
$\ldots$	$\ldots$
$(m, 1)$	$(\frac{1}{2})^{n-1}$
$(m, 0)$	$(\frac{1}{2})^{n-1}$

Case 3, $m = n > 0$.

Next point	Probability
$(m-2, n)$, $(m, n-2)$	$\frac{1}{4}$, $\frac{1}{4}$
$(m-3, n)$, $(m, n-3)$	$\frac{1}{8}$, $\frac{1}{8}$
$\ldots$	$\ldots$
$(0, n)$, $(m, 0)$	$(\frac{1}{2})^m$, $(\frac{1}{2})^m$
terminate	$(\frac{1}{2})^{m-1}$

For example, from points $(5, 3)$ the lattice-point model would go to points $(4, 3)$, $(3, 3)$, $(2, 3)$, $(1, 3)$, $(0, 3)$ with the respective probabilities $\frac{1}{2}$, $\frac{1}{4}$, $\frac{1}{8}$, $\frac{1}{16}$, $\frac{1}{16}$; from $(4, 4)$ it would go to $(2, 4)$, $(1, 4)$, $(0, 4)$, $(4, 2)$, $(4, 1)$, $(4, 0)$, or would terminate, with the respective probabilities $\frac{1}{4}$, $\frac{1}{8}$, $\frac{1}{16}$, $\frac{1}{4}$, $\frac{1}{8}$, $\frac{1}{16}$, $\frac{1}{8}$. When m and n are both 0, the formulas above do not apply; the algorithm always terminates in such a case, since $m = n = 0$ implies that $u = v = 1$.

The detailed calculations of exercise 18 show that this lattice-point model is somewhat pessimistic. In fact, when $m > 3$ the actual probability that Algorithm B goes from (m, m) to one of the two points $(m-2, m)$ or $(m, m-2)$ is equal to $\frac{1}{8}$, although we have assumed the value $\frac{1}{2}$; the algorithm actually goes from (m, m) to $(m-3, m)$ or $(m, m-3)$ with probability $\frac{7}{32}$, not $\frac{1}{4}$; and it actually goes from $(m+1, m)$ to (m, m) with probability $\frac{1}{8}$, not $\frac{1}{2}$. The probabilities in the model are nearly correct when $|m - n|$ is large, but when $|m - n|$ is small the model predicts slower convergence than is actually obtained. In spite of the fact that our model is not a completely faithful representation of Algorithm B, it has one great virtue: It can be completely analyzed! Furthermore, empirical experiments with Algorithm B show that the behavior predicted by the lattice-point model is analogous to the true behavior.

An analysis of the lattice-point model can be carried out by solving the following rather complicated set of double recurrence relations:

$$\begin{aligned} A_{mm} &= a + \frac{1}{2}A_{m(m-2)} + \cdots + \frac{1}{2^{m-1}}A_{m0} + \frac{b}{2^{m-1}}, && \text{if } m \geq 1; \\ A_{mn} &= c + \frac{1}{2}A_{(m-1)n} + \cdots + \frac{1}{2^{m-1}}A_{1n} + \frac{1}{2^{m-1}}A_{0n}, && \text{if } m > n \geq 0; \\ A_{mn} &= A_{nm}, && \text{if } n > m \geq 0. \end{aligned} \tag{34}$$

The problem is to solve for A_{mn} in terms of m, n, and the parameters a, b, c, and A_{00}. This is an interesting set of recurrence equations, which have an interesting solution.

First we observe that if $0 \leq n < m$,

$$\begin{aligned} A_{(m+1)n} &= c + \sum_{1\leq k\leq m} 2^{-k}A_{(m+1-k)n} + 2^{-m}A_{0n} \\ &= c + \tfrac{1}{2}A_{mn} + \sum_{1\leq k<m} 2^{-k-1}A_{(m-k)n} + 2^{-m}A_{0n} \\ &= c + \tfrac{1}{2}A_{mn} + \tfrac{1}{2}(A_{mn} - c) \\ &= \tfrac{1}{2}c + A_{mn}. \end{aligned}$$

Hence $A_{(m+k)n} = \frac{1}{2}ck + A_{mn}$, by induction on k. In particular, since $A_{10} = c + A_{00}$, we have

$$A_{m0} = \tfrac{1}{2}c(m+1) + A_{00}, \qquad m > 0. \tag{35}$$

Now let $A_m = A_{mm}$. If $m > 0$, we have

$$\begin{aligned} A_{(m+1)m} &= c + \sum_{1\leq k\leq m+1} 2^{-k}A_{(m+1-k)m} + 2^{-m-1}A_{0m} \\ &= c + \tfrac{1}{2}A_{mm} + \sum_{1\leq k\leq m} \big(2^{-k-1}(A_{(m-k)(m+1)} - c/2)\big) + 2^{-m-1}A_{0m} \\ &= c + \tfrac{1}{2}A_m + \tfrac{1}{2}(A_{(m+1)(m+1)} - a - 2^{-m}b) - \tfrac{1}{4}c(1-2^{-m}) \\ &\qquad + 2^{-m-1}\big(\tfrac{1}{2}c(m+1) + A_{00}\big) \\ &= \tfrac{1}{2}(A_m + A_{m+1}) + \tfrac{3}{4}c - \tfrac{1}{2}a + 2^{-m-1}(c - b + A_{00}) + m2^{-m-2}c. \end{aligned} \tag{36}$$

Similar maneuvering, as shown in exercise 19, establishes the relation

$$A_{n+1} = \tfrac{3}{4}A_n + \tfrac{1}{4}A_{n-1} + \alpha + 2^{-n-1}\beta + (n+2)2^{-n-1}\gamma, \quad n \geq 2, \tag{37}$$

where $\alpha = \frac{1}{4}a + \frac{7}{8}c$, $\beta = A_{00} - b - \frac{3}{2}c$, and $\gamma = \frac{1}{2}c$.

Thus the double recurrence (34) can be transformed into the single recurrence relation in (37). Use of the generating function $G(z) = A_0 + A_1 z + A_2 z^2 + \cdots$ now transforms (37) into the equation

$$(1 - \tfrac{3}{4}z - \tfrac{1}{4}z^2)G(z) = a_0 + a_1 z + a_2 z^2 + \frac{\alpha}{1-z} + \frac{\beta}{1-z/2} + \frac{\gamma}{(1-z/2)^2}, \quad (38)$$

where a_0, a_1, and a_2 are constants that can be determined by the values of A_0, A_1, and A_2. Since $1 - \frac{3}{4}z + \frac{1}{4}z^2 = (1 + \frac{1}{4}z)(1 - z)$, we can express $G(z)$ by the method of partial fractions in the form

$$G(z) = b_0 + b_1 z + \frac{b_2}{(1-z)^2} + \frac{b_3}{1-z} + \frac{b_4}{(1-z/2)^2} + \frac{b_5}{1-z/2} + \frac{b_6}{1+z/4}.$$

Tedious manipulations produce the values of these constants $b_0, \ldots, b_6$, and thus the coefficients of $G(z)$ are determined. We finally obtain the solution

$$\begin{aligned} A_{nn} &= n(\tfrac{1}{5}a + \tfrac{7}{10}c) + (\tfrac{16}{25}a + \tfrac{2}{5}b - \tfrac{23}{50}c + \tfrac{3}{5}A_{00}) \\ &\quad + 2^{-n}(-\tfrac{1}{3}cn + \tfrac{2}{3}b - \tfrac{1}{9}c - \tfrac{2}{3}A_{00}) \\ &\quad + (-\tfrac{1}{4})^n(-\tfrac{16}{25}a - \tfrac{16}{15}b + \tfrac{16}{225}c + \tfrac{16}{15}A_{00}) + \tfrac{1}{2}c\delta_{n0}; \\ A_{mn} &= \tfrac{1}{2}mc + n(\tfrac{1}{5}a + \tfrac{1}{5}c) + (\tfrac{6}{25}a + \tfrac{2}{5}b + \tfrac{7}{50}c + \tfrac{3}{5}A_{00}) + 2^{-n}(\tfrac{1}{3}c) \\ &\quad + (-\tfrac{1}{4})^n(-\tfrac{6}{25}a - \tfrac{2}{5}b + \tfrac{2}{75}c + \tfrac{2}{5}A_{00}), \qquad m > n. \end{aligned} \quad (39)$$

With these elaborate calculations done, we can readily determine the behavior of the lattice-point model. Assume that the inputs u and v to the algorithm are odd, and let $m = \lfloor \lg u \rfloor$, $n = \lfloor \lg v \rfloor$. The average number of subtraction cycles, namely the quantity C in the analysis of Program B, is obtained by setting $a = 1$, $b = 0$, $c = 1$, $A_{00} = 1$ in the recurrence (34). By (39) we see that (for $m \geq n$) the lattice model predicts

$$C = \tfrac{1}{2}m + \tfrac{2}{5}n + \tfrac{49}{50} - \tfrac{1}{5}\delta_{mn} \quad (40)$$

subtraction cycles, plus terms that rapidly go to zero as n approaches infinity.

The average number of times that $\gcd(u, v) = 1$ is obtained by setting $a = b = c = 0$, $A_{00} = 1$; this gives the probability that u and v are relatively prime, approximately $\frac{3}{5}$. Actually, since u and v are assumed to be odd, they should be relatively prime with probability $8/\pi^2$ (see exercise 13), so this reflects the degree of inaccuracy of the lattice-point model.

The average number of times that a path from (m, n) goes through one of the "diagonal" points (m', m') for some $m' \geq 1$ is obtained by setting $a = 1$, $b = c = A_{00} = 0$ in (34); so we find that this quantity is approximately

$$\tfrac{1}{5}n + \tfrac{6}{25} + \tfrac{2}{5}\delta_{mn}, \qquad \text{when } m \geq n.$$

Now we can determine the average number of shifts, i.e., the number of times that step B3 is performed. (This is the quantity D in Program B.) In any

Table 1

NUMBER OF SUBTRACTIONS IN ALGORITHM B

	n						n						
	0	1	2	3	4	5	0	1	2	3	4	5	
0	1.00	2.00	2.50	3.00	3.50	4.00	1.00	2.00	2.50	3.00	3.50	4.00	0
1	2.00	1.00	2.50	3.00	3.50	4.00	2.00	1.00	3.00	2.75	3.63	3.94	1
2	2.50	2.50	2.25	3.38	3.88	4.38	2.50	3.00	2.00	3.50	3.88	4.25	2
3	3.00	3.00	3.38	3.25	4.22	4.72	3.00	2.75	3.50	2.88	4.13	4.34	3
4	3.50	3.50	3.88	4.22	4.25	5.10	3.50	3.63	3.88	4.13	3.94	4.80	4
5	4.00	4.00	4.38	4.72	5.10	5.19	4.00	3.94	4.25	4.34	4.80	4.60	5
m	Predicted by model						Actual average values						m

execution of Algorithm B, with u and v both odd, the corresponding path in the lattice model must satisfy the relation

$$\text{number of shifts} + \text{number of diagonal points} + 2\lfloor \lg \gcd(u,v) \rfloor = m + n,$$

since we are assuming that r in (33) is always either 0 or 1. The average value of $\lfloor \lg \gcd(u,v) \rfloor$ predicted by the lattice-point model is approximately $\frac{4}{5}$ (see exercise 20). Therefore we have, for the total number of shifts,

$$\begin{aligned} D &= m + n - (\tfrac{1}{5}n + \tfrac{6}{25} + \tfrac{2}{5}\delta_{mn}) - \tfrac{4}{5} \\ &= m + \tfrac{4}{5}n - \tfrac{46}{25} - \tfrac{2}{5}\delta_{mn}, \end{aligned} \tag{41}$$

when $m \geq n$, plus terms that decrease rapidly to zero for large n.

To summarize the most important facts we have derived from the lattice-point model, we have shown that if u and v are odd and if $\lfloor \lg u \rfloor = m$, $\lfloor \lg v \rfloor = n$, then the quantities C and D that are the critical factors in the running time of Program B will have average values given by

$$C = \tfrac{1}{2}m + \tfrac{2}{5}n + O(1), \qquad D = m + \tfrac{4}{5}n + O(1), \qquad m \geq n. \tag{42}$$

But the model that we have used to derive (42) is only a pessimistic approximation to the true behavior; Table 1 compares the true average values of C, computed by actually running Algorithm B with all possible inputs, to the values predicted by the lattice-point model, for small m and n. The lattice model is completely accurate when m or n is zero, but it tends to be less accurate when $|m - n|$ is small and $\min(m,n)$ is large. When $m = n = 9$, the lattice-point model gives $C = 8.78$, compared to the true value $C = 7.58$.

Empirical tests of Algorithm B with several million random inputs and with various values of m, n in the range $29 \leq m, n \leq 37$ indicate that the actual average behavior of the algorithm is given by

$$\begin{aligned} C &\approx \tfrac{1}{2}m + 0.203n + 1.9 - 0.4(0.6)^{m-n}, \\ D &\approx \quad m + 0.41n \quad - 0.5 - 0.7(0.6)^{m-n}, \end{aligned} \qquad m \geq n. \tag{43}$$

These experiments showed a rather small standard deviation from the observed average values. The coefficients $\frac{1}{2}$ and 1 of m in (42) and (43) can be verified rigorously without using the lattice-point approximation (see exercise 21); so the error in the lattice-point model is apparently in the coefficient of n, which is too high.

The above calculations have been made under the assumption that u and v are odd and in the ranges $2^m \le u < 2^{m+1}$ and $2^n \le v < 2^{n+1}$. If we assume instead that u and v are to be *any* integers, independently and uniformly distributed over the ranges

$$1 \le u < 2^N, \qquad 1 \le v < 2^N,$$

then we can calculate the average values of C and D from the data already given; in fact, if C_{mn} denotes the average value of C under our earlier assumptions, exercise 22 shows that we have

$$\begin{aligned}(2^N-1)^2C = N^2C_{00} &+ 2N\sum_{1\le n\le N}(N-n)2^{n-1}C_{n0}\\ &+ 2\sum_{1\le n<m\le N}(N-m)(N-n)2^{m+n-2}C_{mn}\\ &+ \sum_{1\le n\le N}(N-n)^2 2^{2n-2}C_{nn}.\end{aligned} \tag{44}$$

The same formula holds for D in terms of D_{mn}. If the indicated sums are carried out using the approximations in (43), we obtain

$$C \approx 0.70N + O(1), \qquad D \approx 1.41N + O(1).$$

(See exercise 23.) This agrees perfectly with the results of further empirical tests, made on several million random inputs for $N \le 30$; the latter tests show that we may take

$$C = 0.70N - 0.5, \qquad D = 1.41N - 2.7 \tag{45}$$

as good estimates of the values, given this distribution of the inputs u and v.

Richard Brent has discovered a continuous model that accounts for the leading terms in (45). Let us assume that u and v are large, and that the number of shifts per iteration has the value d with probability exactly 2^{-d}. If we let $X = u/v$, the effect of steps B3–B5 is to replace X by $(X-1)/2^d$ if $X > 1$, or by $2^d/(X^{-1}-1)$ if $X < 1$. The random variable X has a limiting distribution that makes it possible to analyze the average value of the ratio by which $\max(u, v)$ decreases at each iteration; see exercise 25. Numerical calculations show that this maximum decreases by $\beta = 0.705971246102$ bits per iteration; the agreement with experiment is so good that Brent's constant β must be the true value of the number "0.70" in (45), and we should replace 0.203 by 0.206 in (43). [See *Algorithms and Complexity*, ed. by J. F. Traub (New York: Academic Press, 1976), 321–355.]

This completes our analysis of the average values of C and D. The other three quantities appearing in the running time of Algorithm B are rather easily analyzed; see exercises 6, 7, and 8.

Thus we know approximately how Algorithm B behaves on the average. Let us now consider a "worst case" analysis: What values of u and v are in some sense the hardest to handle? If we assume as before that

$$\lfloor \lg u \rfloor = m \qquad \text{and} \qquad \lfloor \lg v \rfloor = n,$$

let us try to find (u, v) that make the algorithm run most slowly. In view of the fact that the subtractions take somewhat longer than the shifts, when the auxiliary bookkeeping is considered, this question may be rephrased by asking for the inputs u and v that require most subtractions. The answer is somewhat surprising; the maximum value of C is exactly

$$\max(m, n) + 1, \tag{46}$$

although the lattice-point model would predict that substantially higher values of C are possible (see exercise 26). The derivation of the worst case (46) is quite interesting, so it has been left as an amusing problem for the reader to work out by himself (see exercises 27 and 28).

EXERCISES

1. [*M21*] How can (8), (9), (10), (11), and (12) be derived easily from (6) and (7)?

2. [*M22*] Given that u divides $v_1 v_2 \ldots v_n$, prove that u divides

$$\gcd(u, v_1)\gcd(u, v_2)\ldots\gcd(u, v_n).$$

3. [*M23*] Show that the number of ordered pairs of positive integers (u, v) such that $\operatorname{lcm}(u, v) = n$ is the number of divisors of n^2.

4. [*M21*] Given positive integers u and v, show that there are divisors u' of u and v' of v such that $\gcd(u', v') = 1$ and $u'v' = \operatorname{lcm}(u, v)$.

▶ **5.** [*M26*] Invent an algorithm (analogous to Algorithm B) for calculating the greatest common divisor of two integers based on their *balanced ternary* representation. Demonstrate your algorithm by applying it to the calculation of $\gcd(40902, 24140)$.

6. [*M22*] Given that u and v are random positive integers, find the mean and the standard deviation of the quantity A that enters into the timing of Program B. (This is the number of right shifts applied to both u and v during the preparatory phase.)

7. [*M20*] Analyze the quantity B that enters into the timing of Program B.

▶ **8.** [*M25*] Show that in Program B, the average value of E is approximately equal to $\frac{1}{2}C_{\text{ave}}$, where C_{ave} is the average value of C.

9. [*18*] Using Algorithm B and hand calculation, find $\gcd(31408, 2718)$. Also find integers m and n such that $31408m + 2718n = \gcd(31408, 2718)$, using Algorithm X.

▶ **10.** [*HM24*] Let q_n be the number of ordered pairs of integers (u, v) lying in the range $1 \le u, v \le n$ such that $\gcd(u, v) = 1$. The object of this exercise is to prove that we have $\lim_{n\to\infty} q_n/n^2 = 6/\pi^2$, thereby establishing Theorem D.

a) Use the principle of inclusion and exclusion (Section 1.3.3) to show that

$$q_n = n^2 - \sum_{p_1} \lfloor n/p_1 \rfloor^2 + \sum_{p_1 < p_2} \lfloor n/p_1 p_2 \rfloor^2 - \cdots,$$

where the sums are taken over all *prime* numbers p_i.

b) The *Möbius function* $\mu(n)$ is defined by the rules $\mu(1) = 1$, $\mu(p_1 p_2 \ldots p_r) = (-1)^r$ if $p_1, p_2, \ldots, p_r$ are distinct primes, and $\mu(n) = 0$ if n is divisible by the square of a prime. Show that $q_n = \sum_{k\ge 1} \mu(k)\lfloor n/k \rfloor^2$.

c) As a consequence of (b), prove that $\lim_{n\to\infty} q_n/n^2 = \sum_{k\ge 1} \mu(k)/k^2$.

d) Prove that $(\sum_{k\ge 1} \mu(k)/k^2)(\sum_{m\ge 1} 1/m^2) = 1$. *Hint:* When the series are absolutely convergent we have

$$\Big(\sum_{k\ge 1} a_k/k^z\Big)\Big(\sum_{m\ge 1} b_m/m^z\Big) = \sum_{n\ge 1}\Big(\sum_{d\backslash n} a_d b_{n/d}\Big)\Big/ n^z.$$

11. [*M22*] What is the probability that $\gcd(u, v) \le 3$? (See Theorem D.) What is the *average* value of $\gcd(u, v)$?

12. [*M24*] (E. Cesàro.) If u and v are random positive integers, what is the average number of (positive) divisors they have in common? [*Hint:* See the identity in exercise 10(d), with $a_k = b_m = 1$.]

13. [*HM23*] Given that u and v are random *odd* positive integers, show that they are relatively prime with probability $8/\pi^2$.

14. [*M26*] What are the values of v_1 and v_2 when Algorithm X terminates?

▶ **15.** [*M22*] Design an algorithm to *divide u by v modulo m*, given positive integers u, v, and m, with v relatively prime to m. In other words, your algorithm should find w, in the range $0 \le w < m$, such that $u \equiv vw$ (modulo m).

16. [*21*] Use the text's method to find a general solution in integers to the following sets of equations:

a) $3x + 7y + 11z = 1$
$5x + 7y - 5z = 3$

b) $3x + 7y + 11z = 1$
$5x + 7y - 5z = -3$

▶ **17.** [*M24*] Show how Algorithm L can be extended (as Algorithm A was extended to Algorithm X) to obtain solutions of (15) when u and v are large.

18. [*M37*] Let u and v be odd integers, independently and uniformly distributed in the ranges $2^m \le u < 2^{m+1}$, $2^n \le v < 2^{n+1}$. What is the *exact* probability that a single "subtract and shift" cycle in Algorithm B, namely an operation that starts at step B6 and then stops after step B5 is finished, reduces u and v to the ranges $2^{m'} \le u < 2^{m'+1}$, $2^{n'} \le v < 2^{n'+1}$, as a function of m, n, m', and n'? (This exercise gives more accurate values for the transition probabilities than the text's model does.)

19. [*M24*] Complete the text's derivation of (38) by establishing (37).

20. [*M26*] Let $\lambda = \lfloor \lg \gcd(u, v) \rfloor$. Show that the lattice-point model gives $\lambda = 1$ with probability $\frac{1}{5}$, $\lambda = 2$ with probability $\frac{1}{10}$, $\lambda = 3$ with probability $\frac{1}{20}$, etc., plus correction terms that go rapidly to zero as u and v approach infinity; hence the average value of λ is approximately $\frac{4}{5}$. [*Hint:* Consider the relation between the probability of a path from (m, n) to $(k + 1, k + 1)$ and a corresponding path from $(m - k, n - k)$ to $(1, 1)$.]

21. [*HM26*] Let C_{mn} and D_{mn} be the average number of subtraction and shift cycles, respectively, in Algorithm B, when u and v are odd, $\lfloor \lg u \rfloor = m$, $\lfloor \lg v \rfloor = n$. Show that for fixed n, $C_{mn} = \frac{1}{2}m + O(1)$ and $D_{mn} = m + O(1)$ as $m \to \infty$.

22. [*23*] Prove Eq. (44).

23. [*M28*] Show that if $C_{mn} = \alpha m + \beta n + \gamma$ for some constants α, β, and γ, then

$$\sum_{1 \le n \le m \le N} (N - m)(N - n)2^{m+n-2} C_{mn} = 2^{2N}\left(\tfrac{11}{27}(\alpha + \beta)N + O(1)\right),$$

$$\sum_{1 \le n \le N} (N - n)^2 2^{2n-2} C_{nn} = 2^{2N}\left(\tfrac{5}{27}(\alpha + \beta)N + O(1)\right).$$

▶ **24.** [*M30*] If $v = 1$ but u is large, during Algorithm B, it may take fairly long for the algorithm to determine that $\gcd(u, v) = 1$. Perhaps it would be worthwhile to add a test at the beginning of step B5: "If $t = 1$, the algorithm terminates with 2^k as the answer." Explore the question of whether or not this would be an improvement when the algorithm deals with random inputs, by determining the average number of times that step B6 is executed with $u = 1$ or $v = 1$, using the lattice-point model.

▶ **25.** [*M26*] (R. P. Brent.) Let u_n and v_n be the values of u and v after n iterations of steps B3–B5; let $X_n = u_n/v_n$, and assume that $F_n(x)$ is the probability that $X_n \le x$, for $0 \le x < \infty$. (a) Express $F_{n+1}(x)$ in terms of $F_n(x)$, under the assumption that step B4 always branches to B3 with independent probability $\frac{1}{2}$. (b) Let $G_n(x) = F_n(x) + 1 - F_n(x^{-1})$ be the probability that $Y_n \le x$, for $0 \le x \le 1$, where $Y_n = \min(u_n, v_n)/\max(u_n, v_n)$. Express G_{n+1} in terms of G_n. (c) Express the distribution $H_n(x) =$ probability that $\max(u_{n+1}, v_{n+1})/\max(u_n, v_n) < x$ in terms of G_n.

26. [*M23*] What is the length of the longest path from (m, n) to $(0, 0)$ in the lattice-point model?

▶ **27.** [*M28*] Given $m \ge n \ge 1$, find values of u, v with $\lfloor \lg u \rfloor = m$, $\lfloor \lg v \rfloor = n$ such that Algorithm B requires $m + 1$ subtraction steps.

28. [*M37*] Prove that the subtraction step B6 of Algorithm B is never executed more than $1 + \lfloor \lg \max(u, v) \rfloor$ times.

29. [*M30*] Evaluate the determinant

$$\begin{vmatrix} \gcd(1,1) & \gcd(1,2) & \ldots & \gcd(1,n) \\ \gcd(2,1) & \gcd(2,2) & \ldots & \gcd(2,n) \\ \vdots & \vdots & & \vdots \\ \gcd(n,1) & \gcd(n,2) & \ldots & \gcd(n,n) \end{vmatrix}.$$

30. [*M25*] Show that Euclid's algorithm (Algorithm A) applied to two n-bit binary numbers requires $O(n^2)$ units of time, as $n \to \infty$. (The same upper bound obviously holds for Algorithm B.)

31. [*M22*] Use Euclid's algorithm to find a simple formula for $\gcd(2^m - 1, 2^n - 1)$ when m and n are nonnegative integers.

32. [*M43*] Can the upper bound $O(n^2)$ in exercise 30 be decreased, if another algorithm for calculating the greatest common divisor is used?

33. [*M46*] Analyze V. C. Harris's "binary Euclidean algorithm."

▶ **34.** [*M32*] (R. W. Gosper.) Demonstrate how to modify Algorithm B for large numbers, using ideas analogous to those in Algorithm L.

▶ **35.** [*M28*] (V. R. Pratt.) Extend Algorithm B to an Algorithm Y that is analogous to Algorithm X.

36. [*HM49*] Find a rigorous proof that Brent's model describes the asymptotic behavior of Algorithm B.

*4.5.3. Analysis of Euclid's Algorithm

The execution time of Euclid's algorithm depends on T, the number of times the division step A2 is performed. (See Algorithm 4.5.2A and Program 4.5.2A.) The quantity T is also an important factor in the running time of other algorithms, such as the evaluation of functions satisfying a reciprocity formula (see Section 3.3.3). We shall see in this section that the mathematical analysis of this quantity T is interesting and instructive.

Relation to continued fractions. Euclid's algorithm is intimately connected with *continued fractions*, which are expressions of the form

$$\cfrac{b_1}{a_1+\cfrac{b_2}{a_2+\cfrac{b_3}{\ddots\,\cfrac{}{a_{n-1}+\cfrac{b_n}{a_n}}}}} = b_1/(a_1+b_2/(a_2+b_3/(\cdots/(a_{n-1}+b_n/a_n)\ldots))). \tag{1}$$

Continued fractions have a beautiful theory that is the subject of several books. [See, for example, O. Perron, *Die Lehre von den Kettenbrüchen*, 3rd ed. (Stuttgart: Teubner, 1954), 2 vols.; A. Khinchin, *Continued Fractions*, tr. by Peter Wynn (Groningen: P. Noordhoff, 1963); H. S. Wall, *Analytic Theory of Continued Fractions* (New York: Van Nostrand, 1948); and see also J. Tropfke, *Geschichte der Elementar-Mathematik* **6** (Berlin: Gruyter, 1924), 74–84, for the early history of the subject.] It is necessary to limit ourselves to a comparatively brief treatment of the theory here, studying only those aspects that give us more insight into the behavior of Euclid's algorithm.

The continued fractions of primary interest to us are those in which all of the b's in (1) are equal to unity. For convenience in notation, let us define

$$/x_1, x_2, \ldots, x_n/ = 1/(x_1 + 1/(x_2 + 1/(\cdots(x_{n-1} + 1/x_n)\ldots))). \tag{2}$$

Thus, for example,

$$/x_1/ = \frac{1}{x_1}, \qquad /x_1, x_2/ = \frac{1}{x_1 + 1/x_2} = \frac{x_2}{x_1 x_2 + 1}. \tag{3}$$

If $n = 0$, the symbol $/x_1, \ldots, x_n/$ is taken to mean 0. Let us also define the polynomials $Q_n(x_1, x_2, \ldots, x_n)$ of n variables, for $n \geq 0$, by the rule

$$Q_n(x_1, x_2, \ldots, x_n) = \begin{cases} 1, & \text{if } n = 0; \\ x_1, & \text{if } n = 1; \\ x_1 Q_{n-1}(x_2, \ldots, x_n) + Q_{n-2}(x_3, \ldots, x_n), & \text{if } n > 1. \end{cases} \tag{4}$$

Thus $Q_2(x_1, x_2) = x_1 x_2 + 1, Q_3(x_1, x_2, x_3) = x_1 x_2 x_3 + x_1 + x_3$, etc. In general, as noted by L. Euler in the eighteenth century, $Q_n(x_1, x_2, \ldots, x_n)$ is the sum of all terms obtainable by starting with $x_1 x_2 \ldots x_n$ and deleting zero or more non-overlapping pairs of consecutive variables $x_j x_{j+1}$; there are F_{n+1} such terms. The polynomials defined in (4) are called "continuants."

The basic property of the Q-polynomials is that

$$/x_1, x_2, \ldots, x_n/ = Q_{n-1}(x_2, \ldots, x_n)/Q_n(x_1, x_2, \ldots, x_n), \qquad n \geq 1. \tag{5}$$

This can be proved by induction, since it implies that

$$x_0 + /x_1, \ldots, x_n/ = Q_{n+1}(x_0, x_1, \ldots, x_n)/Q_n(x_1, \ldots, x_n);$$

hence $/x_0, x_1, \ldots, x_n/$ is the reciprocal of the latter quantity.

The Q-polynomials are symmetrical in the sense that

$$Q_n(x_1, x_2, \ldots, x_n) = Q_n(x_n, \ldots, x_2, x_1). \tag{6}$$

This follows from Euler's observation above, and as a consequence we have

$$Q_n(x_1, \ldots, x_n) = x_n Q_{n-1}(x_1, \ldots, x_{n-1}) + Q_{n-2}(x_1, \ldots, x_{n-2}) \tag{7}$$

for $n > 1$. The Q-polynomials also satisfy the important identity

$$Q_n(x_1, \ldots, x_n) Q_n(x_2, \ldots, x_{n+1}) - Q_{n+1}(x_1, \ldots, x_{n+1}) Q_{n-1}(x_2, \ldots, x_n) = (-1)^n, \qquad n \geq 1. \tag{8}$$

(See exercise 4.) The latter equation in connection with (5) implies that

$$/x_1, \ldots, x_n/ = \frac{1}{q_0 q_1} - \frac{1}{q_1 q_2} + \frac{1}{q_2 q_3} - \cdots + \frac{(-1)^{n-1}}{q_{n-1} q_n}, \quad \text{where } q_k = Q_k(x_1, \ldots, x_k). \tag{9}$$

Thus the Q-polynomials are intimately related to continued fractions.

Every real number X in the range $0 \le X < 1$ has a *regular continued fraction* defined as follows: Let $X_0 = X$, and for all $n \ge 0$ such that $X_n \neq 0$ let

$$A_{n+1} = \lfloor 1/X_n \rfloor, \qquad X_{n+1} = 1/X_n - A_{n+1}. \tag{10}$$

If $X_n = 0$, the quantities A_{n+1} and X_{n+1} are not defined, and the regular continued fraction for X is $/A_1, \ldots, A_n/$. If $X_n \neq 0$, this definition guarantees that $0 \le X_{n+1} < 1$, so each of the A's is a positive integer. The definition (10) clearly implies that

$$X = X_0 = \cfrac{1}{A_1 + X_1} = \cfrac{1}{A_1 + 1/(A_2 + X_2)} = \cdots;$$

hence

$$X = /A_1, \ldots, A_{n-1}, A_n + X_n/ \tag{11}$$

for all $n \ge 1$, whenever X_n is defined. In particular, we have $X = /A_1, \ldots, A_n/$ when $X_n = 0$. If $X_n \neq 0$, the number X always lies *between* $/A_1, \ldots, A_n/$ and $/A_1, \ldots, A_n + 1/$, since by (7) the quantity $q_n = Q_n(A_1, \ldots, A_n + X_n)$ increases monotonically from $Q_n(A_1, \ldots, A_n)$ up to $Q_n(A_1, \ldots, A_n + 1)$ as X_n increases from 0 to 1, and by (9) the continued fraction increases or decreases when q_n increases, according as n is even or odd. In fact,

$$\begin{aligned}
|X - /A_1, \ldots, A_n/| &= |/A_1, \ldots, A_n + X_n/ - /A_1, \ldots, A_n/| \\
&= |/A_1, \ldots, A_n, 1/X_n/ - /A_1, \ldots, A_n/| \\
&= \left| \frac{Q_n(A_2, \ldots, A_n, 1/X_n)}{Q_{n+1}(A_1, \ldots, A_n, 1/X_n)} - \frac{Q_{n-1}(A_2, \ldots, A_n)}{Q_n(A_1, \ldots, A_n)} \right| \\
&= 1/(Q_n(A_1, \ldots, A_n) Q_{n+1}(A_1, \ldots, A_n, 1/X_n)) \\
&\le 1/(Q_n(A_1, \ldots, A_n) Q_{n+1}(A_1, \ldots, A_n, A_{n+1})) \qquad (12)
\end{aligned}$$

by (5), (7), (8), and (10). Therefore $/A_1, \ldots, A_n/$ is an extremely close approximation to X, unless n is small. If X is irrational, it is impossible to have $X_n = 0$ for any n, so the regular continued fraction expansion in this case is an *infinite continued fraction* $/A_1, A_2, A_3, \ldots/$. The value of an infinite continued fraction is defined to be

$$\lim_{n \to \infty} /A_1, A_2, \ldots, A_n/,$$

and from the inequality (12) it is clear that this limit equals X.

The regular continued fraction expansion of real numbers has several properties analogous to the representation of numbers in the decimal system. If we use the formulas above to compute the regular continued fraction expansions of

some familiar real numbers, we find, for example, that

$$\begin{aligned}
\tfrac{8}{29} &= /3,1,1,1,2/;\\
\sqrt{\tfrac{8}{29}} &= /1,1,9,2,2,3,2,2,9,1,2,1,9,2,2,3,2,2,9,1,2,1,9,2,2,3,2,2,9,1,\ldots/;\\
\sqrt[3]{2} &= 1+/3,1,5,1,1,4,1,1,8,1,14,1,10,2,1,4,12,2,3,2,1,3,4,1,1,2,14,3,\ldots/;\\
\pi &= 3+/7,15,1,292,1,1,1,2,1,3,1,14,2,1,1,2,2,2,2,1,84,2,1,1,15,3,13,\ldots/;\\
e &= 2+/1,2,1,1,4,1,1,6,1,1,8,1,1,10,1,1,12,1,1,14,1,1,16,1,1,18,1,\ldots/;\\
\gamma &= /1,1,2,1,2,1,4,3,13,5,1,1,8,1,2,4,1,1,40,1,11,3,7,1,7,1,1,5,\ldots/;\\
\phi &= 1+/1,1,1,1,1,1,1,1,1,\ldots/. \qquad (13)
\end{aligned}$$

The numbers $A_1, A_2, \ldots$ are called the *partial quotients* of X. Note the regular pattern that appears in the partial quotients for $\sqrt{8/29}$, ϕ, and e; the reasons for this behavior are discussed in exercises 12 and 16. There is no apparent pattern in the partial quotients for $\sqrt[3]{2}$, π, or γ.

It is interesting to note that the ancient Greeks' first definition of real numbers, once they had discovered the existence of irrationals, was essentially stated in terms of infinite continued fractions. (Later they adopted the suggestion of Eudoxus that $x = y$ should be defined instead as "$x < r$ if and only if $y < r$, for all rational r.") See O. Becker, *Quellen und Studien zur Geschichte Math., Astron., Physik* (B) **2** (1933), 311–333.

When X is a rational number, the regular continued fraction corresponds in a natural way to Euclid's algorithm. Let us assume that $X = v/u$, where $u > v \geq 0$. The regular continued fraction process starts with $X_0 = X$; let us define $U_0 = u$, $V_0 = v$. Assuming that $X_n = V_n/U_n \neq 0$, (10) becomes

$$\begin{aligned}
A_{n+1} &= \lfloor U_n/V_n \rfloor,\\
X_{n+1} &= U_n/V_n - A_{n+1} = (U_n \bmod V_n)/V_n.
\end{aligned} \qquad (14)$$

Therefore, if we define

$$U_{n+1} = V_n, \qquad V_{n+1} = U_n \bmod V_n, \qquad (15)$$

the condition $X_n = V_n/U_n$ holds throughout the process. Furthermore, (15) is precisely the transformation made on the variables u and v in Euclid's algorithm (see Algorithm 4.5.2A, step A2). For example, since $\frac{8}{29} = /3,1,1,1,2/$, we know that Euclid's algorithm applied to $u = 29$ and $v = 8$ will require exactly five division steps, and the quotients $\lfloor u/v \rfloor$ in step A2 will be successively 3, 1, 1, 1, and 2. Note that the last partial quotient A_n must be 2 or more when $X_n = 0$ and $n \geq 1$, since X_{n-1} is less than unity.

From this correspondence with Euclid's algorithm we can see that the regular continued fraction for X terminates at some step with $X_n = 0$ if and only if X is rational; for it is obvious that X_n cannot be zero if X is irrational, and, conversely, we know that Euclid's algorithm always terminates. If the partial quotients obtained during Euclid's algorithm are $A_1, A_2, \ldots, A_n$, then we have,

by (5),

$$\frac{v}{u} = \frac{Q_{n-1}(A_2, \ldots, A_n)}{Q_n(A_1, A_2, \ldots, A_n)}. \tag{16}$$

This formula holds also if Euclid's algorithm is applied for $u < v$, when $A_1 = 0$. Furthermore, because of (8), $Q_{n-1}(A_2, \ldots, A_n)$ and $Q_n(A_1, A_2, \ldots, A_n)$ are relatively prime, and the fraction on the right-hand side of (16) is in lowest terms; therefore

$$u = Q_n(A_1, A_2, \ldots, A_n)d, \qquad v = Q_{n-1}(A_2, \ldots, A_n)d, \tag{17}$$

where $d = \gcd(u, v)$.

The worst case. We can now apply these observations to determine the behavior of Euclid's algorithm in the "worst case," or in other words to give an upper bound on the number of division steps. The worst case occurs when the inputs are consecutive Fibonacci numbers:

Theorem F (G. Lamé, 1845). *For $n \geq 1$, let u and v be integers with $u > v > 0$ such that Euclid's algorithm applied to u and v requires exactly n division steps, and such that u is as small as possible satisfying these conditions. Then $u = F_{n+2}$ and $v = F_{n+1}$.*

Proof. By (17), we must have $u = Q_n(A_1, A_2, \ldots, A_n)d$, where A_1, A_2, $\ldots$, A_n, and d are positive integers and $A_n \geq 2$. Since Q_n is a polynomial with nonnegative coefficients, involving all of the variables, the minimum value is achieved only when $A_1 = 1$, $\ldots$, $A_{n-1} = 1$, $A_n = 2$, $d = 1$. Putting these values in (17) yields the desired result. ∎

(This theorem has the historical claim of being the first practical application of the Fibonacci sequence; since then many other applications of Fibonacci numbers to algorithms and to the study of algorithms have been discovered.)

As a consequence of Theorem F we have an important corollary:

Corollary L. *If $0 \leq u, v < N$, the number of division steps required when Algorithm 4.5.2A is applied to u and v is at most $\lceil \log_\phi(\sqrt{5}\,N) \rceil - 2$.*

Proof. By Theorem F, the maximum number of steps, n, occurs when $u = F_n$ and $v = F_{n+1}$, where n is as large as possible with $F_{n+1} < N$. (The first division step in this case merely interchanges u and v when $n > 1$.) Since $F_{n+1} < N$, we have $\phi^{n+1}/\sqrt{5} < N$ (see Eq. 1.2.8–15), so $n + 1 < \log_\phi(\sqrt{5}\,N)$. This completes the proof. ∎

Note that $\log_\phi(\sqrt{5}\,N)$ is approximately $2.078 \ln N + 1.672 \approx 4.785 \log_{10} N + 1.672$. See exercises 31 and 36 for extensions of Theorem F.

An approximate model. Now that we know the maximum number of division steps that can occur, let us attempt to find the *average* number. Let $T(m,n)$ be the number of division steps that occur when $u = m$ and $v = n$ are input to Euclid's algorithm. Thus

$$T(m,0) = 0; \qquad T(m,n) = 1 + T(n, m \bmod n) \qquad \text{if } n \geq 1. \tag{18}$$

Let T_n be the average number of division steps when $v = n$ and when u is chosen at random; since only the value of $u \bmod v$ affects the algorithm after the first division step, we may write

$$T_n = \frac{1}{n} \sum_{0 \leq k < n} T(k,n). \tag{19}$$

For example, $T(0,5) = 1$, $T(1,5) = 2$, $T(2,5) = 3$, $T(3,5) = 4$, $T(4,5) = 3$, so

$$T_5 = \tfrac{1}{5}(1+2+3+4+3) = 2\tfrac{3}{5}.$$

In order to estimate T_n for large n, let us first try an approximation suggested by R. W. Floyd: We might assume that, for $0 \leq k < n$, the value of n is essentially "random" modulo k, so that we can set

$$T_n \approx 1 + \frac{1}{n}(T_0 + T_1 + \cdots + T_{n-1}).$$

Then $T_n \approx S_n$, where the sequence $\langle S_n \rangle$ is the solution to the recurrence relation

$$S_0 = 0, \qquad S_n = 1 + \frac{1}{n}(S_0 + S_1 + \cdots + S_{n-1}), \qquad n \geq 1. \tag{20}$$

(This approximation is analogous to the "lattice-point model" used to investigate Algorithm B in Section 4.5.2.)

The recurrence (20) is readily solved by the use of generating functions. A more direct way to solve it, analogous to our solution of the lattice-point model, is by noting that

$$\begin{aligned} S_{n+1} &= 1 + \frac{1}{n+1}(S_0 + S_1 + \cdots + S_{n-1} + S_n) \\ &= 1 + \frac{1}{n+1}\big(n(S_n - 1) + S_n\big) = S_n + \frac{1}{n+1}; \end{aligned}$$

hence S_n is $1 + \frac{1}{2} + \cdots + \frac{1}{n} = H_n$, a harmonic number. The approximation $T_n \approx S_n$ now suggests that $T_n \approx \ln n + O(1)$.

Comparison of this approximation with tables of the true value of T_n show, however, that $\ln n$ is too large; T_n does not grow this fast. One way to account for the fact that this approximation is too pessimistic is to observe that the average

value of $n \bmod k$ is less than the average value of $\frac{1}{2}k$, in the range $1 \le k \le n$:

$$\begin{aligned}\frac{1}{n}\sum_{1\le k\le n}(n \bmod k) &= \frac{1}{n}\sum_{\substack{1\le q\le n\\ \lfloor n/(q+1)\rfloor < k \le \lfloor n/q\rfloor}}(n - qk)\\ &= n - \frac{1}{n}\sum_{1\le q\le n} q\left(\binom{\lfloor n/q\rfloor+1}{2} - \binom{\lfloor n/(q+1)\rfloor+1}{2}\right)\\ &= n - \frac{1}{n}\sum_{1\le q\le n}\binom{\lfloor n/q\rfloor+1}{2}\\ &= \left(1-\frac{\pi^2}{12}\right)n + O(\log n) \qquad (21)\end{aligned}$$

(cf. exercise 4.5.2–10(c)). This is only about $.1775n$, not $.25n$; so the value of $n \bmod k$ tends to be smaller than the above model predicts, and Euclid's algorithm works faster than we might expect.

A continuous model. The behavior of Euclid's algorithm with $v = N$ is essentially determined by the behavior of the regular continued fraction process when $X = 0/N,\ 1/N,\ \ldots,\ (N-1)/N$. Assuming that N is very large, we are led naturally to a study of regular continued fractions when X is a random real number uniformly distributed in $[0, 1)$. Therefore let us define the distribution function

$$F_n(x) = \text{probability that } X_n \le x, \qquad \text{for } 0 \le x \le 1, \qquad (22)$$

given a uniform distribution of $X = X_0$. By the definition of regular continued fractions, we have $F_0(x) = x$, and

$$\begin{aligned}F_{n+1}(x) &= \sum_{k\ge 1}\text{probability that } (k \le 1/X_n \le k + x)\\ &= \sum_{k\ge 1}\text{probability that } \big(1/(k+x) \le X_n \le 1/k\big)\\ &= \sum_{k\ge 1}\big(F_n(1/k) - F_n\big(1/(k+x)\big)\big). \qquad (23)\end{aligned}$$

If the distributions $F_0(x), F_1(x), \ldots$ defined by these formulas approach a limiting distribution $F_\infty(x) = F(x)$, we will have

$$F(x) = \sum_{k\ge 1}\big(F(1/k) - F\big(1/(k+x)\big)\big). \qquad (24)$$

One function that satisfies this relation is $F(x) = \log_b(1+x)$, for any base $b > 1$; see exercise 19. The further condition $F(1) = 1$ implies that we should take $b = 2$. Thus it is reasonable to make a guess that $F(x) = \lg(1+x)$, and that $F_n(x)$ approaches this behavior.

We might conjecture, for example, that $F(\frac{1}{2}) = \lg(\frac{3}{2}) \approx 0.58496$; let us see how close $F_n(\frac{1}{2})$ comes to this value for small n. We have $F_0(\frac{1}{2}) = \frac{1}{2}$, and

$$\begin{aligned}
F_1(\tfrac{1}{2}) &= \frac{1}{1} - \frac{1}{1+\frac{1}{2}} + \frac{1}{2} - \frac{1}{2+\frac{1}{2}} + \cdots \\
&= 2\left(\frac{1}{2} - \frac{1}{3} + \frac{1}{4} - \frac{1}{5} + \cdots\right) = 2(1 - \ln 2) \approx 0.6137; \\
F_2(\tfrac{1}{2}) &= \sum_{m\ge 1} \frac{2}{m}\left(\frac{1}{2m+2} - \frac{1}{3m+2} + \frac{1}{4m+2} - \frac{1}{5m+2} + \cdots\right) \\
&= \sum_{m\ge 1} \frac{2}{m^2}\left(\frac{1}{2} - \frac{1}{3} + \frac{1}{4} - \cdots\right) \\
&\quad - \sum_{m\ge 1} \frac{4}{m}\left(\frac{1}{2m(2m+2)} - \frac{1}{3m(3m+2)} + \cdots\right) \\
&= \frac{1}{3}\pi^2(1 - \ln 2) - \sum_{m\ge 1} \frac{4S_m}{m^2},
\end{aligned}$$

where $S_m = 1/(4m+4) - 1/(9m+6) + 1/(16m+8) - \cdots$. Using the values of H_x for fractional x found in Table 3 of Appendix B, we find that

$$S_1 = \tfrac{1}{12}, \qquad S_2 = \tfrac{3}{4} - \ln 2, \qquad S_3 = \tfrac{19}{20} - \pi/(2\sqrt{3}),$$

etc.; a numerical evaluation yields $F_2(\frac{1}{2}) \approx 0.5748$. Although $F_1(x) = H_x$, it is clear that $F_n(x)$ is difficult to calculate exactly when n is large.

The distributions $F_n(x)$ were first studied by K. F. Gauss, who thought of the problem in 1800. His notebook for that year lists various recurrence relations and gives a brief table of values, including the four-place value for $F_2(\frac{1}{2})$ that has just been mentioned. After performing these calculations, Gauss wrote, "*Tam complicatæ evadunt, ut nulla spes superesse videatur,*" i.e., "They come out so complicated that no hope appears to be left." Twelve years later, Gauss wrote a letter to Laplace in which he posed the problem as one he could not resolve to his satisfaction. He said, "I found by very simple reasoning that, for n infinite, $F_n(x) = \log(1+x)/\log 2$. But the efforts that I made since then in my inquiries to assign $F_n(x) - \log(1+x)/\log 2$ for very large but not infinite values of n were fruitless." He never published his "very simple reasoning," and it is not completely clear that he had found a rigorous proof. More than 100 years went by before a proof was finally published, by R. O. Kuz'min [*Atti del Congresso internazionale dei matematici* **6** (Bologna, 1928), 83–89], who showed that

$$F_n(x) = \lg(1+x) + O(e^{-A\sqrt{n}})$$

for some positive constant A. The error term was improved to $O(e^{-An})$ by Paul Lévy shortly afterward [*Bull. Soc. Math. de France* **57** (1929), 178–194]*; but

*An exposition of Lévy's interesting proof appeared in the first edition of this book.

Gauss's problem, namely to find the asymptotic behavior of $F_n(x) - \lg(1+x)$, was not really resolved until 1974, when Eduard Wirsing published a beautiful analysis of the situation [*Acta Arithmetica* **24** (1974), 507–528]. We shall study the simplest aspects of Wirsing's approach here, since his method is an instructive use of linear operators.

If G is any function of x defined for $0 \le x \le 1$, let SG be the function defined by

$$SG(x) = \sum_{k\ge 1}\left(G\Big(\frac{1}{k}\Big) - G\Big(\frac{1}{k+x}\Big)\right). \tag{25}$$

Thus, S is an operator that changes one function into another. In particular, by (23) we have $F_{n+1}(x) = SF_n(x)$, hence

$$F_n = S^n F_0. \tag{26}$$

(In this discussion F_n stands for a distribution function, *not* for a Fibonacci number.) Note that S is a "linear operator"; i.e., $S(cG) = c(SG)$ for all constants c, and $S(G_1 + G_2) = SG_1 + SG_2$.

Now if G has a bounded first derivative, we can differentiate (25) term by term to show that

$$(SG)'(x) = \sum_{k\ge 1} \frac{1}{(k+x)^2} G'\Big(\frac{1}{k+x}\Big); \tag{27}$$

hence SG also has a bounded first derivative. (Term-by-term differentiation of a convergent series is justified when the series of derivatives is uniformly convergent; cf. K. Knopp, *Theory and Application of Infinite series* (Glasgow: Blackie, 1951), §47.)

Let $H = SG$, and let $g(x) = (1+x)G'(x)$, $h(x) = (1+x)H'(x)$. It follows that

$$\begin{aligned} h(x) &= \sum_{k\ge 1} \frac{1+x}{(k+x)^2}\left(1+\frac{1}{k+x}\right)^{-1} g\Big(\frac{1}{k+x}\Big) \\ &= \sum_{k\ge 1}\left(\frac{k}{k+1+x} - \frac{k-1}{k+x}\right) g\Big(\frac{1}{k+x}\Big). \end{aligned}$$

In other words, $h = Tg$, where T is the linear operator defined by

$$Tg(x) = \sum_{k\ge 1}\left(\frac{k}{k+1+x} - \frac{k-1}{k+x}\right) g\Big(\frac{1}{k+x}\Big). \tag{28}$$

Continuing, we see that if g has a bounded first derivative, we can differentiate term by term to show that Tg does also:

$$\begin{aligned}(Tg)'(x) &= -\sum_{k\ge1}\biggl(\Bigl(\frac{k}{(k+1+x)^2}-\frac{k-1}{(k+x)^2}\Bigr)g\Bigl(\frac{1}{k+x}\Bigr)\\ &\qquad+\Bigl(\frac{k}{k+1+x}-\frac{k-1}{k+x}\Bigr)\frac{1}{(k+x)^2}g'\Bigl(\frac{1}{k+x}\Bigr)\biggr)\\ &= -\sum_{k\ge1}\biggl(\frac{k}{(k+1+x)^2}\Bigl(g\Bigl(\frac{1}{k+x}\Bigr)-g\Bigl(\frac{1}{k+1+x}\Bigr)\Bigr)\\ &\qquad+\frac{1+x}{(k+x)^3(k+1+x)}g'\Bigl(\frac{1}{k+x}\Bigr)\biggr).\end{aligned}$$

There is consequently a third linear operator, U, such that $(Tg)' = -U(g')$, namely

$$U\varphi(x) = \sum_{k\ge1}\biggl(\frac{k}{(k+1+x)^2}\int_{1/(k+1+x)}^{1/(k+x)}\varphi(t)\,dt + \frac{1+x}{(k+x)^3(k+1+x)}\varphi\Bigl(\frac{1}{k+x}\Bigr)\biggr). \tag{29}$$

What is the relevance of all this to our problem? Well, if we set

$$F_n(x) = \lg(1+x) + R_n\bigl(\lg(1+x)\bigr), \tag{30}$$

$$f_n(x) = (1+x)F_n'(x) = \frac{1}{\ln 2}\bigl(1+R_n'\bigl(\lg(1+x)\bigr)\bigr), \tag{31}$$

we have

$$f_n'(x) = R_n''\bigl(\lg(1+x)\bigr)/\bigl((\ln 2)^2(1+x)\bigr); \tag{32}$$

the effect of the $\lg(1+x)$ term disappears, after these transformations. Furthermore since $F_n = S^nF_0$ we have $f_n = T^nf_0$ and $f_n' = (-1)^nU^nf_0'$. Both F_n and f_n have bounded derivatives, by induction on n. Thus (32) becomes

$$(-1)^nR_n''\bigl(\lg(1+x)\bigr) = (1+x)(\ln 2)^2\,U^nf_0'(x). \tag{33}$$

Now $F_0(x) = x$, $f_0(x) = 1+x$, and $f_0'(x)$ is the constant function 1. We are going to show that the operator U^n takes the constant function into a function with very small values, hence $|R_n''(x)|$ must be very small for $0 \le x \le 1$. Finally we can clinch the argument by showing that $R_n(x)$ itself is small: Since we have $R_n(0) = R_n(1) = 1$, it follows from a well-known interpolation formula (cf. exercise 4.6.4–15 with $x_0 = 0$, $x_1 = x$, $x_2 = 1$) that

$$R_n(x) = -\frac{x(1-x)}{2}R_n''\bigl(\xi(x)\bigr) \tag{34}$$

for some function $\xi(x)$, where $0 \le \xi(x) \le 1$ when $0 \le x \le 1$.

Thus everything hinges on our being able to prove that U^n produces small function values, where U is the linear operator defined in (29). Note that U is a *positive* operator, in the sense that $U\varphi(x) \geq 0$ for all x if $\varphi(x) \geq 0$ for all x. It follows that U is order-preserving: If $\varphi_1(x) \leq \varphi_2(x)$ for all x then we have $U\varphi_1(x) \leq U\varphi_2(x)$ for all x.

One way to exploit this property is to find a function φ for which we can calculate $U\varphi$ exactly and to use constant multiples of this function to bound the ones that we are really interested in. First let us look for a function g such that Tg is easy to compute. If we consider functions defined for all $x \geq 0$, instead of only on $[0, 1]$, it is easy to remove the summation from (25) by observing that

$$SG(x+1)-SG(x) = G\Big(\frac{1}{1+x}\Big) - \lim_{k\to\infty} G\Big(\frac{1}{k+x}\Big) = G\Big(\frac{1}{1+x}\Big) - G(0) \tag{35}$$

when G is continuous. Since $T\big((1+x)G'\big) = (1+x)(SG)'$, it follows (see exercise 20) that

$$\frac{Tg(x)}{x+1} - \frac{Tg(x+1)}{x+2} = \Big(\frac{1}{x+1} - \frac{1}{x+2}\Big) g\Big(\frac{1}{1+x}\Big). \tag{36}$$

If we set $Tg(x) = 1/(x+1)$, we find that the corresponding value of $g(x)$ is $1 + x - 1/(1+x)$. Let $\varphi(x) = g'(x) = 1 + 1/(1+x)^2$, so that $U\varphi(x) = -(Tg)'(x) = 1/(1+x)^2$; this is the function φ we have been looking for.

For this choice of φ we have $2 \leq \varphi(x)/U\varphi(x) = (1+x)^2 + 1 \leq 5$ for $0 \leq x \leq 1$, hence

$$\tfrac{1}{5}\varphi \leq U\varphi \leq \tfrac{1}{2}\varphi.$$

By the positivity of U and φ we can apply U to this inequality again, obtaining $\frac{1}{25}\varphi \leq \frac{1}{5}U\varphi \leq U^2\varphi \leq \frac{1}{2}U\varphi \leq \frac{1}{4}\varphi$; and after $n-1$ applications we have

$$5^{-n}\varphi \leq U^n\varphi \leq 2^{-n}\varphi \tag{37}$$

for this particular φ. Let $\chi(x) = f_0'(x) = 1$ be the constant function; then for $0 \leq x \leq 1$ we have $\frac{5}{4}\chi \leq \varphi \leq 2\chi$, hence

$$\tfrac{5}{8}5^{-n}\chi \leq \tfrac{1}{2}5^{-n}\varphi \leq \tfrac{1}{2}U^n\varphi \leq U^n\chi \leq \tfrac{4}{5}U^n\varphi \leq \tfrac{4}{5}2^{-n}\varphi \leq \tfrac{8}{5}2^{-n}\chi.$$

It follows by (33) that

$$\tfrac{5}{8}(\ln 2)^2 5^{-n} \leq (-1)^n R_n''(x) \leq \tfrac{16}{5}(\ln 2)^2 2^{-n}, \qquad \text{for } 0 \leq x \leq 1;$$

hence by (30) and (34) we have proved the following result:

Theorem W. *The distribution $F_n(x)$ equals $\lg(1+x) + O(2^{-n})$ as $n \to \infty$. In fact, $F_n(x) - \lg(1+x)$ lies between $\frac{5}{16}(-1)^{n+1}5^{-n}\big(\ln(1+x)\big)\big(\ln 2/(1+x)\big)$ and $\frac{8}{5}(-1)^{n+1}2^{-n}\big(\ln(1+x)\big)\big(\ln 2/(1+x)\big)$, for $0 \leq x \leq 1$.* ∎

With a slightly different choice of φ, we can obtain tighter bounds (see exercise 21). In fact, Wirsing went much further in his paper, proving that

$$F_n(x) = \lg(1+x) + (-\lambda)^n \Psi(x) + O\big(x(1-x)(\lambda - 0.031)^n\big), \tag{38}$$

where

$$\begin{aligned} \lambda &= 0.30366\,30028\,98732\,65860\ldots \\ &= /3,3,2,2,3,13,1,174,1,1,1,2,2,2,1,1,1,2,2,1,\ldots/ \end{aligned} \tag{39}$$

is a fundamental constant (apparently unrelated to more familiar constants), and where Ψ is an interesting function that is analytic in the entire complex plane except for the negative real axis from -1 to $-\infty$. Wirsing's function satisfies $\Psi(0) = \Psi(1) = 0$, $\Psi'(0) < 0$, and $S\Psi = -\lambda\Psi$; thus by (35) it satisfies the identity

$$\Psi(z) - \Psi(z+1) = \frac{1}{\lambda}\Psi\Big(\frac{1}{1+z}\Big). \tag{40}$$

Furthermore, Wirsing demonstrated that

$$\Psi\Big(-\frac{u}{v} + \frac{i}{N}\Big) = c\lambda^{-n}\log N + O(1) \qquad \text{as } N \to \infty, \tag{41}$$

where c is a constant and $n = T(u,v)$ is the number of iterations when Euclid's algorithm is applied to the integers $u > v > 0$.

A complete solution to Gauss's problem was found a few years later by K. I. Babenko [*Doklady Akad. Nauk SSSR* **238** (1978), 1021–1024], who used powerful techniques of functional analysis to prove that

$$F_n(x) = \lg(1+x) + \sum_{j\ge 2} \lambda_j^n \Psi_j(x) \tag{42}$$

for all $0 \le x \le 1$, $n \ge 1$. Here $|\lambda_2| > |\lambda_3| \ge |\lambda_4| \ge \cdots$, and each $\Psi_j(z)$ is an analytic function in the complex plane except for a cut at $[-\infty, -1]$. The function Ψ_2 is Wirsing's Ψ, and $\lambda_2 = -\lambda$, while $\lambda_3 = 0.1009$, $\lambda_4 = -0.0408$, $\lambda_5 = -0.0355$, $\lambda_6 = 0.0128$. Babenko also established further properties of the eigenvalues λ_j, proving in particular that they are exponentially small as $j \to \infty$, and that the sum for $j \ge k$ in (42) is bounded by $(\pi^2/6)|\lambda_k|^{n-1}\min(x, 1-x)$. [Further information appears in a paper by Babenko and Îur'ev, *Doklady Akad. Nauk SSSR* **240** (1978), 1273–1276.]

From continuous to discrete. We have now derived results about the probability distributions for continued fractions when X is a real number uniformly distributed in the interval $[0,1)$. But a real number is rational with probability zero (almost all numbers are irrational), so these results do not apply directly to Euclid's algorithm. Before we can apply Theorem W to our problem, some technicalities must be overcome. Consider the following observation based on elementary measure theory:

Lemma M. *Let $I_1, I_2, \ldots, J_1, J_2, \ldots$ be pairwise disjoint intervals contained in the interval $[0,1)$, and let*

$$I = \bigcup_{k\ge 1} I_k, \qquad J = \bigcup_{k\ge 1} J_k, \qquad K = [0,1] \setminus (I \cup J).$$

Assume that K has measure zero. Let P_n be the set $\{0/n, 1/n, \ldots, (n-1)/n\}$. Then

$$\lim_{n\to\infty} \frac{\|I \cap P_n\|}{n} = \mu(I). \tag{43}$$

Here $\mu(I)$ is the Lebesgue measure of I, namely, $\sum_{k\ge 1} \text{length}(I_k)$; and $\|I \cap P_n\|$ denotes the number of elements in the set $I \cap P_n$.

Proof. Let $I_N = \bigcup_{1\le k\le N} I_k$ and $J_N = \bigcup_{1\le k\le N} J_k$. Given $\epsilon > 0$, find N large enough so that $\mu(I_N) + \mu(J_N) \ge 1 - \epsilon$, and let

$$K_N = K \cup \bigcup_{k>N} I_k \cup \bigcup_{k>N} J_k.$$

If I is an interval, having any of the forms (a,b) or $[a,b)$ or $(a,b]$ or $[a,b]$, it is clear that $\mu(I) = b - a$ and

$$n\mu(I) - 1 \le \|I \cap P_n\| \le n\mu(I) + 1.$$

Now let $r_n = \|I_N \cap P_n\|$, $s_n = \|J_N \cap P_n\|$, $t_n = \|K_N \cap P_n\|$; we have

$$\begin{aligned} r_n + s_n + t_n &= n; \\ n\mu(I_N) - N \le r_n &\le n\mu(I_N) + N; \\ n\mu(I_N) - N \le s_n &\le n\mu(J_N) + N. \end{aligned}$$

Hence

$$\begin{aligned} \mu(I) - \frac{N}{n} - \epsilon \le \mu(I_N) - \frac{N}{n} \le \frac{r_n}{n} &\le \frac{r_n + t_n}{n} \\ &= 1 - \frac{s_n}{n} \le 1 - \mu(J_N) + \frac{N}{n} \le \mu(I) + \frac{N}{n} + \epsilon. \end{aligned}$$

This holds for all n and for all ϵ; hence $\lim_{n\to\infty} r_n/n = \mu(I)$. ∎

Exercise 25 shows that Lemma M is not trivial, in the sense that some rather restrictive hypotheses are needed to prove (43).

Distribution of partial quotients. Now we can put Theorem W and Lemma M together to derive some solid facts about Euclid's algorithm.

Theorem E. *Let n and k be positive integers, and let $p_k(a,n)$ be the probability that the $(k+1)$st quotient A_{k+1} in Euclid's algorithm is equal to a, when $v = n$ and u is chosen at random. Then*

$$\lim_{n\to\infty} p_k(a,n) = F_k\Big(\frac{1}{a}\Big) - F_k\Big(\frac{1}{a+1}\Big),$$

where $F_k(x)$ is the distribution function (21).

Proof. The set $\mathcal{I}$ of all X in $[0,1)$ for which $A_{k+1} = a$ is a union of disjoint intervals, and so is the set $\mathcal{J}$ of all X for which $A_{k+1} \neq a$. Lemma M therefore applies, with $\mathcal{K}$ the set of all X for which A_{k+1} is undefined. Furthermore, $F_k(1/a) - F_k\big(1/(a+1)\big)$ is the probability that $1/(a+1) < X_k \le 1/a$, which is $\mu(\mathcal{I})$, the probability that $A_{k+1} = a$. ∎

As a consequence of Theorems E and W, we can say that a quotient equal to a occurs with the approximate probability

$$\lg(1 + 1/a) - \lg\big(1 + 1/(a+1)\big) = \lg\big((a+1)^2/((a+1)^2 - 1)\big).$$

Thus

a quotient of 1 occurs about $\lg(\frac{4}{3}) = 41.504$ percent of the time;
a quotient of 2 occurs about $\lg(\frac{9}{8}) = 16.992$ percent of the time;
a quotient of 3 occurs about $\lg(\frac{16}{15}) = 9.311$ percent of the time;
a quotient of 4 occurs about $\lg(\frac{25}{24}) = 5.890$ percent of the time.

Actually, if Euclid's algorithm produces the quotients $A_1, A_2, \ldots, A_t$, the nature of the proofs above will guarantee this behavior only for A_k when k is comparatively small with respect to t; the values $A_{t-1}, A_{t-2}, \ldots$ are not covered by this proof. But we can in fact show that the distribution of the last quotients $A_{t-1}, A_{t-2}, \ldots$ is essentially the same as the first.

For example, consider the regular continued fraction expansions for the set of all proper fractions whose denominator is 29:

$\frac{1}{29} = /\,29\,/$	$\frac{8}{29} = /\,3,1,1,1,2\,/$	$\frac{15}{29} = /\,1,1,14\,/$	$\frac{22}{29} = /\,1,3,7\,/$
$\frac{2}{29} = /\,14,2\,/$	$\frac{9}{29} = /\,3,4,2\,/$	$\frac{16}{29} = /\,1,1,4,3\,/$	$\frac{23}{29} = /\,1,3,1,5\,/$
$\frac{3}{29} = /\,9,1,2\,/$	$\frac{10}{29} = /\,2,1,9\,/$	$\frac{17}{29} = /\,1,1,2,2,2\,/$	$\frac{24}{29} = /\,1,4,1,4\,/$
$\frac{4}{29} = /\,7,4\,/$	$\frac{11}{29} = /\,2,1,1,1,3\,/$	$\frac{18}{29} = /\,1,1,1,1,1,3\,/$	$\frac{25}{29} = /\,1,6,4\,/$
$\frac{5}{29} = /\,5,1,4\,/$	$\frac{12}{29} = /\,2,2,2,2\,/$	$\frac{19}{29} = /\,1,1,1,9\,/$	$\frac{26}{29} = /\,1,8,1,2\,/$
$\frac{6}{29} = /\,4,1,5\,/$	$\frac{13}{29} = /\,2,4,3\,/$	$\frac{20}{29} = /\,1,2,4,2\,/$	$\frac{27}{29} = /\,1,13,2\,/$
$\frac{7}{29} = /\,4,7\,/$	$\frac{14}{29} = /\,2,14\,/$	$\frac{21}{29} = /\,1,2,1,1,1,2\,/$	$\frac{28}{29} = /\,1,28\,/$

Several things can be observed in this table.

a) As mentioned earlier, the last quotient is always 2 or more. Furthermore, we have the obvious identity

$$/x_1, \ldots, x_{n-1}, x_n + 1/ = /x_1, \ldots, x_{n-1}, x_n, 1/, \tag{44}$$

and this shows how partial fractions whose last quotient is unity are related to regular continued fractions.

b) The values in the right-hand columns have a simple relationship to the values in the left-hand columns; can the reader see the correspondence before reading any further? The relevant identity is

$$1 - /x_1, x_2, \ldots, x_n/ = /1, x_1 - 1, x_2, \ldots, x_n/; \tag{45}$$

see exercise 9.

c) There is symmetry between left and right in the first two columns: If $/A_1, A_2, \ldots, A_t/$ occurs, so does $/A_t, \ldots, A_2, A_1/$. This will always be the case (see exercise 26).

d) If we examine all of the quotients in the table, we find that there are 96 in all, of which $\frac{39}{96} = 40.6$ percent are equal to 1, $\frac{21}{96} = 21.9$ percent are equal to 2, $\frac{8}{96} = 8.3$ percent are equal to 3; this agrees reasonably well with the probabilities listed above.

The number of division steps. Let us now return to our original problem and investigate T_n, the average number of division steps when $v = n$. (See Eq. (19).) Here are some sample values of T_n:

$n =$	95	96	97	98	99	100	101	102	103	104	105
$T_n =$	5.0	4.4	5.3	4.8	4.7	4.6	5.3	4.6	5.3	4.7	4.6
$n =$	996	997	998	999	1000	1001	$\cdots$	9999	10000	10001	
$T_n =$	6.5	7.3	7.0	6.8	6.4	6.7	$\cdots$	8.6	8.3	9.1	
$n =$	49999	50000	50001	$\cdots$	99999	100000	100001				
$T_n =$	10.6	9.7	10.0	$\cdots$	10.7	10.3	11.0				

Note the somewhat erratic behavior; T_n tends to be higher than its neighbors when n is prime, and it is correspondingly lower when n has many divisors. (In this list, 97, 101, 103, 997, and 49999 are primes; $10001 = 73 \cdot 137$, $50001 = 3 \cdot 7 \cdot 2381$, $99999 = 3 \cdot 3 \cdot 41 \cdot 271$, and $100001 = 11 \cdot 9091$.) It is not difficult to understand why this happens: if $\gcd(u, v) = d$, Euclid's algorithm applied to u and v behaves essentially the same as if it were applied to u/d and v/d. Therefore, when $v = n$ has several divisors, there are many choices of u for which n behaves as if it were smaller.

Accordingly let us consider *another* quantity, τ_n, which is the average number of division steps when $v = n$ and when u is *relatively prime* to n. Thus

$$\tau_n = \frac{1}{\varphi(n)} \sum_{\substack{0 \le m < n \\ \gcd(m,n)=1}} T(m, n). \tag{46}$$

It follows that

$$T_n = \frac{1}{n}\sum_{d\backslash n} \varphi(d)\tau_d. \tag{47}$$

Here is a table of τ_n for the same values of n considered above:

$n =$	95	96	97	98	99	100	101	102	103	104	105
$\tau_n =$	5.4	5.3	5.3	5.6	5.2	5.2	5.4	5.3	5.4	5.3	5.6
$n =$	996	997	998	999	1000	1001	$\cdots$	9999	10000	10001	
$\tau_n =$	7.2	7.3	7.3	7.3	7.3	7.4	$\cdots$	9.21	9.21	9.22	
$n =$	49999	50000	50001	$\cdots$	99999	100000	100001				
$\tau_n =$	10.58	10.57	10.59	$\cdots$	11.170	11.172	11.172				

Clearly τ_n is much more well-behaved than T_n, and it should be more susceptible to analysis. Inspection of a table of τ_n for small n reveals some curious anomalies; for example, $\tau_{50} = \tau_{100}$ and $\tau_{60} = \tau_{120}$. But as n grows, the values of τ_n behave quite regularly indeed, as the above table indicates, and they show no significant relation to the factorization properties of n. If the reader will plot the values of τ_n versus $\ln n$ on graph paper, for the values of τ_n given above, he will see that the values lie very nearly on a straight line, and that the formula

$$\tau_n \approx 0.843 \ln n + 1.47 \tag{48}$$

is a very good approximation.

We can account for this behavior if we study the regular continued fraction process a little further. Note that in Euclid's algorithm as expressed in (15) we have

$$\frac{V_0}{U_0}\frac{V_1}{U_1}\cdots\frac{V_{t-1}}{U_{t-1}} = \frac{V_{t-1}}{U_0},$$

since $U_{k+1} = V_k$; therefore if $U = U_0$ and $V = V_0$ are relatively prime, and if there are t division steps, we have

$$X_0X_1\ldots X_{t-1} = 1/U.$$

Setting $U = N$ and $V = m < N$, we find that

$$\ln X_0 + \ln X_1 + \cdots + \ln X_{t-1} = -\ln N. \tag{49}$$

We know the approximate distribution of X_0, X_1, X_2, $\ldots$, so we can use this equation to estimate

$$t = T(N, m) = T(m, N) - 1.$$

Returning to the formulas preceding Theorem W, we find that the average value of $\ln X_n$, when X_0 is a real number uniformly distributed in $[0, 1)$, is

$$\int_0^1 \ln x\, F_n'(x)\, dx = \int_0^1 \ln x\, f_n(x)\, dx/(1+x), \tag{50}$$

where $f_n(x)$ is defined in (31). Now

$$f_n(x) = \frac{1}{\ln 2} + O(2^{-n}), \tag{51}$$

using the facts we have derived earlier (see exercise 23); hence the average value of $\ln X_n$ is very well approximated by

$$\begin{aligned}
\frac{1}{\ln 2}\int_0^1 \frac{\ln x}{1+x}\,dx &= -\frac{1}{\ln 2}\int_0^\infty \frac{ue^{-u}}{1+e^{-u}}\,du \\
&= -\frac{1}{\ln 2}\sum_{k\ge 1}(-1)^{k+1}\int_0^\infty ue^{-ku}\,du \\
&= -\frac{1}{\ln 2}\left(1-\frac{1}{4}+\frac{1}{9}-\frac{1}{16}+\frac{1}{25}-\cdots\right) \\
&= -\frac{1}{\ln 2}\left(1+\frac{1}{4}+\frac{1}{9}+\cdots-2\left(\frac{1}{4}+\frac{1}{16}+\frac{1}{36}+\cdots\right)\right) \\
&= -\frac{1}{2\ln 2}\left(1+\frac{1}{4}+\frac{1}{9}+\cdots\right) \\
&= -\pi^2/(12\ln 2).
\end{aligned}$$

By (49) we therefore expect to have the approximate formula

$$-t\pi^2/(12\ln 2) \approx -\ln N;$$

that is, t should be approximately equal to $\big((12\ln 2)/\pi^2\big)\ln N$. This constant $(12\ln 2)/\pi^2 = 0.842765913\ldots$ agrees perfectly with the empirical formula (48) obtained earlier, so we have good reason to believe that the formula

$$\tau_n \approx \frac{12\ln 2}{\pi^2}\ln n + 1.47 \tag{52}$$

indicates the true asymptotic behavior of τ_n as $n \to \infty$.

If we assume that (52) is valid, we obtain the formula

$$T_n \approx \frac{12\ln 2}{\pi^2}\left(\ln n - \sum_{d\backslash n}\Lambda(d)/d\right) + 1.47, \tag{53}$$

where $\Lambda(d)$ is *von Mangoldt's function* defined by the rules

$$\Lambda(n) = \begin{cases} \ln p, & \text{if } n = p^r \text{ for } p \text{ prime and } r \ge 1; \\ 0, & \text{otherwise.} \end{cases} \tag{54}$$

For example,

$$\begin{aligned} T_{100} &\approx \frac{12\ln 2}{\pi^2}\left(\ln 100 - \frac{\ln 2}{2} - \frac{\ln 2}{4} - \frac{\ln 2}{5} - \frac{\ln 5}{25}\right) + 1.47 \\ &\approx (0.843)(4.605 - 0.347 - 0.173 - 0.322 - 0.064) + 1.47 \\ &\approx 4.59; \end{aligned}$$

the exact value of T_{100} is 4.56.

We can also estimate the average number of division steps when u and v are both uniformly distributed between 1 and N, by calculating

$$\frac{1}{N}\sum_{1\le n\le N} T_n. \tag{55}$$

Assuming formula (53), exercise 27 shows that this sum has the form

$$\frac{12\ln 2}{\pi^2}\ln N + O(1), \tag{56}$$

and empirical calculations with the same numbers used to derive Eq. 4.5.2–45 show good agreement with the formula

$$\frac{12\ln 2}{\pi^2}\ln N + 0.06. \tag{57}$$

Of course we have not yet *proved* anything about T_n and τ_n in general; so far we have only been considering plausible reasons why the above formulas ought to hold. Fortunately it is now possible to supply rigorous proofs, based on a careful analysis by several mathematicians.

The leading coefficient $(12\ln 2)/\pi^2$ in the above formulas was established first, in independent studies by John D. Dixon and Hans A. Heilbronn. Dixon [*J. Number Theory* **2** (1970), 414–422] developed the theory of the $F_n(x)$ distributions to show that individual partial quotients are essentially independent of each other in an appropriate sense, and proved that for all positive ϵ we have $\left|T(m,n) - \left((12\ln 2)/\pi^2\right)\ln n\right| < (\ln n)^{(1/2)+\epsilon}$ except for $\exp\left(-c(\epsilon)(\log N)^{\epsilon/2}\right)N^2$ values of m and n in the range $1 \le m < n \le N$, where $c(\epsilon) > 0$. Heilbronn's approach was completely different, working entirely with integers instead of continuous variables. His idea, which is presented in slightly modified form in exercises 33 and 34, is based on the fact that τ_n can be related to the number of ways to represent n in a certain manner. Furthermore, his paper [*Number Theory and Analysis*, ed. by Paul Turán (New York: Plenum, 1969), 87–96] shows that the distribution of individual partial quotients 1, 2, ... that we have discussed above actually applies to the entire collection of partial quotients belonging to the fractions having a given denominator; this is a sharper form of Theorem E. A still sharper result was obtained several years later by J. W. Porter [*Mathematika* **22**

(1975), 20–28], who established that

$$\tau_n = \frac{12\ln 2}{\pi^2}\ln n + C + O(n^{-1/6+\epsilon}), \tag{58}$$

where [illegible] is the constant

[illegible]

see D. E. Knuth, *Computers and Math. with Applic.* **2** (1976), 137–139. Thus the conjecture (48) is fully proved.

The average running time for Euclid's algorithm on multiple-precision integers, using classical algorithms for arithmetic, was shown to be of order

$$\big(1 + \log(\max(u,v)/\gcd(u,v))\big)\log\min(u,v)$$

by G. E. Collins, in *SIAM J. Computing* **3** (1974), 1–10.

Summary. We have found that the worst case of Euclid's algorithm occurs when its inputs u and v are consecutive Fibonacci numbers (Theorem F); the number of division steps when $v = n$ will never exceed $\lceil 4.8\log_{10} N - 0.32\rceil$. We have determined the frequency of the values of various partial quotients, showing, for example, that the division step finds $\lfloor u/v\rfloor = 1$ about 41 percent of the time (Theorem E). And, finally, the theorems of Heilbronn and Porter prove that the average number T_n of division steps when $v = n$ is approximately

$$\big((12\ln 2)/\pi^2\big)\ln n \approx 1.9405\log_{10} n,$$

minus a correction term based on the divisors of n as shown in Eq. (53).

EXERCISES

▶ **1.** [*20*] Since the quotient $\lfloor u/v\rfloor$ is equal to unity over 40 percent of the time in Algorithm 4.5.2A, it may be advantageous on some computers to make a test for this case and to avoid the division when the quotient is unity. Is the following MIX program for Euclid's algorithm more efficient than Program 4.5.2A?

```
    LDX  U     rX ← u.
    JMP  2F
1H  STX  V     v ← rX.
    SUB  V     rA ← u − v.
    CMPA V
    SRAX 5     rAX ← rA.
    JL   2F    Is u − v < v?
    DIV  V     rX ← rAX mod v.
2H  LDA  V     rA ← v.
    JXNZ 1B    Done if rX = 0.  ∎
```

2. [*M21*] Evaluate the matrix product

$$\begin{pmatrix} x_1 & 1 \\ 1 & 0 \end{pmatrix}\begin{pmatrix} x_2 & 1 \\ 1 & 0 \end{pmatrix}\cdots\begin{pmatrix} x_n & 1 \\ 1 & 0 \end{pmatrix}.$$

3. [*M21*] What is the value of

$$\det\begin{pmatrix} x_1 & 1 & 0 & \dots & 0 \\ -1 & x_2 & 1 & & 0 \\ 0 & -1 & x_3 & 1 & \vdots \\ \vdots & & -1 & & \\ 0 & 0 & \dots & -1 & x_n \end{pmatrix}?$$

4. [*M20*] Prove Eq. (8).

5. [*HM25*] Let x_1, x_2, ... be a sequence of real numbers that are each greater than some positive real number ϵ. Prove that the infinite continued fraction $/x_1, x_2, \dots/ = \lim_{n\to\infty} /x_1, \dots, x_n/$ exists. Show also that $/x_1, x_2, \dots/$ need not exist if we assume only that $x_j > 0$ for all j.

6. [*M23*] Prove that the regular continued fraction expansion of a number is *unique* in the following sense: If B_1, B_2, ... are positive integers, then the infinite continued fraction $/B_1, B_2, \dots/$ is an irrational number X between 0 and 1 whose regular continued fraction has $A_n = B_n$ for all $n \geq 1$; and if B_1, ..., B_m are positive integers with $B_m > 1$, then the regular continued fraction for $X = /B_1, \dots, B_m/$ has $A_n = B_n$ for $1 \leq n \leq m$.

7. [*M26*] Find all permutations $p(1)p(2)\dots p(n)$ of the integers $\{1, 2, \dots, n\}$ such that $Q_n(x_1, x_2, \dots, x_n) = Q_n(x_{p(1)}, x_{p(2)}, \dots, x_{p(n)})$ holds for all x_1, x_2, ..., x_n.

8. [*M20*] Show that $-1/X_n = /A_n, \dots, A_1, -X/$, whenever X_n is defined, in the regular continued fraction process.

9. [*M21*] Show that continued fractions satisfy the following identities:

a) $/x_1, \dots, x_n/ = /x_1, \dots, x_k + /x_{k+1}, \dots, x_n//, \qquad 1 \leq k \leq n;$

b) $/0, x_1, x_2, \dots, x_n/ = x_1 + /x_2, \dots, x_n/, \qquad n \geq 1;$

c) $/x_1, \dots, x_{k-1}, x_k, 0, x_{k+1}, x_{k+2}, \dots, x_n/$
$= /x_1, \dots, x_{k-1}, x_k + x_{k+1}, x_{k+2}, \dots, x_n/, \qquad 1 \leq k < n;$

d) $1 - /x_1, x_2, \dots, x_n/ = /1, x_1 - 1, x_2, \dots, x_n/, \qquad n \geq 1.$

10. [*M28*] By the result of exercise 6, every irrational real number X has a unique regular continued fraction representation of the form

$$X = A_0 + /A_1, A_2, A_3, \dots/,$$

where A_0 is an integer and A_1, A_2, A_3, ... are positive integers. Show that if X has this representation then the regular continued fraction for $1/X$ is

$$1/X = B_0 + /B_1, \dots, B_m, A_5, A_6, \dots/$$

for suitable integers B_0, B_1, ..., B_m. (The case $A_0 < 0$ is, of course, the most interesting.) Explain how to determine the B's in terms of A_0, A_1, A_2, A_3, and A_4.

11. [*M30*] (J. Lagrange.) Let $X = A_0 + /A_1, A_2, \ldots/$, $Y = B_0 + /B_1, B_2, \ldots/$ be the regular continued fraction representations of two real numbers X and Y, in the sense of exercise 10. Show that these representations [illegible] in the sense that $A_{m+k} = B_{n+k}$ for some m and n and for all $k \geq 0$, if and only if we have $X = (qY + r)/(sY + t)$ for some integers q, r, s, t with $|qt - rs| = 1$. (This theorem is the analog, for continued fraction representations, of the simple result that the representations of X and Y in the decimal system eventually agree if and only if [illegible] for some integers q, r, and s.)

▶ **12.** [*M30*] A *quadratic irrationality* is a number of the form $(\sqrt{D} - U)/V$, where D, U, and V are integers, $D > 0$, $V \neq 0$, and D is not a perfect square. We may assume without loss of generality that V is a divisor of $D - U^2$, for otherwise the number may be rewritten as $(\sqrt{DV^2} - U|V|)/V|V|$.

a) Prove that the regular continued fraction expansion (in the sense of exercise 10) of a quadratic irrationality $X = (\sqrt{D} - U)/V$ is obtained by the following formulas:

$$V_0 = V, \qquad A_0 = \lfloor X \rfloor, \qquad U_0 = U + A_0 V;$$
$$V_{n+1} = (D - U_n^2)/V_n, \qquad A_{n+1} = \lfloor (\sqrt{D} + U_n)/V_{n+1} \rfloor,$$
$$U_{n+1} = A_{n+1} V_{n+1} - U_n.$$

[*Note:* An algorithm based on this process has many applications to the solution of quadratic equations in integers; see, for example, H. Davenport, *The Higher Arithmetic* (London: Hutchinson, 1952); W. J. LeVeque, *Topics in Number Theory* (Reading, Mass.: Addison–Wesley, 1956); and see also Section 4.5.4. By exercise 1.2.4–35, we have $A_{n+1} = \lfloor (\lfloor \sqrt{D} \rfloor + U_n)/V_{n+1} \rfloor$ when $V_{n+1} > 0$, and $A_{n+1} = \lfloor (\lfloor \sqrt{D} \rfloor + 1 + U_n)/V_{n+1} \rfloor$ when $V_{n+1} < 0$; hence such an algorithm need only work with the positive integer $\lfloor \sqrt{D} \rfloor$.]

b) Prove that $0 < U_n < \sqrt{D}$, $0 < V_n < 2\sqrt{D}$, for all $n > N$, where N is some integer depending on X; hence the regular continued fraction representation of every quadratic irrationality is eventually periodic. [*Hint:* Show that $(-\sqrt{D} - U)/V = A_0 + /A_1, \ldots, A_n, -V_n/(\sqrt{D} + U_n)/$, and use Eq. (5) to prove that $(\sqrt{D} + U_n)/V_n$ is positive when n is large.]

c) Letting $p_n = Q_{n+1}(A_0, A_1, \ldots, A_n)$ and $q_n = Q_n(A_1, \ldots, A_n)$, prove the identity $Vp_n^2 + 2Up_nq_n + ((U^2 - D)/V)q_n^2 = (-1)^{n+1} V_{n+1}$.

d) Prove that the regular continued fraction representation of an irrational number X is eventually periodic if and only if X is a quadratic irrationality. (This is the continued fraction analog of the fact that the decimal expansion of a real number X is eventually periodic if and only if X is rational.)

13. [*M40*] (J. Lagrange, 1797.) Let $f(x) = a_n x^n + \cdots + a_0$, $a_n > 0$, be a polynomial with integer coefficients, having no rational roots, and having exactly one real root $\xi > 1$. Design a computer program to find the first thousand or so partial quotients of ξ, using the following algorithm (which essentially involves only addition):

L1. Set $A \leftarrow 1$.

L2. For $k = 0, 1, \ldots, n - 1$ (in this order) and for $j = n - 1, \ldots, k$ (in this order), set $a_j \leftarrow a_{j+1} + a_j$. (This step replaces $f(x)$ by $g(x) = f(x + 1)$, a polynomial whose roots are one less than those of f.)

L3. If $a_n + a_{n-1} + \cdots + a_0 < 0$, set $A \leftarrow A + 1$ and return to L2.

L4. Output A (which is the value of the next partial quotient). Replace the coefficients $(a_n, a_{n-1}, \ldots, a_0)$ by $(-a_0, -a_1, \ldots, -a_n)$ and return to L1. (This step replaces $f(x)$ by a polynomial whose roots are reciprocals of those of f.)

For example, starting with $f(x) = x^3 - 2$, the algorithm will output "1" (changing $f(x)$ to $x^3 - 3x^2 - 3x - 1$); then "3" (changing $f(x)$ to $10x^3 - 6x^2 - 6x - 1$); etc.

14. [*M22*] (A. Hurwitz, 1891.) Show that the following rules make it possible to find the regular continued fraction expansion of $2X$, given the partial quotients of X:

$$2/\,2a, b, c, \ldots/ = /\,a, 2b + 2/c, \ldots//;$$
$$2/\,2a + 1, b, c, \ldots/ = /\,a, 1, 1 + 2/b - 1, c, \ldots//.$$

Use this idea to find the regular continued fraction expansion of $\frac{1}{2}e$, given the expansion of e in (13).

▶ **15.** [*M31*] (R. W. Gosper.) Generalizing exercise 14, design an algorithm that computes the continued fraction $X_0 + /X_1, X_2, \ldots/$ for $(ax + b)/(cx + d)$, given the continued fraction $x_0 + /x_1, x_2, \ldots/$ for x, and given integers a, b, c, d with $ad \neq bc$. Make your algorithm an "on-line coroutine" that outputs as many X_k as possible before inputting each x_j. Demonstrate how your algorithm computes $(97x + 39)/(-62x - 25)$ when $x = -1 + /5, 1, 1, 1, 2, 1, 2/$.

16. [*HM30*] (L. Euler, 1731.) Let $f_0(z) = (e^z - e^{-z})/(e^z + e^{-z}) = \tanh z$, and let $f_{n+1}(z) = 1/f_n(z) - (2n + 1)/z$. Prove that, for all n, $f_n(z)$ is an analytic function of the complex variable z in a neighborhood of the origin, and it satisfies the differential equation $f_n'(z) = 1 - f_n(z)^2 - 2nf_n(z)/z$. Use this fact to prove that

$$\tanh z = /z^{-1}, 3z^{-1}, 5z^{-1}, 7z^{-1}, \ldots/.$$

Then apply Hurwitz's rule (exercise 14) to prove that

$$e^{-1/n} = /\overline{1, (2m + 1)n - 1, 1}/, \qquad m \geq 0.$$

(This notation denotes the infinite continued fraction $/1,\ n - 1,\ 1,\ 1,\ 3n - 1,\ 1,\ 1,\ 5n - 1,\ 1,\ \ldots/$.) Also find the regular continued fraction expansion of $e^{-2/n}$ when $n > 0$ is odd.

▶ **17.** [*M23*] (a) Prove that $/x_1, -x_2/ = /x_1 - 1, 1, x_2 - 1/$. (b) Generalize this identity, obtaining a formula for $/x_1, -x_2, x_3, -x_4, \ldots, x_{2n-1}, -x_{2n}/$ in which all partial quotients are positive integers when the x's are large positive integers. (c) The result of exercise 16 implies that $\tan 1 = /1, -3, 5, -7, \ldots/$. Find the regular continued fraction expansion of $\tan 1$.

18. [*M40*] Develop a computer program to find as many partial quotients of x as possible, when x is a real number given with high precision. Use your program to calculate the first one thousand or so partial quotients of Euler's constant γ, based on D. W. Sweeney's 3566-place value [*Math. Comp.* **17** (1963), 170–178]. (According to the theory in the text, we expect to get about 0.97 partial quotients per decimal digit. Cf. Algorithm 4.5.2L and the article by J. W. Wrench, Jr. and D. Shanks, *Math. Comp.* **20** (1966), 444–447.)

19. [*M20*] Prove that $F(x) = \log_b(1 + x)$ satisfies Eq. (24).

20. [*HM20*] Derive (36) from (35).

21. [*HM29*] (E. Wirsing.) The bounds (37) were obtained for a function φ corresponding to g with $Tg(x) = 1/(x+1)$. Show that the function corresponding to $Tg(x) = 1/(x+c)$ yields better bounds, when $c > 0$ is an appropriate constant.

22. [*HM46*] (K. I. Babenko.) Develop efficient means to calculate accurate approximations to the quantities λ_j and $\Psi_j(x)$ in (42), for small $j \geq 3$ and for $0 \leq x \leq 1$.

23. [*HM23*] Prove (51), using results from the proof of Theorem W.

24. [*M22*] What is the average value of a partial quotient A_n in the regular continued fraction expansion of a random real number?

25. [*HM25*] Find an example of a set $I = I_1 \cup I_2 \cup I_3 \cup \cdots \subseteq [0,1]$, where the I's are disjoint intervals, for which (43) does not hold.

26. [*M23*] Show that if the numbers $\{1/n, 2/n, \ldots, \lfloor n/2 \rfloor / n\}$ are expressed as regular continued fractions, the result is symmetric between left and right, in the sense that $/A_t, \ldots, A_2, A_1/$ appears whenever $/A_1, A_2, \ldots, A_t/$ does.

27. [*M21*] Derive (53) from (47) and (52).

28. [*M23*] Prove the following identities involving the three number-theoretic functions $\varphi(n)$, $\mu(n)$, $\Lambda(n)$:

a) $\displaystyle\sum_{d\backslash n} \mu(d) = \delta_{n1}$. b) $\displaystyle\ln n = \sum_{d\backslash n} \Lambda(d)$, $\displaystyle n = \sum_{d\backslash n} \varphi(d)$.

c) $\displaystyle\Lambda(n) = \sum_{d\backslash n} \mu\Big(\frac{n}{d}\Big) \ln d$, $\displaystyle\varphi(n) = \sum_{d\backslash n} \mu\Big(\frac{n}{d}\Big) d$.

29. [*M23*] Assuming that T_n is given by (53), show that (55) equals (56).

▶ **30.** [*HM32*] The following variant of Euclid's algorithm is often suggested: Instead of replacing v by $u \bmod v$ during the division step, replace it by $|(u \bmod v) - v|$ if $u \bmod v > \frac{1}{2}v$. Thus, for example, if $u = 26$ and $v = 7$, we have $\gcd(26,7) = \gcd(-2,7) = \gcd(7,2)$; -2 is the *remainder of smallest magnitude* when multiples of 7 are subtracted from 26. Compare this procedure with Euclid's algorithm; estimate the number of division steps this method saves, on the average.

▶ **31.** [*M35*] Find the "worst case" of the modification of Euclid's algorithm suggested in exercise 30; what are the smallest inputs $u > v > 0$ that require n division steps?

32. [*20*] (a) A Morse code sequence of length n is a string of r dots and s dashes, where $r + 2s = n$. For example, the Morse code sequences of length 4 are

$$\cdot\cdot\cdot\cdot,\quad \cdot\cdot{-},\quad \cdot{-}\cdot,\quad {-}\cdot\cdot,\quad {-}{-}.$$

Noting that the continuant $Q_4(x_1, x_2, x_3, x_4)$ is $x_1x_2x_3x_4 + x_1x_2 + x_1x_4 + x_3x_4 + 1$, find and prove a simple relation between $Q_n(x_1, \ldots, x_n)$ and Morse code sequences of length n. (b) (L. Euler, *Novi Comm. Acad. Sci. Pet.* **9** (1762), 53–69.) Prove that

$$Q_{m+n}(x_1, \ldots, x_{m+n}) = Q_m(x_1, \ldots, x_m)Q_n(x_{m+1}, \ldots, x_{m+n}) + Q_{m-1}(x_1, \ldots, x_{m-1})Q_{n-1}(x_{m+2}, \ldots, x_{m+n}).$$

33. [*M32*] Let $h(n)$ be the number of representations of n in the form

$$n = xx' + yy', \quad x > y > 0, \quad x' > y' > 0, \quad \gcd(x, y) = 1, \quad \text{integer } x, x', y, y'.$$

(a) Show that if the conditions are relaxed to allow $x' = y'$, the number of representations is $h(n) + \lfloor (n-1)/2 \rfloor$. (b) Show that for fixed $y > 0$ and $0 < t \leq y$, where $\gcd(t, y) = 1$, and for each fixed x' in the range $0 < x' < n/(y+t)$ such that $x't \equiv n$ (modulo y), there is exactly one representation of n satisfying the restrictions of (a) and the condition $x \equiv t$ (modulo y). (c) Consequently

$$h(n) = \sum \left\lceil \left(\frac{n}{y+t} - t' \right) \frac{1}{y} \right\rceil - \lfloor (n-1)/2 \rfloor,$$

where the sum is over all positive integers y, t, t' such that $\gcd(t, y) = 1$, $t \leq y$, $t' \leq y$, $tt' \equiv n$ (modulo y). (d) Show that each of the $h(n)$ representations can be expressed uniquely in the form

$$\begin{aligned} x &= Q_m(x_1, \ldots, x_m), & y &= Q_{m-1}(x_1, \ldots, x_{m-1}), \\ x' &= Q_k(x_{m+1}, \ldots, x_{m+k})\, d, & y' &= Q_{k-1}(x_{m+2}, \ldots, x_{m+k})\, d, \end{aligned}$$

where m, k, d, and the x_j are positive integers with $x_1 \geq 2$, $x_{m+k} \geq 2$, and d is a divisor of n. The identity of exercise 32 now implies that $n/d = Q_{m+k}(x_1, \ldots, x_{m+k})$. Conversely, any given sequence of positive integers $x_1, \ldots, x_{m+k}$ such that $x_1 \geq 2$, $x_{m+k} \geq 2$, and $Q_{m+k}(x_1, \ldots, x_{m+k})$ divides n, corresponds in this way to $m + k - 1$ representations of n. (e) Therefore $nT_n = \lfloor (5n-3)/2 \rfloor + 2h(n)$.

34. [*HM40*] (H. Heilbronn.) (a) Let $h_d(n)$ be the number of representations of n as in exercise 33 such that $xd < x'$, plus half the number of representations with $xd = x'$. Let $g(n)$ be the number of representations without the requirement that $\gcd(x, y) = 1$. Prove that

$$h(n) = \sum_{d \backslash n} \mu(d) g\Big(\frac{n}{d}\Big), \qquad g(n) = 2 \sum_{d \backslash n} h_d\Big(\frac{n}{d}\Big).$$

(b) Generalizing exercise 33(b), show that for $d \geq 1$, $h_d(n) = \sum (n/(y(y+t))) + O(n)$, where the sum is over all integers y and t such that $\gcd(t, y) = 1$ and $0 < t \leq y < \sqrt{n/d}$. (c) Show that $\sum_{1 \leq y \leq n} (y/(y+t)) = \varphi(y) \ln 2 + O(\sigma_{-1}(y))$, where the sum is over the range $0 < t \leq y$, $\gcd(t, y) = 1$; and where $\sigma_{-1}(y) = \sum_{d \backslash y} (1/d)$. (d) Show that $\sum_{1 \leq y \leq n} \varphi(y)/y^2 = \sum_{1 \leq d \leq n} \mu(d) H_{\lfloor n/d \rfloor}/d^2$. (e) Hence we have the asymptotic formula $T_n = ((12 \ln 2)/\pi^2)(\ln n - \sum_{d \backslash n} \Lambda(d)/d) + O(\sigma_{-1}(n)^2)$.

35. [*HM41*] (A. C. Yao and D. E. Knuth.) Prove that the sum of all partial quotients for the fractions m/n, for $1 \leq m < n$, is equal to $2(\sum \lfloor x/y \rfloor + \lfloor n/2 \rfloor)$, where the sum is over all representations $n = xx' + yy'$ satisfying the conditions of exercise 33(a). Show that $\sum \lfloor x/y \rfloor = 3\pi^{-2} n (\ln n)^2 + O(n \log n (\log \log n)^2)$, and apply this to the "ancient" form of Euclid's algorithm that uses only subtraction instead of division.

36. [*M35*] (G. H. Bradley.) What is the smallest value of u_n such that the calculation of $\gcd(u_1, \ldots, u_n)$ by steps C1 and C2 in Section 4.5.2 requires N divisions, if Euclid's algorithm is used throughout? Assume that $N \geq n$.

37. [*M38*] (T. S. Motzkin and E. G. Straus.) Let $a_1, \ldots, a_n$ be positive integers. Show that $\max Q_n(a_{p(1)}, \ldots, a_{p(n)})$, over all permutations $p(1)\ldots p(n)$ of $\{1, 2, \ldots, n\}$, occurs when $a_{p(1)} \geq a_{p(n)} \geq a_{p(2)} \geq a_{p(n-1)} \geq \cdots$; and the minimum occurs when $a_{p(1)} \leq a_{p(n)} \leq a_{p(3)} \leq a_{p(n-2)} \leq a_{p(5)} \leq \cdots \leq a_{p(6)} \leq a_{p(n-3)} \leq a_{p(4)} \leq a_{p(n-1)} \leq a_{p(2)}$.

38. [*M25*] (J. Mikusiński.) Let $K(n) = \max_{m \geq 0} T(m, n)$. Theorem F shows that $K(n) \leq \lfloor \log_\phi(\sqrt{5}\, n + 1) \rfloor - 2$; prove that $K(n) \geq \frac{1}{2} \lceil \log_\phi(\sqrt{5}\, n + 1) \rceil - 2$.

▶ **39.** [*M25*] (R. W. Gosper.) If a baseball player's batting average is .334, what is the fewest possible number of times he has been at bat? [Note for non-baseball-fans: Batting average = (number of hits)/(times at bat), rounded to three decimal places.]

▶ **40.** [*M28*] (*The Stern–Peirce tree.*) Consider an infinite binary tree in which each node is labeled with the fraction $(p_l + p_r)/(q_l + q_r)$, where p_l/q_l is the label of the node's nearest left ancestor and p_r/q_r is the label of the node's nearest right ancestor. (A left ancestor is one that precedes a node in symmetric order, while a right ancestor follows the node. See Section 2.3.1 for the definition of symmetric order.) If the node has no left ancestors, $p_l/q_l = 0/1$; if it has no right ancestors, $p_r/q_r = 1/0$. Thus the label of the root is 1/1; the labels of its two sons are 1/2 and 2/1; the labels of the four nodes on level 2 are 1/3, 2/3, 3/2, and 3/1, from left to right; the labels of the eight nodes on level 3 are 1/4, 2/5, 3/5, 3/4, 4/3, 5/3, 5/2, 4/1; and so on.

Prove that p is relatively prime to q in each label p/q; furthermore, the node labeled p/q precedes the node labeled p'/q' in symmetric order if and only if the labels satisfy $p/q < p'/q'$. Find a connection between the continued fraction for the label of a node and the path to that node, thereby showing that each positive rational number appears as the label of exactly one node in the tree.

[redacted][*M40*] (J. Shallit, 1979.) Show that the regular continued fraction expansion of

$$\frac{1}{2^1} + \frac{1}{2^3} + \frac{1}{2^7} + \cdots = \sum_{n \geq 1} \frac{1}{2^{2^n - 1}}$$

contains only 1's and 2's and has a fairly [redacted]" Prove that the partial quotients of Liouville's numbers $\sum_{n \geq 1} l^{-n!}$ also have a regular pattern, when l is any integer ≥ 2. [The latter numbers, introduced by J. Liouville in *J. de Math. Pures et Appl.* **16** (1851), 133–142, were the first explicitly defined numbers to be proved *transcendental*. The former number and similar constants were first proved transcendental by A. J. Kempner, *Trans. Amer. Math. Soc.* **17** (1916), 476–482.]

42. [*M30*] (J. Lagrange, 1798.) Let X have the regular continued fraction expansion $/A_1, A_2, \ldots/$, and let $q_n = Q_n(A_1, \ldots, A_n)$. Let $\|x\|$ denote the distance from x to the nearest integer, namely $\min_p |x - p|$. Show that $\|qX\| \geq \|q_{n-1}X\|$ for $1 \leq q < q_n$. (Thus the denominators q_n of the so-called convergents $p_n/q_n = /A_1, \ldots, A_n/$ are the "record-breaking" integers that make $\|qX\|$ achieve new lows.)

43. [*M30*] (D. W. Matula.) Show that the "mediant rounding" rule for fixed-slash or floating-slash numbers, Eq. 4.5.1–1, can be implemented simply as follows, when the number $x > 0$ is not representable: Let the regular continued fraction expansion of x be $a_0 + /a_1, a_2, \ldots/$, and let $p_n = Q_{n+1}(a_0, \ldots, a_n)$, $q_n = Q_n(a_1, \ldots, a_n)$. Then $\text{round}(x) = (p_i/q_i)$, where (p_i/q_i) is representable but (p_{i+1}/q_{i+1}) is not. [*Hint:* See exercise 40.]

44. [*M25*] Suppose we are doing fixed slash arithmetic with mediant rounding, where the fraction (u/u') is representable if and only if $|u| < M$ and $0 \le u' < N$ and $\gcd(u, u') = 1$. Prove or disprove the identity $((u/u') \oplus (v/v')) \ominus (v/v') = (u/u')$ for all representable (u/u') and (v/v'), provided that $u' < \sqrt{N}$ and no overflow occurs.

45. [*HM48*] Develop the analysis of algorithms for computing the greatest common divisor of three or more integers.

4.5.4. Factoring into Primes

Several of the computational methods we have encountered in this book rest on the fact that every positive integer n can be expressed in a unique way in the form

$$n = p_1 p_2 \dots p_t, \qquad p_1 \le p_2 \le \cdots \le p_t, \tag{1}$$

where each p_k is prime. (When $n = 1$, this equation holds for $t = 0$.) It is unfortunately not a simple matter to find this prime factorization of n, or to determine whether or not n is prime. So far as anyone knows, it is a great deal harder to factor a large number n than to compute the greatest common divisor of two large numbers m and n; therefore we should avoid factoring large numbers whenever possible. But several ingenious ways to speed up the factoring process have been discovered, and we will now investigate some of them.

Divide and factor. First let us consider the most obvious algorithm for factorization: If $n > 1$, we can divide n by successive primes $p = 2, 3, 5, \dots$ until discovering the smallest p for which $n \bmod p = 0$. Then p is the smallest prime factor of n, and the same process may be applied to $n \leftarrow n/p$ in an attempt to divide this new value of n by p and by higher primes. If at any stage we find that $n \bmod p \neq 0$ but $\lfloor n/p \rfloor \le p$, we can conclude that n is prime; for if n is not prime, then by (1) we must have $n \ge p_1^2$, but $p_1 > p$ implies that $p_1^2 \ge (p+1)^2 > p(p+1) > p^2 + (n \bmod p) \ge \lfloor n/p \rfloor p + (n \bmod p) = n$. This leads us to the following procedure:

Algorithm A (*Factoring by division*). Given a positive integer N, this algorithm finds the prime factors $p_1 \le p_2 \le \cdots \le p_t$ of N as in Eq. (1). The method makes use of an auxiliary sequence of "trial divisors"

$$2 = d_0 < d_1 < d_2 < d_3 < \cdots, \tag{2}$$

which includes all prime numbers $\le \sqrt{N}$ (and which may also include values that are *not* prime, if it is convenient to do so). The sequence of d's must also include at least one value such that $d_k \ge \sqrt{N}$.

A1. [Initialize.] Set $t \leftarrow 0$, $k \leftarrow 0$, $n \leftarrow N$. (During this algorithm the variables t, k, n are related by the following condition: "$n = N/p_1 \dots p_t$, and n has no prime factors less than d_k.")

A2. [$n = 1$?] If $n = 1$, the algorithm terminates.

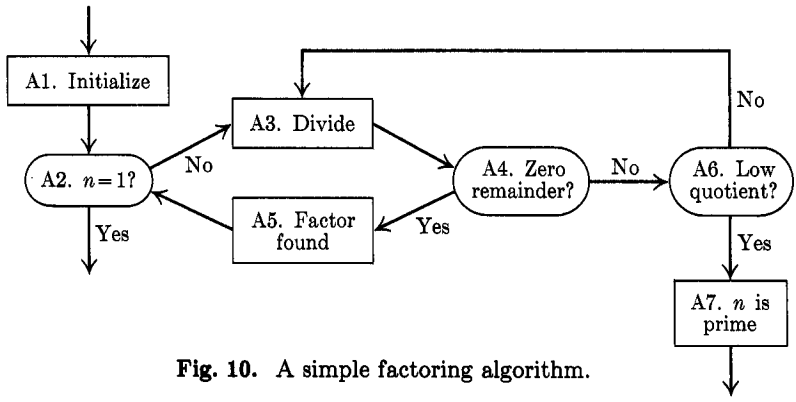

Fig. 10. A simple factoring algorithm.

A3. [Divide.] Set $q \leftarrow \lfloor n/d_k \rfloor$, $r \leftarrow n \bmod d_k$. (Here q and r are the quotient and remainder obtained when n is divided by d_k.)

A4. [Zero remainder?] If $r \neq 0$, go to step A6.

A5. [Factor found.] Increase t by 1, and set $p_t \leftarrow d_k$, $n \leftarrow q$. Return to step A2.

A6. [Low quotient?] If $q > d_k$, increase k by 1 and return to step A3.

A7. [n is prime.] Increase t by 1, set $p_t \leftarrow n$, and terminate the algorithm. ∎

As an example of Algorithm A, consider the factorization of the number $N = 25852$. We immediately find that $N = 2 \cdot 12926$; hence $p_1 = 2$. Furthermore, $12926 = 2 \cdot 6463$, so $p_2 = 2$. But now $n = 6463$ is not divisible by 2, 3, 5, ..., 19; we find that $n = 23 \cdot 281$, hence $p_3 = 23$. Finally $281 = 12 \cdot 23 + 5$ and $12 \leq 23$; hence $p_4 = 281$. The determination of 25852's factors has therefore involved a total of 12 division operations; on the other hand, if we had tried to factor the slightly smaller number 25849 (which is prime), at least 38 division operations would have been performed. This illustrates the fact that Algorithm A requires a running time roughly proportional to $\max(p_{t-1}, \sqrt{p_t})$. (If $t = 1$, this formula is valid if we adopt the convention $p_0 = 1$.)

The sequence d_0, d_1, d_2, ... of trial divisors used in Algorithm A can be taken to be simply 2, 3, 5, 7, 11, 13, 17, 19, 23, 25, 29, 31, 35, ..., where we alternately add 2 and 4 after the first three terms. This sequence contains all numbers that are not multiples of 2 or 3; it also includes numbers such as 25, 35, 49, etc., which are not prime, but the algorithm will still give the correct answer. A further savings of 20 percent in computation time can be made by removing the numbers $30m \pm 5$ from the list for $m \geq 1$, thereby eliminating all of the spurious multiples of 5. The exclusion of multiples of 7 shortens the list by 14 percent more, etc. A compact bit table can be used to govern the choice of trial divisors.

If N is known to be small, it is reasonable to have a table of all the necessary primes as part of the program. For example, if N is less than a million, we need only include the 168 primes less than a thousand (followed by the value $d_{168} = 1000$, to terminate the list in case N is a prime larger than 997^2). Such a table

can be set up by means of a short auxiliary program, which builds the table just after the factoring program has been loaded into the computer; see Algorithm 1.3.2P, or see exercise 8.

How many trial divisions are necessary in Algorithm A? Let $\pi(x)$ be the number of primes $\le x$, so that $\pi(2) = 1$, $\pi(10) = 4$; the asymptotic behavior of this function has been studied extensively by many of the world's greatest mathematicians, beginning with Legendre in 1798. Numerous advances made during the nineteenth century culminated in 1899, when Charles de la Vallée Poussin proved that, for some $A > 0$,

$$\pi(x) = \int_2^x \frac{dt}{\ln t} + O(xe^{-A\sqrt{\log x}}). \tag{3}$$

[*Mém. Couronnés Acad. Roy. Belgique* **59** (1899), 1–74.] Integrating by parts yields

$$\pi(x) = \frac{x}{\ln x} + \frac{x}{(\ln x)^2} + \frac{2!\,x}{(\ln x)^3} + \cdots + \frac{r!\,x}{(\ln x)^{r+1}} + O\left(\frac{x}{(\log x)^{r+2}}\right) \tag{4}$$

for all fixed $r \ge 0$. The error term in (3) has subsequently been improved; for example, it can be replaced by $O(x\exp(-A(\log x)^{3/5}/(\log\log x)^{1/5}))$. [See A. Walfisz, *Weyl'sche Exponentialsummen in der neueren Zahlentheorie* (Berlin, 1963), Chapter 5.] Bernhard Riemann conjectured in 1859 that

$$\pi(x) = \sum_{k\ge 1} \mu(k)L(\sqrt[k]{x})/k + O(1) = L(x) - \frac{1}{2}L(\sqrt{x}) - \frac{1}{3}L(\sqrt[3]{x}) + \cdots \tag{5}$$

where $L(x) = \int_2^x dt/\ln t$, and his formula agrees well with actual counts when x is of reasonable size. For example, we have the following table:

x	$\pi(x)$	$x/\ln x$	$L(x)$	Riemann's formula
10^3	168	144.8	176.6	168.36
10^6	78498	72382.4	78626.5	78527.40
10^9	50847534	48254942.4	50849233.9	50847455.43

However, the distribution of large primes is not that simple, and Riemann's conjecture (5) was disproved by J. E. Littlewood in 1914; see Hardy and Littlewood, *Acta Math.* **41** (1918), 119–196, where it is shown that there is a positive constant C such that $\pi(x) > L(x) + C\sqrt{x}\log\log\log x/\log x$ for infinitely many x. Littlewood's result shows that prime numbers are inherently somewhat mysterious, and it will be necessary to develop deep properties of mathematics before their distribution is really understood. Riemann made another much more plausible conjecture, the famous "Riemann hypothesis," which states that the complex function $\zeta(z)$ is zero only when the real part of z is equal to $\frac{1}{2}$, except in the trivial cases where z is a negative even integer. This hypothesis, if true,

would imply that $\pi(x) = L(x) + O(\sqrt{x}\log x)$; see exercise 25. Richard Brent has used a method of D. H. Lehmer to verify Riemann's hypothesis computationally for all "small" values of z, by showing that $\zeta(z)$ has exactly 75,000,000 zeros whose imaginary part is in the range $0 < \Im z < 32585736.4$; all of these zeros have $\Re z = \frac{1}{2}$ and $\zeta'(z) \neq 0$. [*Math. Comp.* **33** (1979), 1361–1372.]

In order to analyze the average behavior of Algorithm A, we would like to know how large the largest prime factor p_t will tend to be. This question was first investigated by Karl Dickman [*Arkiv för Mat., Astron. och Fys.* **22A**, 10 (1930), 1–14], who studied the probability that a random integer between 1 and x will have its largest prime factor $\leq x^\alpha$. Dickman gave a heuristic argument to show that this probability approaches the limiting value $F(\alpha)$ as $x \to \infty$, where F can be calculated from the functional equation

$$F(\alpha) = \int_0^\alpha F\left(\frac{t}{1-t}\right)\frac{dt}{t}, \quad \text{for } 0 \leq \alpha \leq 1; \qquad F(\alpha) = 1 \quad \text{for } \alpha \geq 1. \tag{6}$$

His argument was essentially this: Given $0 < t < 1$, the number of integers less than x whose largest prime factor is between x^t and x^{t+dt} is $xF'(t)\,dt$. The number of primes p in that range is $\pi(x^{t+dt}) - \pi(x^t) = \pi(x^t + (\ln x)x^t\,dt) - \pi(x^t) = x^t\,dt/t$. For every such p, the number of integers n such that "$np \leq x$ and the largest prime factor of n is $\leq p$" is the number of $n \leq x^{1-t}$ whose largest prime factor is $\leq (x^{1-t})^{t/(1-t)}$, namely $x^{1-t}F\big(t/(1-t)\big)$. Hence $xF'(t)\,dt = (x^t\,dt/t)\big(x^{1-t}F\big(t/(1-t)\big)\big)$, and (6) follows by integration. This heuristic argument can be made rigorous; V. Ramaswami [*Bull. Amer. Math. Soc.* **55** (1949), 1122–1127] showed that the probability in question for fixed α is asymptotically $F(\alpha) + O(1/\log x)$, as $x \to \infty$, and many other authors have extended the analysis [see the survey by Karl K. Norton, *Memoirs Amer. Math. Soc.* **106** (1971), 9–27].

If $\frac{1}{2} \leq \alpha \leq 1$, formula (6) simplifies to

$$F(\alpha) = 1 - \int_\alpha^1 F\left(\frac{t}{1-t}\right)\frac{dt}{t} = 1 - \int_\alpha^1 \frac{dt}{t} = 1 + \ln\alpha.$$

Thus, for example, the probability that a random positive integer $\leq x$ has a prime factor $> \sqrt{x}$ is $1 - F(\frac{1}{2}) = \ln 2$, about 69 percent. In all such cases, Algorithm A must work hard.

The net result of this discussion is that Algorithm A will give the answer rather quickly if we want to factor a six-digit number; but for large N the amount of computer time for factorization by trial division will rapidly exceed practical limits, unless we are unusually lucky.

Later in this section we will see that there are fairly good ways to determine whether or not a reasonably large number n is prime, without trying all divisors up to $\sqrt{n}$. Therefore Algorithm A would often run faster if we inserted a primality test between steps A2 and A3; the running time for this improved algorithm would then be roughly proportional to p_{t-1}, the *second-largest* prime factor of N, instead of to $\max(p_{t-1}, \sqrt{p_t})$. By an argument analogous to

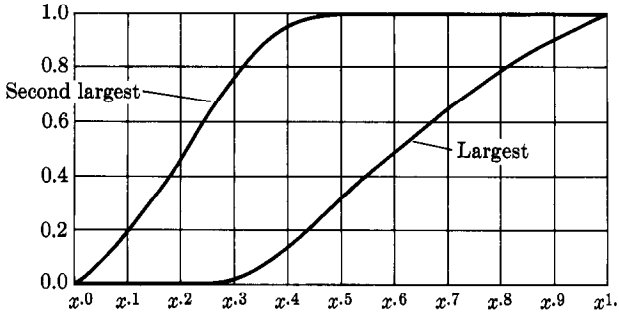

Fig. 11. Probability distribution functions for the two largest prime factors of a random integer $\leq x$.

Dickman's (see exercise 18), we can show that the second-largest prime factor of a random integer x will be $\leq x^{\beta}$ with approximate probability $G(\beta)$, where

$$G(\beta) = \int_0^{\beta} \left(G\left(\frac{t}{1-t}\right) - F\left(\frac{t}{1-t}\right)\right) \frac{dt}{t}, \quad \text{for } 0 \leq \beta \leq \tfrac{1}{2}. \tag{7}$$

Clearly $G(\beta) = 1$ for $\beta \geq \frac{1}{2}$. (See Fig. 11.) Numerical evaluation of (6) and (7) yields the following "percentage points":

$F(\alpha), G(\beta) =$	.01	.05	.10	.20	.35	.50	.65	.80	.90	.95	.99
$\alpha =$	.2697	.3348	.3785	.4430	.5220	.6065	.7047	.8187	.9048	.9512	.9900
$\beta =$	.0056	.0273	.0531	.1003	.1611	.2117	.2582	.3104	.3590	.3967	.4517

Thus, the second-largest prime factor will be $\leq x^{.2117}$ about half the time, etc.

The *total number of prime factors*, t, has also been intensively analyzed. Obviously $1 \leq t \leq \lg N$, but these lower and upper bounds are seldom achieved. It is possible to prove that if N is chosen at random between 1 and x, the probability that $t \leq \ln\ln x + c\sqrt{\ln\ln x}$ approaches

$$\frac{1}{\sqrt{2\pi}} \int_{-\infty}^{c} e^{-u^2/2}\, du \tag{8}$$

as $x \to \infty$, for any fixed c. In other words, the distribution of t is essentially normal, with mean and variance $\ln\ln x$; about 99.73 percent of all the large integers $\leq x$ have $|t - \ln\ln x| \leq 3\sqrt{\ln\ln x}$. Furthermore the average value of $t - \ln\ln x$ for $1 \leq N \leq x$ is known to approach

$$\gamma + \sum_{p \text{ prime}} \big(\ln(1 - 1/p) + 1/(p-1)\big) = \mathbf{1.03465\ 38818\ 97438}.$$

[Cf. G. H. Hardy and E. M. Wright, *Introduction to the Theory of Numbers*, 4th ed. (Oxford, 1960), §22.11; see also [redacted].]

The size of prime factors has a remarkable connection with permutations: The average number of bits in the kth largest prime factor of a random n-bit integer is asymptotically the same as the average length of the kth largest cycle of a random n-element permutation, as $n \to \infty$. [See D. E. Knuth and L. Trabb Pardo, *Theoretical Comp. Sci.* **3** (1976), 321–348.] It follows that Algorithm A usually finds a few small factors and then begins a long-drawn-out search for the big ones that are left.

Factoring à la Monte Carlo. Near the beginning of Chapter 3, we observed that "a random number generator chosen at random isn't very random." This principle, which worked against us in that chapter, has the redeeming virtue that it leads to a surprisingly efficient method of factorization, discovered by J. M. Pollard [*BIT* **15** (1975), 331–334]. The number of computational steps in Pollard's method is on the order of $\sqrt{p_{t-1}}$, so it is significantly faster than Algorithm A when N is large. According to (7) and Fig. 11, the running time will usually be well under $N^{1/4}$.

Let $f(x)$ be any polynomial with integer coefficients, and consider the two sequences defined by

$$x_0 = y_0 = A; \qquad x_{m+1} = f(x_m) \bmod N, \qquad y_{m+1} = f(y_m) \bmod p, \tag{9}$$

where p is any prime factor of N. It follows that

$$y_m = x_m \bmod p, \qquad \text{for } m \geq 1. \tag{10}$$

Now exercise 3.1–7 shows that we will have $y_m = y_{l(m)-1}$ for some $m \geq 1$, where $l(m)$ is the greatest power of 2 that is $\leq m$. Thus $x_m - x_{l(m)-1}$ will be a multiple of p. Furthermore if $f(y) \bmod p$ behaves as a random mapping from the set $\{0, 1, \ldots, p-1\}$ into itself, exercise 3.1–12 shows that the average value of the least such m will be of order $\sqrt{p}$. In fact, exercise 4 below shows that this average value for random mappings is less than $1.625\,Q(p)$, where the function $Q(p) \approx \sqrt{\pi p/2}$ was defined in Section 1.2.11.3. If the different prime divisors of N correspond to different values of m (as they almost surely will, when N is large), we will be able to find them by calculating $\gcd(x_m - x_{l(m)-1}, N)$ for $m = 1, 2, 3, \ldots$, until the unfactored residue is prime.

From the theory in Chapter 3, we know that a linear polynomial $f(x) = ax + c$ will not be sufficiently random for our purposes. The next-simplest case is quadratic, say $f(x) = x^2 + 1$; although we don't *know* that this function is sufficiently random, our lack of knowledge tends to support the hypothesis of randomness, and empirical tests show that this f does work essentially as predicted. In fact, f is probably slightly *better* than random, since $x^2 + 1$ takes on only $\frac{1}{2}(p+1)$ distinct values mod p. Therefore the following procedure is reasonable:

Algorithm B (*Monte Carlo factorization*). This algorithm outputs the prime factors of a given integer $N \geq 2$, with high probability, although there is a chance that it will fail.

B1. [Initialize.] Set $x \leftarrow 5$, $x' \leftarrow 2$, $k \leftarrow 1$, $l \leftarrow 1$, $n \leftarrow N$. (During this algorithm, n is the unfactored part of N, and the variables x and x' represent the quantities $x_m \bmod n$ and $x_{l(m)-1} \bmod n$ in (9), where $f(x) = x^2+1$, $A = 1$, $l = l(m)$, and $k = 2l - m$.)

B2. [Test primality.] If n is prime (see the discussion below), output n; the algorithm terminates.

B3. [Factor found?] Set $g \leftarrow \gcd(x'-x, n)$. If $g = 1$, go on to step B4; otherwise output g. Now if $g = n$, the algorithm terminates (and it has failed, because we know that n isn't prime). Otherwise set $n \leftarrow n/g$, $x \leftarrow x \bmod n$, $x' \leftarrow x' \bmod n$, and return to step B2. (Note that g may not be prime; this should be tested. In the rare event that g isn't prime, its prime factors probably won't be determinable with this algorithm.)

B4. [Advance.] Set $k \leftarrow k - 1$. If $k = 0$, set $x' \leftarrow x$, $l \leftarrow 2l$, $k \leftarrow l$. Set $x \leftarrow (x^2 + 1) \bmod n$ and return to B3. ∎

As an example of Algorithm B, let's try to factor $N = 25852$ again. The third execution of step B3 will output $g = 4$ (which isn't prime). After six more iterations the algorithm finds the factor $g = 23$. Algorithm B has not distinguished itself in this example, but of course it was designed to factor *big* numbers. Algorithm A takes much longer to find large prime factors, but it can't be beat when it comes to removing the small ones. In practice, we should run Algorithm A awhile before switching over to Algorithm B.

We can get a better idea of Algorithm B's prowess by considering the ten largest six-digit primes. The number of iterations, $m(p)$, that Algorithm B needs to find the factor p is given in the following table:

$p =$	999863	999883	999907	999917	999931	999953	999959	999961	999979	999983
$m(p) =$	276	409	2106	1561	1593	1091	474	1819	395	814

Experiments indicate that $m(p)$ has an average value of about $2\sqrt{p}$, and it never exceeds $12\sqrt{p}$ when $p < 1000000$. The maximum $m(p)$ for $p < 10^6$ is $m(874771) = 7685$; and the maximum of $m(p)/\sqrt{p}$ occurs when $p = 290047$, $m(p) = 6251$. According to these experimental results, almost all 12-digit numbers can be factored in fewer than 2000 iterations of Algorithm B (compared to roughly 100,000 divisions in Algorithm A).

The time-consuming operations in each iteration of Algorithm B are the multiple-precision multiplication and division in step B4, and the gcd in step B3. If the gcd operation is slow, Pollard suggests gaining speed by accumulating the product mod n of, say, ten consecutive $(x'-x)$ values before taking each gcd; this replaces 90 percent of the gcd operations by a single multiplication and division while only slightly increasing the chance of failure. He also suggests starting with $m = q$ instead of $m = 1$ in step B1, where q is, say, $\frac{1}{10}$ the number of iterations you are planning to use.

In those rare cases where failure occurs for large N, we could try using $f(x) = x^2 + c$ for some $c \neq 0$ or 1. The value $c = -2$ should also be avoided, since the recurrence $x_{m+1} = x_m^2 - 2$ has solutions of the form $x_m = r^{2^m} + r^{-2^m}$. Other values of c do not seem to lead to simple relationships mod p, and they should all be satisfactory when used with suitable starting values.

Richard Brent used a modification of Algorithm B in 1980 to discover the prime factor 1238926361552897 of $2^{256} + 1$.

Fermat's method. Another approach to the factoring problem, which was used by Pierre de Fermat in 1643, is more suited to finding large factors than small ones. [Fermat's original description of his method, translated into English, can be found in L. E. Dickson's monumental *History of the Theory of Numbers* **1** (New York: Chelsea, 1952), 357.]

Assume that $N = uv$, where $u \leq v$. For practical purposes we may assume that N is odd; this means that u and v are odd, and we can let

$$x = (u + v)/2, \qquad y = (v - u)/2, \tag{11}$$

$$N = x^2 - y^2, \qquad 0 \leq y < x \leq N. \tag{12}$$

Fermat's method consists of searching systematically for values of x and y that satisfy Eq. (12). The following algorithm shows how factoring can therefore be done *without using any division:*

Algorithm C (*Factoring by addition and subtraction*). Given an odd number N, this algorithm determines the largest factor of N less than or equal to $\sqrt{N}$.

C1. [Initialize.] Set $x' \leftarrow 2\lfloor\sqrt{N}\rfloor + 1$, $y' \leftarrow 1$, $r \leftarrow \lfloor\sqrt{N}\rfloor^2 - N$. (During this algorithm x', y', r correspond respectively to $2x + 1$, $2y + 1$, $x^2 - y^2 - N$ as we search for a solution to (12); we will have $|r| < x'$ and $y' < x'$.)

C2. [Test r.] If $r \leq 0$, go to step C4.

C3. [Step y.] Set $r \leftarrow r - y'$, $y' \leftarrow y' + 2$, and return to C2.

C4. [Done?] If $r = 0$, the algorithm terminates; we have

$$N = \big((x' - y')/2\big)\big((x' + y' - 2)/2\big),$$

and $(x' - y')/2$ is the largest factor of N less than or equal to $\sqrt{N}$.

C5. [Step x.] Set $r \leftarrow r + x'$, $x' \leftarrow x' + 2$, and return to C3. ∎

The reader may find it amusing to find the factors of 377 by hand, using this algorithm. The number of steps needed to find the factors u and v of $N = uv$ is essentially proportional to $(x' + y' - 2)/2 - \lfloor\sqrt{N}\rfloor = v - \lfloor\sqrt{N}\rfloor$; this can, of course, be a very large number, although each step can be done very rapidly on most computers. An improvement that requires only $O(N^{1/3})$ operations in the worst case has been developed by R. S. Lehman [*Math. Comp.* **28** (1974), 637–646].

It is not quite correct to call Algorithm C "Fermat's method," since Fermat used a somewhat more streamlined approach. Algorithm C's main loop is quite

fast on computers, but it is not very suitable for hand calculation. Fermat actually did not keep the running value of y; he would look at $x^2 - N$ and tell whether or not this quantity was a perfect square by looking at its least significant digits. (The last two digits of a perfect square must be 00, $e1$, $e4$, 25, $o6$, or $e9$, where e is an even digit and o is an odd digit.) Therefore he avoided the operations of steps C2 and C3, replacing them by an occasional determination that a certain number is not a perfect square.

Fermat's method of looking at the rightmost digits can, of course, be generalized by using other moduli. Suppose for clarity that $N = 11111$, and consider the following table:

m	if $x \bmod m$ is	then $x^2 \bmod m$ is	and $(x^2 - N) \bmod m$ is
3	0, 1, 2	0, 1, 1	1, 2, 2
5	0, 1, 2, 3, 4	0, 1, 4, 4, 1	4, 0, 3, 3, 0
7	0, 1, 2, 3, 4, 5, 6	0, 1, 4, 2, 2, 4, 1	5, 6, 2, 0, 0, 2, 6
8	0, 1, 2, 3, 4, 5, 6, 7	0, 1, 4, 1, 0, 1, 4, 1	1, 2, 5, 2, 1, 2, 5, 2
11	0, 1, 2, 3, 4, 5, 6, 7, 8, 9, 10	0, 1, 4, 9, 5, 3, 3, 5, 9, 4, 1	10, 0, 3, 8, 4, 2, 2, 4, 8, 3, 0

If $x^2 - N$ is to be a perfect square y^2, it must have a residue mod m consistent with this fact, for all m. For example, if $N = 11111$ and $x \bmod 3 \neq 0$, then $(x^2 - N) \bmod 3 = 2$, so $x^2 - N$ cannot be a perfect square; therefore x must be a multiple of 3 whenever $11111 = x^2 - y^2$. The table tells us, in fact, that

$$\begin{aligned} x \bmod 3 &= 0; \\ x \bmod 5 &= 0, \text{ 1, or 4}; \\ x \bmod 7 &= 2, \text{ 3, 4, or 5}; \\ x \bmod 8 &= 0 \text{ or 4 (hence } x \bmod 4 = 0); \\ x \bmod 11 &= 1, \text{ 2, 4, 7, 9, or 10.} \end{aligned} \tag{13}$$

This narrows down the search for x considerably. For example, x must be a multiple of 12. We must have $x \geq \lceil \sqrt{N} \rceil = 106$, and it is easy to verify that the first value of $x \geq 106$ that satisfies all of the conditions in (13) is $x = 144$. Now $144^2 - 11111 = 9625$, and by attempting to take the square root of 9625 we find that it is not a square. The first value of $x > 144$ that satisfies (13) is $x = 156$. In this case $156^2 - 11111 = 13225 = 115^2$; so we have found the desired solution $x = 156$, $y = 115$. This calculation shows that $11111 = 41 \cdot 271$.

The hand calculations involved in the above example are comparable to the amount of work required to divide 11111 by 13, 17, 19, 23, 29, 31, 37, and 41, even though the factors 41 and 271 are not very close to each other; thus we can see the advantages of Fermat's method.

In place of the moduli considered in (13), we can use any powers of distinct primes. For example, if we had used 25 in place of 5, we would find that the only permissible values of $x \bmod 25$ are 0, 5, 6, 10, 15, 19, and 20. This gives more information than (13). In general, we will get more information modulo p^2 than we do modulo p, for odd primes p, whenever $x^2 - N \equiv 0$ (modulo p) has a solution x.

The modular method just used is called a *sieve procedure*, since we can imagine passing all integers through a "sieve" for which only those values with $x \bmod 3 = 0$ come out, then sifting these numbers through another sieve that allows only numbers with $x \bmod 5 = 0$, 1, or 4 to pass, etc. Each sieve by itself will remove about half of the remaining values (see exercise 6); and when we sieve with respect to moduli that are relatively prime in pairs, each sieve is independent of the others because of the Chinese remainder theorem (Theorem 4.3.2C). So if we sieve with respect to, say, 30 different primes, only about one value in every 2^{30} will need to be examined to see if $x^2 - N$ is a perfect square y^2.

Algorithm D (*Factoring with sieves*). Given an odd number N, this algorithm determines the largest factor of N less than or equal to $\sqrt{N}$. The procedure uses moduli $m_1, m_2, \ldots, m_r$ that are relatively prime to each other in pairs and relatively prime to N. We assume that r "sieve tables" $S[i, j]$ for $0 \le j < m_i$, $1 \le i \le r$, have been prepared, where

$$S[i,j] = \begin{cases} 1, & \text{if } j^2 - N \equiv y^2 \text{ (modulo } m_i) \text{ has a solution } y; \\ 0, & \text{otherwise.} \end{cases}$$

D1. [Initialize.] Set $x \leftarrow \lceil \sqrt{N} \rceil$, and set $k_i \leftarrow (-x) \bmod m_i$ for $1 \le i \le r$. (Throughout this algorithm the index variables $k_1, k_2, \ldots, k_r$ will be set so that $(-x) \bmod m_i = k_i$.)

D2. [Sieve.] If $S[i, k_i] = 1$ for $1 \le i \le r$, go to step D4.

D3. [Step x.] Set $x \leftarrow x + 1$, and set $k_i \leftarrow (k_i - 1) \bmod m_i$ for $1 \le i \le r$. Return to step D2.

D4. [Test $x^2 - N$.] Set $y \leftarrow \lfloor \sqrt{x^2 - N} \rfloor$ or to $\lceil \sqrt{x^2 - N} \rceil$. If $y^2 = x^2 - N$, then $(x - y)$ is the desired factor, and the algorithm terminates. Otherwise return to step D3. ∎

There are several ways to make this procedure run fast. For example, we have seen that if $N \bmod 3 = 2$, then x must be a multiple of 3; we can set $x = 3x'$, and use a different sieve corresponding to x', increasing the speed threefold. If $N \bmod 9 = 1$, 4, or 7, then x must be congruent respectively to ± 1, ± 2, or ± 4 (modulo 9); so we run two sieves (one for x' and one for x'', where $x = 9x' + a$ and $x = 9x'' - a$) to increase the speed by a factor of $4\frac{1}{2}$. If $N \bmod 4 = 3$, then $x \bmod 4$ is known and the speed is increased by an additional factor of 4; in the other case, when $N \bmod 4 = 1$, x must be odd so the speed may be doubled. Another way to double the speed of the algorithm (at the expense of storage space) is to combine pairs of moduli, using $m_{r-k} m_k$ in place of m_k for $1 \le k < \frac{1}{2}r$.

An even more important method of speeding up Algorithm D is to use the "Boolean operations" found on most binary computers. Let us assume, for example, that MIX is a binary computer with 30 bits per word. The tables $S[i, k_i]$ can be kept in memory with one bit per entry; thus 30 values can be stored in a single word. The operation AND, which replaces the kth bit of the accumulator

by zero if the kth bit of a specified word in memory is zero, for $1 \le k \le 30$, can be used to process 30 values of x at once! For convenience, we can make several copies of the tables $S[i,j]$ so that the table entries for m_i involve $\operatorname{lcm}(m_i, 30)$ bits; then the sieve tables for each modulus fill an integral number of words. Under these assumptions, 30 executions of the main loop in Algorithm D are equivalent to code of the following form:

```
D2  LD1  K1      rI1 ← k'_1.
    LDA  S1,1    rA ← S'[1, rI1].
    DEC1 1       rI1 ← rI1 − 1.
    J1NN *+2
    INC1 M1      If rI1 < 0, set rI1 ← rI1 + lcm(m_1, 30).
    ST1  K1      k'_1 ← rI1.
    LD1  K2      rI1 ← k'_2.
    AND  S2,1    rA ← rA ∧ S'[2, rI1].
    DEC1 1       rI1 ← rI1 − 1.
    J1NN *+2
    INC1 M2      If rI1 < 0, set rI1 ← rI1 + lcm(m_2, 30).
    ST1  K2      k'_2 ← rI1.
    LD1  K3      rI1 ← k'_3.
    ...          (m_3 through m_r are like m_2)
    ST1  Kr      k'_r ← rI1.
    INCX 30      x ← x + 30.
    JAZ  D2      Repeat if all sieved out. ∎
```

The number of cycles for 30 iterations is essentially $2 + 8r$; if $r = 11$, this means three cycles are being used on each iteration, just as in Algorithm C, and Algorithm C involves $y = \frac{1}{2}(v - u)$ more iterations.

If the table entries for m_i do not come out to be an integral number of words, further shifting of the table entries would be necessary on each iteration in order to align the bits properly. This would add quite a lot of coding to the main loop and it would probably make the program too slow to compete with Algorithm C unless $v/u \le 100$ (see exercise 7).

Sieve procedures can be applied to a variety of other problems, not necessarily having much to do with arithmetic. A survey of these techniques has been prepared by Marvin C. Wunderlich, *JACM* **14** (1967), 10–19.

Special sieve machines (of reasonably low cost) have been constructed by D. H. Lehmer and his associates over a period of many years; see, for example, *AMM* **40** (1933), 401–406. Lehmer's electronic delay-line sieve, which began operating in 1965, processes one million numbers per second. Thus, each iteration of the loop in Algorithm D can be performed in one microsecond on this device. Another way to factor with sieves is described by D. H. and Emma Lehmer in *Math. Comp.* **28** (1974), 625–635.

Primality testing. None of the algorithms we have discussed so far is an efficient way to determine that a large number n is prime. Fortunately, there are other methods available for settling this question; efficient methods have been devised

by É. Lucas and others, notably D. H. Lehmer [see *Bull. Amer. Math. Soc.* **33** (1927), 327–340].

According to Fermat's theorem (Theorem 1.2.4F), we have $x^{p-1} \bmod p = 1$ whenever p is prime and x is not a multiple of p. Furthermore, there are efficient ways to calculate $x^{n-1} \bmod n$, requiring only $O(\log n)$ operations of multiplication mod n. (We shall study these in Section 4.6.3 below.) Therefore we can often determine that n is *not* prime when this relationship fails.

For example, Fermat once verified that the numbers 2^1+1, 2^2+1, 2^4+1, 2^8+1, and $2^{16}+1$ are prime. In a letter to Mersenne written in 1640, Fermat conjectured that $2^{2^n}+1$ is always prime, but said he was unable to determine definitely whether the number $4294967297 = 2^{32}+1$ is prime or not. Neither Fermat nor Mersenne ever resolved this problem, although they could have done it as follows: The number $3^{2^{32}} \bmod (2^{32}+1)$ can be computed by doing 32 operations of squaring modulo $2^{32}+1$, and the answer is 3029026160; therefore (by Fermat's own theorem, which he discovered in the same year 1640!) the number $2^{32}+1$ is *not* prime. This argument gives us absolutely no idea what the factors are, but it answers Fermat's question.

Fermat's theorem is a powerful test for showing non-primality of a given number. When n is not prime, it is always possible to find a value of $x < n$ such that $x^{n-1} \bmod n \neq 1$; experience shows that, in fact, such a value can almost always be found very quickly. There are some rare values of n for which $x^{n-1} \bmod n$ is frequently equal to unity, but then n has a factor less than $\sqrt[3]{n}$; see exercise 9.

The same method can be extended to prove that a large prime number n really *is* prime, by using the following idea: *If there is a number x for which the order of x modulo n is equal to $n-1$, then n is prime.* (The order of x modulo n is the smallest positive integer k such that $x^k \bmod n = 1$; see Section 3.2.1.2.) For this condition implies that the numbers $x^1 \bmod n, \ldots, x^{n-1} \bmod n$ are distinct and relatively prime to n, so they must be the numbers $1, 2, \ldots, n-1$ in some order; thus n has no proper divisors. If n is prime, such a number x (called a "primitive root" of n) will always exist; see exercise 3.2.1.2–16. In fact, primitive roots are rather numerous. There are $\varphi(n-1)$ of them, and this is quite a substantial number, since $n/\varphi(n-1) = O(\log\log n)$.

It is unnecessary to calculate $x^k \bmod n$ for all $k \leq n-1$ to determine if the order of x is $n-1$ or not. The order of x will be $n-1$ if and only if

i) $x^{n-1} \bmod n = 1$;

ii) $x^{(n-1)/p} \bmod n \neq 1$ for all primes p that divide $n-1$.

For $x^s \bmod n = 1$ if and only if s is a multiple of the order of x modulo n. If the two conditions hold, and if k is the order of x modulo n, we therefore know that k is a divisor of $n-1$, but not a divisor of $(n-1)/p$ for any prime factor p of $n-1$; the only remaining possibility is $k = n-1$. This completes the proof that conditions (i) and (ii) suffice to establish the primality of n.

Exercise 10 shows that we can in fact use different values of x for each of the primes p, and n will still be prime. We may restrict consideration to prime

values of x, since the order of uv modulo n divides the least common multiple of the orders of u and v by exercise 3.2.1.2–15. Conditions (i) and (ii) can be tested efficiently by using the rapid methods for evaluating powers of numbers discussed in Section 4.6.3. But it is necessary to know the prime factors of $n-1$, so we have an interesting situation in which the factorization of n depends on that of $n-1$.

An example. The study of a reasonably typical large factorization will help to fix the ideas we have discussed so far. Let us try to find the prime factors of $2^{214}+1$, a 65-digit number. The factorization can be initiated with a bit of clairvoyance if we notice that

$$2^{214}+1=(2^{107}-2^{54}+1)(2^{107}+2^{54}+1); \tag{14}$$

this identity is a special case of some factorizations discovered by A. Aurifeuille in 1873 [see Dickson's *History*, **1**, p. 383]. The problem now boils down to examining each of the 33-digit factors in (14).

A computer program readily discovers that $2^{107}-2^{54}+1=5\cdot 857\cdot n_0$, where

$$n_0=37866809061660057264219253397 \tag{15}$$

is a 29-digit number having no prime factors less than 1000. A multiple-precision calculation using the "binary method" of Section 4.6.3 shows that

$$3^{n_0-1} \bmod n_0 = 1,$$

so we suspect that n_0 is prime. It is certainly out of the question to prove that n_0 is prime by trying the 10 million million or so potential divisors, but the method discussed above gives a feasible test for primality: our next goal is to factor n_0-1. With little difficulty, our computer will tell us that

$$n_0-1=2\cdot 2\cdot 19\cdot 107\cdot 353\cdot n_1, \qquad n_1=1319127075410822604930 1.$$

Here $3^{n_1-1} \bmod n_1 \neq 1$, so n_1 is not prime; by continuing Algorithm A or Algorithm B we find

$$n_1=91813\cdot n_2, \qquad n_2=143675413657196977.$$

This time $3^{n_2-1} \bmod n_2 = 1$, so we will try to prove that n_2 is prime. This requires the factorization $n_2-1=2\cdot 2\cdot 2\cdot 2\cdot 3\cdot 3\cdot 547\cdot n_3$, where $n_3=1824032775457$. Since $3^{n_3-1} \bmod n_3 \neq 1$, we know that n_3 is composite, and Algorithm A finds that $n_3=1103\cdot n_4$, where $n_4=1653701519$. The number n_4 behaves like a prime (i.e., $3^{n_4-1} \bmod n_4 = 1$), so we calculate

$$n_4-1=2\cdot 7\cdot 19\cdot 23\cdot 137\cdot 1973.$$

Good; this is our first complete factorization. We are now ready to backtrack to the previous subproblem, proving that n_4 is prime. Using the procedure suggested by exercise 10, we compute the following values:

x	p	$x^{(n_4-1)/p} \bmod n_4$	$x^{n_4-1} \bmod n_4$
2	2	1	(1)
2	7	766408626	(1)
2	19	332952683	(1)
2	23	1154237810	(1)
2	137	373782186	(1)
2	1973	490790919	(1)
3	2	1	(1)
5	2	1	(1)
7	2	1653701518	1

(16)

(Here "(1)" means a result of 1 that needn't be computed since it can be deduced from previous calculations.) Thus n_4 is prime, and $n_2 - 1$ has been completely factored. A similar calculation shows that n_2 is prime, and this complete factorization of $n_0 - 1$ finally shows [after still another calculation like (16)] that n_0 is prime.

The last three lines of (16) represent a search for an integer x that satisfies $x^{(n_4-1)/2} \not\equiv x^{n_4-1} \equiv 1$ (modulo n_4). If n_4 is prime, we have only a 50-50 chance of success, so the case $p = 2$ is typically the hardest one to verify. We could streamline this part of the calculation by using the law of quadratic reciprocity (cf. exercise 23), which tells us for example that $5^{(q-1)/2} \equiv 1$ (modulo q) whenever q is a prime congruent to ± 1 (modulo 5). Merely calculating $n_4 \bmod 5$ would have told us right away that $x = 5$ could not possibly help in showing that n_4 is prime. In fact, however, the result of exercise 26 implies that the case $p = 2$ doesn't really need to be considered at all when testing n for primality, unless $n - 1$ is divisible by a high power of 2, so we could have dispensed with the last three lines of (16) entirely.

The next quantity to be factored is the other half of (14), namely

$$n_5 = 2^{107} + 2^{54} + 1.$$

Since $3^{n_5-1} \bmod n_5 \neq 1$, we know that n_5 is not prime, and Algorithm B shows that $n_5 = 843589 \cdot n_6$, where $n_6 = 192343993140277293096491917$. Unfortunately, $3^{n_6-1} \bmod n_6 \neq 1$, so we are left with a 27-digit nonprime. Continuing Algorithm B might well exhaust our patience (not our budget—nobody is paying for this, we're using idle time on a weekend rather than "prime time"). But the sieve method of Algorithm D will be able to crack n_6 into its two factors,

$$n_6 = 8174912477117 \cdot 23528569104401.$$

This result could *not* have been discovered by Algorithm A in a reasonable length of time. (A few million iterations of Algorithm B would probably have sufficed.)

Now the computation is complete: $2^{214}+1$ has the prime factorization

$$5 \cdot 857 \cdot 843589 \cdot 8174912477117 \cdot 23528569104401 \cdot n_0,$$

where n_0 is the 29-digit prime in (15). A certain amount of good fortune entered into these calculations, for if we had not started with the known factorization (14) it is quite probable that we would first have cast out the small factors, reducing n to $n_6 n_0$. This 55-digit number would have been much more difficult to factor—Algorithm D would be useless and Algorithm B would have to work overtime because of the high precision necessary.

Dozens of further numerical examples can be found in an article by John Brillhart and J. L. Selfridge, *Math. Comp.* **21** (1967), 87–96.

Improved primality tests. Since the above procedure for proving that n is prime requires the complete factorization of $n-1$, it will bog down for large n. Another technique, which uses the factorization of $n+1$ instead, is described in exercise 15; if $n-1$ turns out to be too hard, $n+1$ might be easier.

Significant improvements are available for dealing with large n. For example, it is not difficult to prove a stronger converse of Fermat's theorem that requires only a partial factorization of $n-1$. Exercise 26 shows that we could have avoided most of the calculations in (16); the three conditions $2^{n_4-1} \bmod n_4 = \gcd(2^{(n_4-1)/23}-1, n_4) = \gcd(2^{(n_4-1)/1973}-1, n_4) = 1$ are sufficient by themselves to prove that n_4 is prime. Brillhart, Lehmer, and Selfridge have in fact developed a method that works when the numbers $n-1$ and $n+1$ have been only partially factored [*Math. Comp.* **29** (1975), 620–647, Corollary 11]: Suppose $n-1 = f^- r^-$ and $n+1 = f^+ r^+$, where we know the complete factorizations of f^- and f^+, and we also know that all factors of r^- and r^+ are $\geq b$. If the product $\big(b^3 f^- f^+ \max(f^-, f^+)\big)$ is greater than $2n$, a small amount of additional computation, described in their paper, will determine whether or not n is prime. Therefore numbers of up to 35 digits can usually be tested for primality in 2 or 3 seconds, simply by casting out all prime factors < 30030 from $n \pm 1$ [see J. L. Selfridge and M. C. Wunderlich, *Proc. Fourth Manitoba Conf. Numer. Math.* (1974), 109–120]. The partial factorization of other quantities like $n^2 \pm n + 1$ and $n^2 + 1$ can be used to improve this method still further [see H. C. Williams and J. S. Judd, *Math. Comp.* **30** (1976), 157–172, 867–886].

In practice, when n has no small prime factors and $3^{n-1} \bmod n = 1$, it has almost always turned out that n is prime. (One of the rare exceptions in the author's experience is $n = \frac{1}{7}(2^{28}-9) = 2341 \cdot 16381$.) On the other hand, some nonprime values of n are definitely bad news for the primality test we have discussed, because it might happen that $x^{n-1} \bmod n = 1$ for all x relatively prime to n (see exercise 9). One such number is $n = 3 \cdot 11 \cdot 17 = 561$; here $\lambda(n) = \operatorname{lcm}(2, 10, 16) = 80$ in the notation of Eq. 3.2.1.2–9, so $x^{80} \bmod 561 = 1 = x^{560} \bmod 561$ whenever x is relatively prime to 561. Our procedure would repeatedly fail to show that such an n is prime, until we had stumbled across one of its divisors. To improve the method, we need a quick way to determine the nonprimality of nonprime n, even in such pathological cases.

The following surprisingly simple procedure is guaranteed to do the job with high probability:

Algorithm P (*Probabilistic primality test*). Given an odd integer n, this algorithm attempts to decide whether or not n is prime. By repeating the algorithm several times, as explained in the remarks below, it is possible to be extremely confident about the primality of n, in a precise sense, yet the primality will not be rigorously proved. Let $n = 1 + 2^k q$, where q is odd.

P1. [Generate x.] Let x be a random integer in the range $1 < x < n$.

P2. [Exponentiate.] Set $j \leftarrow 0$ and $y \leftarrow x^q \bmod n$. (As in our previous primality test, $x^q \bmod n$ should be calculated in $O(\log q)$ steps, cf. Section 4.6.3.)

P3. [Done?] (Now $y = x^{2^j q} \bmod n$.) If $j = 0$ and $y = 1$, or if $y = n - 1$, terminate the algorithm and say "n is probably prime." If $j > 0$ and $y = 1$, go to step P5.

P4. [Increase j.] Increase j by 1. If $j < k$, set $y \leftarrow y^2 \bmod n$ and return to step P3.

P5. [Not prime.] Terminate the algorithm and say that "n is definitely not prime." ∎

The idea underlying Algorithm P is that if $n = 1 + 2^k q$ is prime and $x^q \bmod n \neq 1$, the sequence of values

$$x^q \bmod n, \quad x^{2q} \bmod n, \quad x^{4q} \bmod n, \quad \ldots, \quad x^{2^k q} \bmod n$$

will end with 1, and the value just preceding the first appearance of 1 will be $n - 1$. (The only solutions to $y^2 \equiv 1$ (modulo p) are $y \equiv \pm 1$, when p is prime, since $(y - 1)(y + 1)$ must be a multiple of p.)

Exercise 22 proves the basic fact that Algorithm P will be wrong at most $\frac{1}{4}$ of the time, for all n. Actually it will rarely fail at all, for most n; but the crucial point is that the probability of failure is bounded *regardless* of the value of n.

Suppose we invoke Algorithm P repeatedly, choosing x independently and at random whenever we get to step P1. If the algorithm ever reports that n is nonprime, we can say that n definitely isn't prime. But if the algorithm reports 25 times in a row that n is "probably prime," we can say that n is "almost surely prime." For the probability is less than $(1/4)^{25}$ that such a 25-times-in-a-row procedure gives the wrong information about n. This is less than one chance in a quadrillion; even if we certified a billion different primes with such a procedure, the expected number of mistakes would be less than $\frac{1}{1000000}$. It's much more likely that our computer has dropped a bit in its calculations, due to hardware malfunctions or cosmic radiations, than that Algorithm P has repeatedly guessed wrong!

Probabilistic algorithms like this lead us to question our traditional standards of reliability. Do we really *need* to have a rigorous proof of primality? For people unwilling to abandon traditional notions of proof, Gary L. Miller

has demonstrated that if $\sqrt[r]{n}$ is not an integer for any integer $r \geq 2$ (this condition being easily checked), and if a certain well-known conjecture in number theory called the Generalized Riemann Hypothesis can be proved, then either n is prime or there is an $x < 4(\ln n)^2$ such that Algorithm P will discover the nonprimality of n. [See *J. Comp. System Sci.* **13** (1976), 300–317. The constant 4 in this upper bound is due to Peter Weinberger, whose paper on the subject is not yet published.] Thus, we would have a rigorous way to test primality in $O(\log n)^5$ elementary operations, as opposed to a probabilistic method whose running time is $O(\log n)^3$. But one might well ask whether any purported proof of the Generalized Riemann Hypothesis will ever be as reliable as repeated application of Algorithm P on random x's.

A probabilistic test for primality was first proposed in 1974 by R. Solovay and V. Strassen, who devised the interesting but more complicated test described in exercise 23(b). [See *SIAM J. Computing* **6** (1977), 84–85; **7** (1978), 118.] Algorithm P is a simplified version of a procedure due to M. O. Rabin, based in part on ideas of Gary L. Miller [cf. *Algorithms and Complexity*, ed. by J. F. Traub (New York: Academic Press, 1976), 35–36].

A completely different approach to primality testing was discovered in 1980 by Leonard M. Adleman. His highly interesting method is based on the theory of algebraic integers, so it is beyond the scope of this book; but it leads to a non-probabilistic procedure that will decide the primality of any number of up to, say, 250 digits, in a few hours at most. [See L. M. Adleman and R. S. Rumely, to appear.]

Factoring via continued fractions. The factorization procedures we have discussed so far will often balk at numbers of 30 digits or more, and another idea is needed if we are to go much further. Fortunately there is such an idea; in fact, there were two ideas, due respectively to A. M. Legendre and M. Kraitchik, that D. H. Lehmer and R. E. Powers used to devise a new technique many years ago [*Bull. Amer. Math. Soc.* **37** (1931), 770–776]. However, the method was not used at the time because it was comparatively unsuitable for desk calculators. This negative judgment prevailed until the late 1960s, when John Brillhart found that the Lehmer–Powers approach deserved to be resurrected, since it was quite well suited to computer programming. In fact, he and Michael A. Morrison later developed it into the champion of all known methods for factoring large numbers: Their program would handle typical 25-digit numbers in about 30 seconds, and 40-digit numbers in about 50 minutes, on an IBM 360/91 computer [see *Math. Comp.* **29** (1975), 183–205]. In 1970 the method had its first triumphant success, discovering that $2^{128} + 1 = 59649589127497217 \cdot 5704689200685129054721$.

The basic idea is to search for numbers x and y such that

$$x^2 \equiv y^2 \text{ (modulo } N), \qquad 0 < x, y < N, \qquad x \neq y, \qquad x + y \neq N. \tag{17}$$

Fermat's method imposes the stronger requirement $x^2 - y^2 = N$, but actually the congruence (17) is enough to split N into factors: It implies that N is a divisor of $x^2 - y^2 = (x-y)(x+y)$, yet N divides neither $x-y$ nor $x+y$; hence

$\gcd(N, x-y)$ and $\gcd(N, x+y)$ are proper factors of N that can be found by the efficient methods of Section 4.5.2.

One way to discover solutions of (17) is to look for values of x such that $x^2 \equiv a$ (modulo N), for small values of $|a|$. As we will see, it is often a simple matter to piece together solutions of this congruence to obtain solutions of (17). Now if $x^2 = a + kNd^2$ for some k and d, with small $|a|$, the fraction x/d is a good approximation to $\sqrt{kN}$; conversely, if x/d is an especially good approximation to $\sqrt{kN}$, the difference $|x^2 - kNd^2|$ will be small. This observation suggests looking at the continued fraction expansion of $\sqrt{kN}$, since we have seen (in Eq. 4.5.3–12 and exercise 4.5.3–42) that continued fractions yield good rational approximations.

Continued fractions for quadratic irrationalities have many pleasant properties, which are proved in exercise 4.5.3–12. The algorithm below makes use of these properties to derive solutions to the congruence

$$x^2 \equiv (-1)^{e_0} p_1^{e_1} p_2^{e_2} \ldots p_m^{e_m} \pmod{N}. \tag{18}$$

Here we use a fixed set of small primes $p_1 = 2$, $p_2 = 3$, ..., up to p_m; only primes p such that either $p = 2$ or $(kN)^{(p-1)/2} \bmod p \leq 1$ should appear in this list, since other primes will never be factors of the numbers generated by the algorithm (see exercise 14). If $(x_1, e_{01}, e_{11}, \ldots, e_{m1})$, ..., $(x_r, e_{0r}, e_{1r}, \ldots, e_{mr})$ are solutions of (18) such that the vector sum

$$(e_{01}, e_{11}, \ldots, e_{m1}) + \cdots + (e_{0r}, e_{1r}, \ldots, e_{mr}) = (2e'_0, 2e'_1, \ldots, 2e'_m) \tag{19}$$

is even in each component, then

$$x = (x_1 \ldots x_r) \bmod N, \qquad y = \big((-1)^{e'_0} p_1^{e'_1} \ldots p_m^{e'_m}\big) \bmod N \tag{20}$$

yields a solution to (17), except for the possibility that $x \equiv \pm y$. Condition (19) essentially says that the vectors are linearly dependent modulo 2, so we must have a solution to (19) if we have found at least $m + 2$ solutions to (18).

Algorithm E (*Factoring via continued fractions*). Given a positive integer N and a positive integer k such that kN is not a perfect square, this algorithm attempts to discover solutions to the congruence (18) for fixed m, by analyzing the convergents of the continued fraction for $\sqrt{kN}$. (Another algorithm, which uses the outputs to discover factors of N, is the subject of exercise 12.)

E1. [Initialize.] Set $D \leftarrow kN$, $R \leftarrow \lfloor\sqrt{D}\rfloor$, $R' \leftarrow 2R$, $U \leftarrow U' \leftarrow R'$, $V \leftarrow 1$, $V' \leftarrow D - R^2$, $P \leftarrow R$, $P' \leftarrow 1$, $A \leftarrow 0$, $S \leftarrow 0$. (This algorithm follows the general procedure of exercise 4.5.3–12, finding the continued fraction expansion of $\sqrt{kN}$. The variables U, U', V, V', P, P', A, and S represent, respectively, what that exercise calls $R + U_n$, $R + U_{n-1}$, V_n, V_{n-1}, $p_n \bmod N$, $p_{n-1} \bmod N$, A_n, and $n \bmod 2$. We will always have

$$0 < V \leq U \leq R',$$

so the highest precision is needed only for P and P'.)

E2. [Advance U, V, S.] Set $T \leftarrow V$, $V \leftarrow A(U'-U)+V'$, $V' \leftarrow T$, $A \leftarrow \lfloor U/V \rfloor$, $U' \leftarrow U$, $U \leftarrow R' - (U \bmod V)$, $S \leftarrow 1 - S$.

E3. [Factor V.] (Now we have $P^2 - kNQ^2 = (-1)^S V$, for some Q relatively prime to P, by exercise 4.5.3–12(c).) Set $(e_0, e_1, \ldots, e_m) \leftarrow (S, 0, \ldots, 0)$, $T \leftarrow V$. Now do the following, for $1 \le j \le m$: If $T \bmod p_j = 0$, set $T \leftarrow T/p_j$ and $e_j \leftarrow e_j + 1$, and repeat this process until $T \bmod p_j \neq 0$.

E4. [Solution?] If $T = 1$, output the values $(P, e_0, e_1, \ldots, e_m)$, which comprise a solution to (18). (If enough solutions have been generated, we may terminate the algorithm now.)

E5. [Advance P, P'.] If $V \neq 1$, set $T \leftarrow P$, $P \leftarrow (AP + P') \bmod N$, $P' \leftarrow T$, and return to step E2. Otherwise the continued fraction process has started to repeat its cycle, except perhaps for S, so the algorithm terminates. The cycle will usually be so long that this doesn't happen.) ∎

We can illustrate the application of Algorithm E to relatively small numbers by considering the case $N = 197209$, $k = 1$, $m = 3$, $p_1 = 2$, $p_2 = 3$, $p_3 = 5$. The computation proceeds as follows:

	U	V	A	P	S	T	Output
After E1:	888	1	0	444	0	—	
After E4:	876	73	12	444	1	73	
After E4:	882	145	6	5329	0	29	
After E4:	857	37	23	32418	1	37	
After E4:	751	720	1	159316	0	1	$159316^2 \equiv +2^4 \cdot 3^2 \cdot 5^1$
After E4:	852	143	5	191734	1	143	
After E4:	681	215	3	131941	0	43	
After E4:	863	656	1	193139	1	41	
After E4:	883	33	26	127871	0	11	
After E4:	821	136	6	165232	1	17	
After E4:	877	405	2	133218	0	1	$133218^2 \equiv +2^0 \cdot 3^4 \cdot 5^1$
After E4:	875	24	36	37250	1	1	$37250^2 \equiv -2^3 \cdot 3^1 \cdot 5^0$
After E4:	490	477	1	93755	0	53	

Continuing the computation gives 25 outputs in the first 100 iterations; in other words, the algorithm is finding solutions quite rapidly. But some of the solutions are trivial. For example, if the above computation were continued 13 more times, we would obtain the output $197197^2 \equiv 2^4 \cdot 3^2 \cdot 5^0$, which is of no interest since $197197 \equiv -12$. The first two solutions above are already enough to complete the factorization: We have found that

$$(159316 \cdot 133218)^2 \equiv (2^2 \cdot 3^3 \cdot 5^1)^2 \pmod{197209};$$

thus (17) holds with $x = (159316 \cdot 133218) \bmod 197209 = 126308$, $y = 540$. By Euclid's algorithm, $\gcd(126308-540, 197209) = 199$; hence we obtain the pretty factorization

$$197209 = 199 \cdot 991.$$

We can get some understanding of why Algorithm E factors large numbers so successfully by considering a heuristic analysis of its running time, following unpublished ideas that R. Schroeppel communicated to the author in 1975. Let us assume for convenience that $k = 1$. The number of outputs needed to produce a factorization of N will be roughly proportional to the number m of small primes being cast out. Each execution of step E3 takes about order $m \log N$ units of time, so the total running time will be roughly proportional to $m^2 \log N/P$, where P is the probability of a successful output per iteration. If we make the conservative assumption that V is randomly distributed between 0 and $2\sqrt{N}$, the probability P is $(2\sqrt{N})^{-1}$ times the number of integers $< 2\sqrt{N}$ whose prime factors are all in the set $\{p_1, \ldots, p_m\}$. Exercise 29 gives a lower bound for P, from which we conclude that the running time is at most of order

$$\frac{2\sqrt{N}\, m^2 \log N}{m^r/r!}, \qquad \text{where } r = \left\lfloor \frac{\log 2\sqrt{N}}{\log p_m} \right\rfloor. \tag{21}$$

If we let $\ln m = \frac{1}{2}\sqrt{\ln N \ln\ln N}$, we find that $r = \sqrt{\ln N/\ln\ln N} - 1 + O(\log\log\log N/\log\log N)$, assuming that $p_m = O(m \log m)$, so formula (21) reduces to

$$\exp\bigl(2\sqrt{(\ln N)(\ln\ln N)} + O\bigl((\log N)^{1/2}(\log\log N)^{-1/2}(\log\log\log N)\bigr)\bigr).$$

Stating this another way, the running time of Algorithm E is expected to be at most $N^{\epsilon(N)}$ under reasonably plausible assumptions, where the exponent $\epsilon(N) \approx 2\sqrt{\ln\ln N/\ln N}$ goes to 0 as $N \to \infty$.

When N is in a practical range, we should of course be careful not to take such asymptotic estimates too seriously. For example, if $N = 10^{50}$ we have $N^{1/\alpha} = (\lg N)^\alpha$ when $\alpha \approx 4.75$, and the same relation holds for $\alpha \approx 8.42$ when $N = 10^{200}$. The function $N^{\epsilon(N)}$ has an order of growth that is sort of a cross between $N^{1/\alpha}$ and $(\lg N)^\alpha$; but all three of these forms are about the same, unless N is intolerably large. Extensive computational experiments by M. C. Wunderlich have shown that a well-tuned version of Algorithm E performs much better than our estimate would indicate [cf. *Lecture Notes in Math.* **751** (1979), 328–342]; although $2\sqrt{\ln\ln N/\ln N} \approx .41$ when $N = 10^{50}$, he obtained running times of about $N^{.15}$ while factoring thousands of numbers in the range $10^{13} \le N \le 10^{42}$.

Algorithm E begins its attempt to factorize N by essentially replacing N by kN, and this is a rather curious way to proceed (if not downright stupid). Nevertheless, it turns out to be a good idea, since certain values of k will make the V numbers potentially divisible by more small primes, hence they will be more likely to factor completely in step E3. On the other hand, a large value of k will make the V numbers larger, hence they will be less likely to factor completely; we want to balance these tendencies by choosing k wisely. Consider, for example, the divisibility of V by powers of 5. We have $P^2 - kNQ^2 = (-1)^S V$ in step E3, so if 5 divides V we have $P^2 \equiv kNQ^2$ (modulo 5). In this

congruence Q cannot be a multiple of 5, since it is relatively prime to P, so we may write $(P/Q)^2 \equiv kN \pmod 5$. If we assume that P and Q are random relatively prime integers, so that the 24 possible pairs $(P \bmod 5, Q \bmod 5) \neq (0,0)$ are equally likely, the probability that 5 divides V is therefore $\frac{4}{24}$, $\frac{8}{24}$, 0, 0, or $\frac{8}{24}$ according as $kN \bmod 5$ is 0, 1, 2, 3, or 4. Similarly the probability that 25 divides V is 0, $\frac{40}{600}$, 0, 0, $\frac{40}{600}$ respectively, unless kN is a multiple of 25. In general, given an odd prime p with $(kN)^{(p-1)/2} \bmod p = 1$, we find that V is a multiple of p^e with probability $2/(p^{e-1}(p+1))$; and the average number of times p divides V comes to $2p/(p^2-1)$. This analysis, suggested by R. Schroeppel, suggests that the best choice of k is the value that maximizes

$$\sum_{p \text{ prime}} f(p, kN) \log p - \tfrac{1}{2} \log k, \tag{22}$$

where f is the function defined in exercise 28 and the sum is over all primes less than or equal to p_m, for this is essentially the expected value of the logarithm of $\sqrt{N}/T$ when we reach step E4.

Best results will be obtained with Algorithm E when both k and m are well chosen. The proper choice of m can only be made by experimental testing, since the asymptotic analysis we have made is too crude to give sufficiently precise information, and since a variety of refinements to the algorithm tend to have unpredictable effects. For example, we can make an important improvement by comparing step E3 with Algorithm A: The factoring of V can stop whenever we find $T \bmod p_j \neq 0$ and $\lfloor T/p_j \rfloor \leq p_j$, since T will then be either 1 or prime. If T is a prime greater than p_m (it will be at most $p_m^2 + p_m - 1$ in such a case), we can still output $(P, e_0, \ldots, e_m, T)$, since a complete factorization has been obtained. The second phase of the algorithm will use only those outputs whose prime T's have occurred at least twice. This modification gives the effect of a much longer list of primes, without increasing the factorization time. Wunderlich's experiments indicate that $m \approx 150$ works well in the presence of this refinement, when N is in the neighborhood of 10^{40}.

Since step E3 is by far the most time-consuming part of the algorithm, Morrison, Brillhart, and Schroeppel have suggested several ways to abort this step when success becomes improbable: (a) Whenever T changes to a single-precision value, continue only if $\lfloor T/p_j \rfloor > p_j$ and $3^{T-1} \bmod T \neq 1$. (b) Give up if T is still $> p_m^2$ after casting out factors $< \frac{1}{10} p_m$. (c) Cast out factors only up to p_5, say, for batches of 100 or so consecutive V's; continue the factorization later, but only on the V from each batch that has produced the smallest residual T. (Before casting out the factors up to p_5, it is wise to calculate $N \bmod p_1^{f_1} p_2^{f_2} p_3^{f_3} p_4^{f_4} p_5^{f_5}$, where the f's are small enough to make $p_1^{f_1} p_2^{f_2} p_3^{f_3} p_4^{f_4} p_5^{f_5}$ fit in single precision, but large enough to make $N \bmod p_i^{f_i+1} = 0$ unlikely. One single-precision remainder will therefore characterize the value of N modulo five small primes.)

For estimates of the cycle length in the output of Algorithm E, see D. R. Hickerson, *Pacific J. Math.* **46** (1973), 429–432; D. Shanks, *Proc. Boulder Number Theory Conference* (Univ. of Colorado: 1972), 217–224.

Other approaches. A completely different method of factorization, based on composition of binary quadratic forms, has been introduced by Daniel Shanks [*Proc. Symp. Pure Math.* **20** (1971), 415–440]. Like Algorithm B, it will factor a given N in $O(N^{(1/4)+\epsilon})$ steps except under wildly improbable circumstances.

Still another important technique has been suggested by John M. Pollard [*Proc. Cambridge Phil. Soc.* **76** (1974), 521–528]. He shows in essence that each prime factor $\leq m$ can be found in $O(\sqrt{m}(\log mN)^4)$ steps, with a probabilistic algorithm that uses a random x as in Algorithm P and performs suitable convolutions. In this paper Pollard also gives a practical algorithm for discovering prime factors p of N when $p-1$ has no large prime factors. The latter algorithm (see exercise 19) is probably the first thing to try after Algorithms A and B have run too long on a large N.

A survey paper by R. K. Guy, written in collaboration with J. H. Conway, *Proc. Fifth Manitoba Conf. Numer. Math.* (1975), 49–89, gives a unique perspective on these developments.

***A theoretical upper bound.** From the standpoint of computational complexity, we would like to know if there is any method of factorization whose expected running time can be proved to be $O(N^{\epsilon(N)})$, where $\epsilon(N) \to 0$ as $N \to \infty$. We showed that Algorithm E probably has such behavior, but it seems hopeless to find a rigorous proof, because continued fractions are not sufficiently well disciplined. The first proof that a good factorization algorithm exists in this sense was discovered by John Dixon in 1978; Dixon showed, in fact, that it suffices to consider a simplified version of Algorithm E, in which the continued fraction apparatus is removed but the basic idea of (17) remains.

Dixon's method is simply this, assuming that N is known to have at least two distinct prime factors, and that N is not divisible by the first m primes $p_1, p_2, \ldots, p_m$: Choose a random integer X in the range $0 < X < N$, and let $V = X^2 \bmod N$. If $V = 0$, the number $\gcd(X, N)$ is a proper factor of N. Otherwise cast out all of the small prime factors of V as in step E3; in other words, express V in the form

$$V = p_1^{e_1} \ldots p_m^{e_m} T,$$

where T is not divisible by any of the first m primes. If $T = 1$, the algorithm proceeds as in step E4 to output $(X, e_1, \ldots, e_m)$, which represents a solution to (18) with $e_0 = 0$. This process continues with new random values of X until there are sufficiently many outputs to discover a factor of N by the method of exercise 12.

In order to analyze this algorithm, we want to find bounds on (a) the probability that a random X will yield an output, and (b) the probability that a large number of outputs will be required before a factor is found. Let $P(m, N)$ be the probability (a), i.e., the probability that $T = 1$ when X is chosen at random. After M values of X have been tried, we will obtain $MP(m, N)$ outputs, on the average; and the number of outputs has a binomial distribution, so the standard deviation is less than the square root of the mean. The probability (b) is fairly

easy to deal with, since exercise 13 proves that the algorithm needs more than $m + k$ outputs with probability $\le 2^{-k}$.

Exercise 30 proves that $P(m, N) \ge m^r/(r!N)$ when $r = 2\lfloor \log N/(2 \log p_m) \rfloor$, so we can estimate the running time as we did in (21) but with the quantity $2\sqrt{N}$ replaced by N. This time we choose $\ln m = \sqrt{(\ln N \ln\ln N)/2}$, so that

$$r = \sqrt{\frac{2 \ln N}{\ln\ln N}} - 1 + O\left(\frac{\log\log\log N}{\log\log N}\right),$$

$$\frac{m^r}{r!\,N} = \exp\left(-\sqrt{2 \ln N \ln\ln N} + O(r \log\log\log N)\right).$$

We will choose M so that $Mm^r/(r!\,N) \ge 4m$; thus the expected number of outputs $MP(m, N)$ will be at least $4m$. The running time of the algorithm is of order $Mm \log N$, plus $O(m^3)$ steps for exercise 12; it turns out that $O(m^3)$ is less than $Mm \log N$, which is

$$\exp\left(\sqrt{8(\ln N)(\ln\ln N)} + O\big((\log N)^{1/2}(\log\log N)^{-1/2}(\log\log\log N)\big)\right).$$

The probability that this method fails to find a factor is negligibly small, since the probability is at most $e^{-m/2}$ that fewer than $2m$ outputs are obtained (see exercise 31), while the probability is at most 2^{-m} that no factors are found from the first $2m$ outputs, and $m \gg \ln N$. We have proved the following slight strengthening of Dixon's original theorem:

Theorem D. *There is an algorithm whose running time is $O(N^{\epsilon(N)})$, where $\epsilon(N) = c\sqrt{\ln\ln N/\ln N}$ and c is any constant greater than $\sqrt{8}$, that finds a nontrivial factor of N with probability $1 - O(1/N)$, whenever N has at least two distinct prime divisors.* ∎

Secret factors. Worldwide interest in the problem of factorization increased dramatically in 1977, when R. L. Rivest, A. Shamir, and L. Adleman discovered a way to encode messages that can apparently be decoded only by knowing the factors of a large number N, even though the method of encoding is known to everyone. Since a significant number of the world's greatest mathematicians have been unable to find efficient methods of factoring, this scheme [*CACM* **21** (1979), 120–126] almost certainly provides a secure way to protect confidential data and communications in computer networks.

Let us imagine a small electronic device called an *RSA box* that has two large prime numbers p and q stored in its memory. We will assume that $p-1$ and $q-1$ are not divisible by 3. The RSA box is connected somehow to a computer, and it has told the computer the product $N = pq$; however, no human being will be able to discover the values of p and q except by factoring N, since the RSA box is cleverly designed to self-destruct if anybody tries to tamper with it. In other words, it will erase its memory if it is jostled or if it is subjected to any radiation that could change or read out the data stored inside. Furthermore, the RSA box is sufficiently reliable that it never needs to be maintained; we simply

would discard it and buy another, if an emergency arose or if it wore out. The prime factors p and q were generated by the RSA box itself, using some scheme based on truly random phenomena in nature like cosmic rays. The important point is that *nobody* knows p or q, not even a person or organization that owns or has access to this RSA box; there is no point in bribing or blackmailing anyone or holding anybody hostage in order to discover N's factors.

To send a secret message to the owner of an RSA box whose product number is N, you break the message up into a sequence of numbers $(x_1, \ldots, x_k)$, where each x_i is between 0 and N, then you transmit the numbers

$$(x_1^3 \bmod N,\ \ldots,\ x_k^3 \bmod N).$$

The RSA box, knowing p and q, can decode the message, because it has precomputed a number $d < N$ such that $3d \equiv 1$ (modulo $(p-1)(q-1)$); it can now compute $(x^3)^d \bmod N = x$ in a reasonable amount of time, using the method of Section 4.6.3. Naturally the RSA box keeps this magic number d to itself; in fact, the RSA box might choose to remember only d instead of p and q, because its only duties after having computed N are to protect its secrets and to take cube roots mod N.

If $x < \sqrt[3]{N}$, the above encoding scheme is ineffective, since $x^3 \bmod N = x^3$ and the cube root will easily be found. The logarithmic law of leading digits in Section 4.2.4 implies that the leading place x_1 of a k-place message $(x_1, \ldots, x_k)$ will be less than $\sqrt[3]{N}$ about $\frac{1}{3}$ of the time, so this is a problem that needs to be resolved. Exercise 32 presents one way to do this.

The security of the RSA encoding scheme relies on the fact that nobody has been able to discover how to take cube roots mod N without knowing N's factors. It seems likely that no such method will be found, but we cannot be absolutely sure. So far all that can be said for certain is that all of the ordinary ways to discover cube roots will fail. For example, there is essentially no point in trying to compute the number d as a function of N; the reason is that if d is known, or in fact if any number m of reasonable size is known such that $x^m \bmod N = 1$ holds for a significant number of x's, then we can find the factors of N in a few more steps (see exercise 34). Thus, any method of attack based explicitly or implicitly on finding such an m can be no better than factoring.

The numbers p and q shouldn't merely be "random" primes in order to make the RSA scheme effective. We have mentioned that $p-1$ and $q-1$ should not be divisible by 3, since we want to ensure that unique cube roots exist modulo N. Another condition is that $p-1$ should have at least one very large prime factor, and so should $q-1$; otherwise N can be factored using the algorithm of exercise 19. In fact, that algorithm essentially relies on finding a fairly small number m with the property that $x^m \bmod N$ is frequently equal to 1, and we have just seen that such an m is dangerous. When $p-1$ and $q-1$ have large prime factors p_1 and q_1, the theory in exercise 34 implies that m is either a multiple of $p_1 q_1$ (hence m will be hard to discover) or the probability that $x^m \equiv 1$ will be less than $1/p_1 q_1$ (hence $x^m \bmod N$ will almost never be 1).

Besides this condition, we don't want p and q to be close to each other, lest Algorithm D succeed in discovering them; in fact, we don't want the ratio p/q to be near a simple fraction, otherwise Lehman's generalization of Algorithm C could find them.

The following procedure for generating p and q is almost surely unbreakable: Start with a truly random number p_0 between, say, 10^{80} and 10^{81}. Search for the first prime number p_1 greater than p_0; this will require testing about $\frac{1}{2}\ln p_0 \approx 90$ odd numbers, and it will be sufficient to have p_1 a "probable prime" with probability $> 1 - 2^{-100}$ after 50 trials of Algorithm P. Then choose another truly random number p_2 between, say, 10^{39} and 10^{40}. Search for the first prime number p of the form $kp_1 + 1$ where $k \geq p_2$, k is even, and $k \equiv p_1$ (modulo 3). This will require testing about $\frac{1}{6}\ln p_1 p_2 \approx 45$ numbers before a prime p is found. The prime p will be about 120 digits long; a similar construction can be used to find a prime q about 130 digits long. For extra security, it is probably advisable to check that neither $p + 1$ nor $q + 1$ consists entirely of rather small prime factors (see exercise 20). The product $N = pq$, whose order of magnitude will be about 10^{250}, now meets all of our requirements, and it is inconceivable at this time that such an N could be factored.

For example, suppose we knew a method that could factor a 250-digit number N in $N^{0.1}$ microseconds. This amounts to 10^{25} microseconds, and there are only 31,556,952,000,000 μs per year, so we would need more than 3×10^{11} years of CPU time to complete the factorization. Even if a government agency purchased 10 billion computers and set them all to working on this problem, it would take more than 31 years before one of them would crack N into factors; meanwhile the fact that the government had purchased so many specialized machines would leak out, and people would start using 300-digit N's.

Since the encoding method $x \mapsto x^3 \bmod N$ is known to everyone, there are additional advantages besides the fact that the code can be cracked only by the RSA box. Such "public key" systems were first considered by W. Diffie and M. E. Hellman in *IEEE Trans.* **IT-22** (1976), 644–651. As an example of what can be done when the encoding method is public knowledge, suppose that Alice wants to communicate with Bill via electronic mail, and suppose each of them wants the letters to be *signed* so that the receiver can be sure that nobody else is forging any messages. Let $E_A(M)$ be the encoding function for messages M sent to Alice, let $D_A(M)$ be the decoding done by Alice's RSA box, and let $E_B(M)$, $D_B(M)$ be the corresponding encoding and decoding functions for Bill's RSA box. Then Alice can send a signed message by affixing her name and the date to some confidential message, then transmitting $E_B\big(D_A(M)\big)$ to Bill, using her machine to compute $D_A(M)$. When Bill gets this message, his RSA box converts it to $D_A(M)$, and he knows E_A so he can compute $M = E_A\big(D_A(M)\big)$. This should convince him that the message did indeed come from Alice; nobody else could have sent the message $D_A(M)$.

We might ask, how do Alice and Bill know each other's encoding functions E_A and E_B? It wouldn't do simply to have them stored in a public file, since some Charlie could tamper with that file, substituting an N that he has computed

by himself; Charlie could then surreptitiously intercept and decode a private message before Alice or Bill would discover that something is amiss. The solution is to keep the product numbers N_A and N_B in a special public directory that has its own RSA box and its own widely publicized product number N_D. When Alice wants to know how to communicate with Bill, she asks the directory for Bill's product number; the directory computer sends her a *signed* message giving the value of N_B. Nobody can forge such a message, so it must be legitimate.

An interesting alternative to the RSA scheme has been proposed by Michael Rabin [MIT Lab. for Comp. Sci., report TR-212 (1979)], who suggests encoding by the function $x^2 \bmod N$ instead of $x^3 \bmod N$. In this case the decoding mechanism, which we can call a SQRT box, returns four different messages; the reason is that four different numbers have the same square modulo N, namely x, $-x$, $fx \bmod N$, and $(-fx) \bmod N$, where $f = (p^{q-1} - q^{p-1}) \bmod N$. If we agree in advance that x is even, or that $x < \frac{1}{2}N$, then the ambiguity drops to two messages, presumably only one of which makes any sense. The ambiguity can in fact be eliminated entirely, as shown in exercise 35. Rabin's scheme has the important property that it is provably as difficult to find square roots mod N as to find the factorization $N = pq$; for by taking the square root of $x^2 \bmod N$ when x is chosen at random, we have probability $\frac{1}{2}$ of finding a value y such that $x^2 \equiv y^2$ and $x \not\equiv \pm y$, after which $\gcd(x, y) = p$ or q. However, the system has a fatal flaw that does not seem to be present in the RSA scheme (see exercise 33): Anyone with access to a SQRT box can easily determine the factors of its N. This not only permits cheating by dishonest employees, or threats of extortion, it also allows people to reveal their p and q, after which they might claim that their "signature" on some transmitted document was a forgery. Thus it is clear that the goal of secure communication leads to subtle problems quite different from those we usually face in the design and analysis of algorithms.

The largest known primes. We have discussed several computational methods elsewhere in this book that require the use of large prime numbers, and the techniques just described can be used to discover primes of up to, say, 25 digits or fewer, with relative ease. Table 1 shows the ten largest primes that are less than the word size of typical computers. (Some other useful primes appear in the answer to exercise 4.6.4–57.)

Actually much larger primes of special forms are known, and it is occasionally important to find primes that are as large as possible. Let us therefore conclude this section by investigating the interesting manner in which the largest explicitly known primes have been discovered. Such primes are of the form $2^n - 1$, for various special values of n, and so they are especially suited to certain applications of binary computers.

A number of the form $2^n - 1$ cannot be prime unless n is prime, since $2^{uv} - 1$ is divisible by $2^u - 1$. In 1644, Marin Mersenne astonished his contemporaries by stating, in essence, that the numbers $2^p - 1$ are prime for $p = 2$, 3, 5, 7, 13, 17, 19, 31, 67, 127, 257, and for no other p less than 257. (This statement appeared in connection with a discussion of perfect numbers in the preface to his *Cogitata*

Table 1

The ten largest primes less than N are $N - a_1, \ldots, N - a_{10}$.

Physico-Mathematics. Curiously, he also made the following remark: "To tell if a given number of 15 or 20 digits is prime or not, all time would not suffice for the test, whatever use is made of what is already known.") Mersenne, who had corresponded frequently with Fermat, Descartes, and others about similar topics in previous years, gave no proof of his assertions, and for over 200 years nobody knew whether he was correct or not. Euler showed that $2^{31} - 1$ is prime in 1772, after having tried unsuccessfully to prove this in previous years. About 100 years later, É. Lucas discovered that $2^{127} - 1$ is prime, but $2^{67} - 1$ is not; therefore Mersenne was not completely accurate. Then I. M. Pervushin proved in 1883 that $2^{61} - 1$ is prime [cf. *Istoriko-Mat. Issledovaniĭa* **6** (1953), 559], and this touched off speculation that Mersenne had only made a copying error, writing 67 for 61. Eventually other errors in Mersenne's statement were discovered; R. E. Powers [*AMM* **18** (1911), 195] found that $2^{89} - 1$ is prime, as had been conjectured by some earlier writers, and three years later he proved that $2^{107} - 1$ also is prime. M. Kraitchik showed in 1922 that $2^{257} - 1$ is *not* prime [cf. *Recherches sur la Théorie des Nombres* (Paris: 1924), 21].

At any rate, numbers of the form $2^p - 1$ are now called *Mersenne numbers*, and it is known that the first 27 Mersenne primes are obtained for p equal to

$$\begin{aligned} &2, 3, 5, 7, 13, 17, 19, 31, 61, 89, 107, 127, 521, 607, 1279, 2203\,2281, \\ &3217, 4253, 4423, 9689, 9941, 11213, 19937, 21701, 23209, 44497, \end{aligned} \tag{23}$$

The 24th of these was found by Bryant Tuckerman [*Proc. Nat. Acad. Sci.* **68** (1971), 2319–2320], and the 25th was found in 1978 by Laura Nickel and Curt Noll. Shortly afterwards, Noll found the 26th, and David Slowinski harnessed a CRAY-I computer to the task of discovering the 27th; see *J. Recreational Math.* **11** (1979), 258–261. Note that the prime $8191 = 2^{13} - 1$ does not occur in (23); Mersenne had stated that $2^{8191} - 1$ is prime, and others had conjectured that any Mersenne prime could perhaps be used in the exponent.

Since $2^{44497} - 1$ is a 13,395-digit number, it is clear that some special techniques have been used to prove that it is prime. An efficient way to test the primality of a given Mersenne number $2^p - 1$ was first devised by É. Lucas [*Amer. J. Math.* **1** (1878), 184–239, 289–321, especially p. 316] and improved by D. H. Lehmer [*Annals of Math.* **31** (1930), 419–448, especially p. 443]. The Lucas–Lehmer test, which is a special case of the method now used for testing the primality of n when the factors of $n + 1$ are known, is the following:

Theorem L. *Let q be an odd prime, and define the sequence $\langle L_n \rangle$ by the rule*

$$L_0 = 4, \qquad L_{n+1} = (L_n^2 - 2) \bmod (2^q - 1). \tag{24}$$

Then $2^q - 1$ is prime if and only if $L_{q-2} = 0$.

For example, $2^3 - 1$ is prime since $L_1 = (4^2 - 2) \bmod 7 = 0$. This test is particularly well suited to binary computers, using multiple-precision arithmetic when q is large, since calculation mod $(2^q - 1)$ is so convenient; cf. Section 4.3.2.

Proof. We will prove Theorem L using only very simple principles of number theory, by investigating several features of recurring sequences that are of independent interest. Consider the sequences $\langle U_n \rangle$ and $\langle V_n \rangle$ defined by

$$\begin{aligned} U_0 &= 0, \quad U_1 = 1, \quad U_{n+1} = 4U_n - U_{n-1}; \\ V_0 &= 2, \quad V_1 = 4, \quad V_{n+1} = 4V_n - V_{n-1}. \end{aligned} \tag{25}$$

The following equations are readily proved by induction:

$$V_n = U_{n+1} - U_{n-1}; \tag{26}$$

$$U_n = \big((2+\sqrt{3})^n - (2-\sqrt{3})^n\big)/\sqrt{12}; \tag{27}$$

$$V_n = (2+\sqrt{3})^n + (2-\sqrt{3})^n; \tag{28}$$

$$U_{m+n} = U_m U_{n+1} - U_{m-1} U_n. \tag{29}$$

Let us now prove an auxiliary result, when p is prime and $e \geq 1$:

$$\text{if} \quad U_n \equiv 0 \text{ (modulo } p^e) \quad \text{then} \quad U_{np} \equiv 0 \text{ (modulo } p^{e+1}). \tag{30}$$

This follows from the more general considerations of exercise 3.2.2–11, but a direct proof for sequence (25) can be given. Assume that $U_n = bp^e$, $U_{n+1} = a$. By (29) and (25), $U_{2n} = bp^e(2a - 4bp^e) \equiv (2a)U_n$ (modulo p^{e+1}), while we have $U_{2n+1} = U_{n+1}^2 - U_n^2 \equiv a^2$. Similarly, $U_{3n} = U_{2n+1}U_n - U_{2n}U_{n-1} \equiv (3a^2)U_n$ and $U_{3n+1} = U_{2n+1}U_{n+1} - U_{2n}U_n \equiv a^3$. In general,

$$U_{kn} \equiv (ka^{k-1})U_n \quad \text{and} \quad U_{kn+1} \equiv a^k \quad \text{(modulo } p^{e+1}),$$

so (30) follows if we take $k = p$.

From formulas (27) and (28) we can obtain other expressions for U_n and V_n, expanding $(2 \pm \sqrt{3})^n$ by the binomial theorem:

$$U_n = \sum_k \binom{n}{2k+1} 2^{n-2k-1} 3^k, \qquad V_n = \sum_k \binom{n}{2k} 2^{n-2k+1} 3^k. \tag{31}$$

Now if we set $n = p$, where p is an odd prime, and if we use the fact that $\binom{p}{k}$ is a multiple of p except when $k = 0$ or $k = p$, we find that

$$U_p \equiv 3^{(p-1)/2}, \qquad V_p \equiv 4 \qquad \text{(modulo } p). \tag{32}$$

If $p \neq 3$, Fermat's theorem tells us that $3^{p-1} \equiv 1$; hence $(3^{(p-1)/2} - 1) \times (3^{(p-1)/2} + 1) \equiv 0$, and $3^{(p-1)/2} \equiv \pm 1$. When $U_p \equiv -1$, we have $U_{p+1} = 4U_p - U_{p-1} = 4U_p + V_p - U_{p+1} \equiv -U_{p+1}$; hence $U_{p+1} \bmod p = 0$. When $U_p \equiv +1$, we have $U_{p-1} = 4U_p - U_{p+1} = 4U_p - V_p - U_{p-1} \equiv -U_{p-1}$; hence $U_{p-1} \bmod p = 0$. We have proved that, for all primes p, there is an integer $\epsilon(p)$ such that

$$U_{p+\epsilon(p)} \bmod p = 0, \qquad |\epsilon(p)| \leq 1. \tag{33}$$

Now if N is any positive integer, and if $m = m(N)$ is the smallest positive integer such that $U_{m(N)} \bmod N = 0$, we have

$$U_n \bmod N = 0 \qquad \text{if and only if} \qquad n \text{ is a multiple of } m(N). \tag{34}$$

(This number $m(N)$ is called the "rank of apparition" of N in the sequence.) To prove (34), observe that the sequence U_m, U_{m+1}, U_{m+2}, ... is congruent (modulo N) to aU_0, aU_1, aU_2, ..., where $a = U_{m+1} \bmod N$ is relatively prime to N because $\gcd(U_n, U_{n+1}) = 1$.

With these preliminaries out of the way, we are ready to prove Theorem L. By (24) and induction,

$$L_n = V_{2^n} \bmod (2^q - 1). \tag{35}$$

Furthermore, the identity $2U_{n+1} = 4U_n + V_n$ implies that $\gcd(U_n, V_n) \le 2$, since any common factor of U_n and V_n must divide U_n and $2U_{n+1}$, while $\gcd(U_n, U_{n+1}) = 1$. So U_n and V_n have no odd factor in common, and if $L_{q-2} = 0$ we must have

$$U_{2^{q-1}} = U_{2^{q-2}} V_{2^{q-2}} \equiv 0 \pmod{2^q - 1},$$
$$U_{2^{q-2}} \not\equiv 0 \pmod{2^q - 1}.$$

Now if $m = m(2^q - 1)$ is the rank of apparition of $2^q - 1$, it must be a divisor of 2^{q-1} but not of 2^{q-2}; thus $m = 2^{q-1}$. We will prove that $n = 2^q - 1$ must therefore be prime: Let the factorization of n be $p_1^{e_1} \ldots p_r^{e_r}$. All primes p_j are greater than 3, since n is odd and congruent to $(-1)^q - 1 = -2$ (modulo 3). From (30), (33), and (34) we know that $U_t \equiv 0$ (modulo $2^q - 1$), where

$$t = \operatorname{lcm}\bigl(p_1^{e_1-1}(p_1 + \epsilon_1), \ldots, p_r^{e_r-1}(p_r + \epsilon_r)\bigr),$$

and each ϵ_j is ± 1. It follows that t is a multiple of $m = 2^{q-1}$. Let $n_0 = \prod_{1 \le j \le r} p_j^{e_j-1}(p_j + \epsilon_j)$; we have $n_0 \le \prod_{1 \le j \le r} p_j^{e_j-1}(p_j + \frac{1}{5}p_j) = (\frac{6}{5})^r n$. Also, because $p_j + \epsilon_j$ is even, $t \le n_0/2^{r-1}$, since a factor of two is lost each time the least common multiple of two even numbers is taken. Combining these results, we have $m \le t \le 2(\frac{3}{5})^r n < 4(\frac{3}{5})^r m < 3m$; hence $r \le 2$ and $t = m$ or $t = 2m$, a power of 2. Therefore $e_1 = 1$, $e_r = 1$, and if n is not prime we must have $n = 2^q - 1 = (2^k + 1)(2^l - 1)$ where $2^k + 1$ and $2^l - 1$ are prime. The latter factorization is obviously impossible when q is odd, so n is prime.

Conversely, suppose that $n = 2^q - 1$ is prime; we must show that $V_{2^{q-2}} \equiv 0$ (modulo n). For this purpose it suffices to prove that $V_{2^{q-1}} \equiv -2$ (modulo n), since $V_{2^{q-1}} = (V_{2^{q-2}})^2 - 2$. Now

$$V_{2^{q-1}} = \bigl((\sqrt{2} + \sqrt{6})/2\bigr)^{n+1} + \bigl((\sqrt{2} - \sqrt{6})/2\bigr)^{n+1}$$
$$= 2^{-n} \sum_k \binom{n+1}{2k} \sqrt{2}^{\,n+1-2k} \sqrt{6}^{\,2k} = 2^{(1-n)/2} \sum_k \binom{n+1}{2k} 3^k.$$

Since n is prime, the binomial coefficient

$$\binom{n+1}{2k} = \binom{n}{2k} + \binom{n}{2k-1}$$

is divisible by n except when $k = 0$ and $k = (n+1)/2$; hence

$$2^{(n-1)/2} V_{2q-1} \equiv 1 + 3^{(n+1)/2} \text{ (modulo } n).$$

Here $2 \equiv (2^{(q+1)/2})^2$, so $2^{(n-1)/2} \equiv (2^{(q+1)/2})^{(n-1)} \equiv 1$ by Fermat's theorem. Finally, by a simple case of the law of quadratic reciprocity (cf. exercise 23), $3^{(n-1)/2} \equiv -1$, since $n \bmod 3 = 1$ and $n \bmod 4 = 3$. This means $V_{2q-1} \equiv -2$, so $V_{2q-2} \equiv 0$. ∎

The world's largest explicitly known prime numbers have always been Mersenne primes, at least from 1772 until 1980 when this book was written. But the situation will probably change soon, since Mersenne primes are getting harder to find, and since exercise 27 presents an efficient test for primes of other forms.

EXERCISES

1. [*10*] If the sequence d_0, d_1, d_2, ... of trial divisors in Algorithm A contains a number that is not prime, why will it never appear in the output?

2. [*15*] If it is known that the input N to Algorithm A is equal to 3 or more, could step A2 be eliminated?

3. [*M20*] Show that there is a number P with the following property: If $1000 \le n \le 1000000$, then n is prime if and only if $\gcd(n, P) = 1$.

4. [*M29*] In the notation of exercise 3.1–7 and Section 1.2.11.3, prove that the average value of the least n such that $X_n = X_{l(n)-1}$ lies between $1.5\,Q(m) - 0.5$ and $1.625\,Q(m) - 0.5$.

5. [*21*] Use Fermat's method (Algorithm D) to find the factors of 10541 by hand, when the moduli are 3, 5, 7, and 8.

6. [*M24*] If p is an odd prime and if N is not a multiple of p, prove that the number of integers x such that $0 \le x < p$ and $x^2 - N \equiv y^2$ (modulo p) has a solution y is equal to $(p \pm 1)/2$.

7. [*25*] Discuss the problems of programming the sieve of Algorithm D on a binary computer when the table entries for modulus m_i do not exactly fill an integral number of memory words.

▶ **8.** [*23*] (*The "sieve of Eratosthenes,"* 3rd century B.C.) The following procedure evidently discovers all odd prime numbers less than a given integer N, since it removes all the nonprime numbers: Start with all the odd numbers less than N; then successively strike out the multiples p_k^2, $p_k(p_k+2)$, $p_k(p_k+4)$, ..., of the kth prime p_k, for $k = 2$, 3, 4, ..., until reaching a prime p_k with $p_k^2 > N$.

Show how to adapt the procedure just described into an algorithm that is directly suited to efficient computer calculation, using no multiplication.

9. [*M25*] Let n be an odd number, $n \geq 3$. Show that if the number $\lambda(n)$ of Theorem 3.2.1.2B is a divisor of $n-1$ but not equal to $n-1$, then n must have the form $p_1 p_2 \ldots p_t$ where the p's are distinct primes and $t \geq 3$.

▶ **10.** [*M26*] (John Selfridge.) Prove that if, for each prime divisor p of $n-1$, there is a number x_p such that $x_p^{(n-1)/p} \bmod n \neq 1$ but $x_p^{n-1} \bmod n = 1$, then n is prime.

11. [*M20*] What outputs does Algorithm E give when $N = 197209$, $k = 5$, $m = 1$? [*Hint:* $\sqrt{5 \cdot 197209} = 992 + /\overline{1, 495, 2, 495, 1, 1984}/$.]

▶ **12.** [*M28*] Design an algorithm that uses the outputs of Algorithm E to find a proper factor of N, provided that Algorithm E has produced enough outputs to deduce a solution of (17).

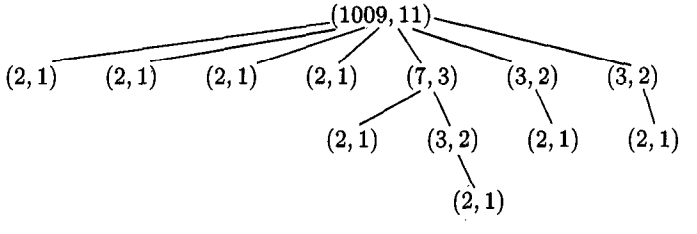
13. [*HM25*] (J. D. Dixon.) Prove that whenever the algorithm of exercise 12 is presented with a solution $(x, e_0, \ldots, e_m)$ whose exponents are linearly dependent modulo 2 on the exponents of previous solutions, the probability is 2^{1-d} that a factorization will be found, when n has d distinct prime factors and x is chosen at random.

14. [*M20*] Prove that the number T in step E3 of Algorithm E will never be a multiple of an odd prime p for which $(kN)^{(p-1)/2} \bmod p > 1$.

▶ **15.** [*M34*] (Lucas and Lehmer.) Let P and Q be relatively prime integers, and let $U_0 = 0$, $U_1 = 1$, $U_{n+1} = PU_n - QU_{n-1}$ for $n \geq 1$. Prove that if N is a positive integer relatively prime to $2P^2 - 8Q$, and if $U_{N+1} \bmod N = 0$, while $U_{(N+1)/p} \bmod N \neq 0$ for each prime p dividing $N+1$, then N is prime. (This gives a test for primality when the factors of $N+1$ are known instead of the factors of $N-1$. We can evaluate U_m in $O(\log m)$ steps; cf. exercise 4.6.3–26.) [*Hint:* See the proof of Theorem L.]

16. [*M50*] Are there infinitely many Mersenne primes?

17. [*M25*] (V. R. Pratt.) A complete proof of primality by the converse of Fermat's theorem takes the form of a tree whose nodes have the form (q, x), where q and x are positive integers satisfying the following arithmetic conditions: (i) If $(q_1, x_1), \ldots, (q_t, x_t)$ are the sons of (q, x) then $q = q_1 \ldots q_t + 1$. [In particular, if (q, x) has no sons, then $q = 2$.] (ii) If (r, y) is a son of (q, x), then $x^{(q-1)/r} \bmod q \neq 1$. (iii) For each node (q, x), we have $x^{q-1} \bmod q = 1$. From these conditions it follows that q is prime and x is a primitive root modulo q, for all nodes (q, x). [For example, the tree



demonstrates that 1009 is prime.] Prove that such a tree with root (q, x) has at most $f(q)$ nodes, where f is a rather slowly growing function.

▶ **18.** [*HM23*] Give a heuristic proof of (7), analogous to the text's derivation of (6). What is the approximate probability that $p_{t-1} \leq \sqrt{p_t}$?

▸ **19.** [*M25*] (J. M. Pollard.) Show how to compute a number M that is divisible by all primes p such that $p - 1$ is a divisor of some given number D. [*Hint:* Consider numbers of the form $a^n - 1$.] Such an M is useful in factorization, for by computing $\gcd(M, N)$ we may discover a factor of N. Extend this idea to an efficient method that has high probability of discovering prime factors p of a given large number N, when all prime power factors of $p - 1$ are less than 10^3 except for at most one prime factor less than 10^5. [For example, the second-largest prime dividing (14) would be detected by this method, since it is $1 + 2^4 \cdot 5^2 \cdot 67 \cdot 107 \cdot 199 \cdot 41231$.]

20. [*M40*] Consider exercise 19 with $p + 1$ replacing $p - 1$.

21. [*M49*] (R. K. Guy.) Let $m(p)$ be the number of iterations required by Algorithm B to cast out the prime factor p. Is $m(p) = O(\sqrt{p \log p})$ as $p \to \infty$?

▸ **22.** [*M30*] (M. O. Rabin.) Let p_n be the probability that Algorithm P guesses wrong, given n. Show that $p_n < \frac{1}{4}$ for all n.

23. [*M35*] The *Jacobi symbol* $(\frac{p}{q})$ is defined to be -1, 0, or $+1$ for all integers $p \geq 0$ and all odd integers $q > 1$ by the rules $(\frac{p}{q}) \equiv p^{(q-1)/2}$ (modulo q) when q is prime; $(\frac{p}{q}) = (\frac{p}{q_1}) \ldots (\frac{p}{q_t})$ when q is the product $q_1 \ldots q_t$ of t primes (not necessarily distinct).

a) Prove that $(\frac{p}{q})$ satisfies the following relationships, hence it can be computed efficiently: $(\frac{0}{q}) = 0$; $(\frac{1}{q}) = 1$; $(\frac{p}{q}) = (\frac{p \bmod q}{q})$; $(\frac{2}{q}) = (-1)^{(q^2-1)/8}$; $(\frac{p_1 p_2}{q}) = (\frac{p_1}{q})(\frac{p_2}{q})$; $(\frac{p}{q}) = (-1)^{(p-1)(q-1)/4}(\frac{q}{p})$ if both p and q are odd. [The latter law, which is a reciprocity relation reducing the evaluation of $(\frac{p}{q})$ to the evaluation of $(\frac{q}{p})$, has been proved in exercise 1.2.4–47(d) when both p and q are prime, so you may assume its validity in that special case.]

b) (Solovay and Strassen.) Prove that if n is odd but not prime, the number of integers x such that $1 \leq x < n$ and $0 \neq (\frac{x}{n}) \equiv x^{(n-1)/2}$ (modulo n) is at most $\frac{1}{2}\varphi(n)$. (Thus, the following testing procedure correctly determines whether or not a given n is prime, with probability $\geq \frac{1}{2}$ for all fixed n: "Generate x at random with $1 \leq x < n$. If $0 \neq (\frac{x}{n}) \equiv x^{(n-1)/2}$ (modulo n), say that n is probably prime, otherwise say that n is definitely not prime.")

c) (L. Monier.) Prove that if n and x are numbers for which Algorithm P concludes that "n is probably prime", then $0 \neq (\frac{x}{n}) \equiv x^{(n-1)/2}$ (modulo n). [Hence Algorithm P is always superior to the test in (b).]

▸ **24.** [*M25*] (L. Adleman.) When $n > 1$ and $x > 1$ are integers, n odd, let us say that n "passes the x test of Algorithm P" if either $x = n$ or if steps P2–P5 lead to the conclusion that n is probably prime. Prove that, for any N, there exists a set of positive integers $x_1, \ldots, x_m \leq N$ with $m \leq \lfloor \lg N \rfloor$ such that a positive odd integer in the range $1 < n \leq N$ is prime if and only if it passes the x test of Algorithm P for $x = x_1 \bmod n, \ldots, x = x_m \bmod n$. Thus, the probabilistic test for primality can in principle be converted into an efficient test that leaves nothing to chance. (You need not show how to compute the x_j efficiently; just prove that they exist.)

25. [*HM41*] (B. Riemann.) Prove that

$$\pi(x) = \int_2^x dt/\ln t + \sum \int_{-\infty}^{\sigma} e^{(t+i\tau)\ln x} dt/(t + i\tau) + O(1),$$

where the sum is over all complex $\sigma + i\tau$ such that $\tau \neq 0$ and $\zeta(\sigma + i\tau) = 0$.

▶ **26.** [*M25*] (H. C. Pocklington, 1914.) Let $N = fr + 1 > 1$, where $0 < r \leq f + 1$. Prove that N is prime if, for every prime divisor p of f, there is an integer x such that $x^{N-1} \bmod N = \gcd(x^{(N-1)/p} - 1, N) = 1$.

▶ **27.** [*M30*] Show that there is a way to test numbers of the form $5 \cdot 2^n + 1$ for primality, using the same amount of computer time as the Lucas–Lehmer test for Mersenne primes in Theorem L, except for an additional $O(n \log n)$ seconds.

28. [*M27*] Given a prime p and a positive integer d, what is the value of $f(p, d)$, the average number of times p divides $A^2 - dB^2$, when A and B are random integers that are independent except for the condition $\gcd(A, B) = 1$?

29. [*M25*] Prove that the number of positive integers $\leq n$ whose prime factors are all contained in a given set of primes $\{p_1, \ldots, p_m\}$ is at least $m^r/r!$, when $r = \lfloor \log n / \log p_m \rfloor$ and $p_1 < \cdots < p_m$.

30. [*HM35*] (J. D. Dixon and Claus-Peter Schnorr.) Let $p_1 < \cdots < p_m$ be primes that do not divide the odd number N, and let r be an even integer $\leq \log N / \log p_m$. Prove that the number of integers X in the range $0 \leq X < N$ such that $X^2 \bmod N = p_1^{e_1} \ldots p_m^{e_m}$ is at least $m^r/r!$. [*Hint:* Let the prime factorization of N be $q_1^{f_1} \ldots q_d^{f_d}$. Show that a sequence of exponents $(e_1, \ldots, e_m)$ leads to 2^d solutions X whenever we have $e_1 + \cdots + e_m \leq r$ and $p_1^{e_1} \ldots p_m^{e_m}$ is a quadratic residue modulo q_i for $1 \leq i \leq d$. Such exponent sequences can be obtained as ordered pairs $(e'_1, \ldots, e'_m; e''_1, \ldots, e''_m)$ where $e'_1 + \cdots + e'_m \leq \frac{1}{2}r$ and $e''_1 + \cdots + e''_m \leq \frac{1}{2}r$ and

$$(p_1^{e'_1} \ldots p_m^{e'_m})^{(q_i-1)/2} \equiv (p_1^{e''_1} \ldots p_m^{e''_m})^{(q_i-1)/2} \text{ (modulo } q_i)$$

for $1 \leq i \leq d$.]

31. [*M20*] Use formula 3.5–33 to show that the probability is less than $e^{-m/2}$ that Dixon's factorization algorithm (as described preceding Theorem D) obtains fewer than $2m$ outputs.

▶ **32.** [*M21*] Show how to modify the RSA encoding scheme so that there is no problem with messages $< \sqrt[3]{N}$, in such a way that the length of messages is not substantially increased.

33. [*M50*] Prove or disprove: If a reasonably efficient algorithm exists that has a nonnegligible probability of being able to find $x \bmod N$, given a number $N = pq$ whose prime factors satisfy $p \equiv q \equiv 2$ (modulo 3) and given the value of $x^3 \bmod N$, then there is a reasonably efficient algorithm that has a nonnegligible probability of being able to find the factors of N. [If this could be proved, it would not only show that the cube root problem is as difficult as factoring, it would also show that the RSA scheme has the same fatal flaw as the SQRT scheme.]

34. [*M30*] (Peter Weinberger.) Suppose $N = pq$ in the RSA scheme, and suppose you know a number m such that $x^m \bmod N = 1$ for at least 10^{-12} of all positive integers x. Explain how you would go about factoring N without great difficulty, if m is not too large.

▶ **35.** [*M25*] (H. C. Williams, 1979.) Let N be the product of two primes p and q, where $p \bmod 8 = 3$ and $q \bmod 8 = 7$. Prove that the Jacobi symbol satisfies $(\frac{-x^2}{N}) = (\frac{x}{N}) = -(\frac{2x}{N})$, and use this to design an encoding/decoding scheme analogous to Rabin's SQRT box but with no ambiguity of messages.

36. [*HM24*] The asymptotic analysis following (21) is too coarse to give meaningful values unless N is extremely large, since $\ln\ln N$ is always rather small when N is in a practical range. Carry out a more precise analysis that gives insight into the behavior of (21) for reasonable values of N; also explain how to choose a value of $\ln m$ that minimizes (21) except for a factor of size at most $\exp(O(\log\log N))$.

37. [*M27*] Prove that the square root of every positive integer D has a periodic continued fraction of the form

$$\sqrt{D} = R + /a_1, \ldots, a_n, 2R, a_1, \ldots, a_n, 2R, a_1, \ldots, a_n, 2R, \ldots /,$$

unless D is a perfect square, where $R = \lfloor\sqrt{D}\rfloor$ and $(a_1, \ldots, a_n)$ is a *palindrome* (i.e., $a_i = a_{n+1-i}$ for $1 \le i \le n$).

▶ **38.** [*M36*] (A. Shamir.) Consider an abstract computer that can perform the operations $x + y$, $x - y$, $x \cdot y$, and $\lfloor x/y \rfloor$ on integers x and y of arbitrary length, in just one unit of time, no matter how large those integers are. The machine stores integers in a random-access memory and it can select different program steps depending on whether or not $x = y$, given x and y. The purpose of this exercise is to demonstrate that there is an amazingly fast way to factorize numbers on such a computer. (Therefore it will probably be quite difficult to show that factorization is inherently complicated on *real* machines, although we suspect that it is.)

a) Find a way to compute $n!$ in $O(\log n)$ steps on such a computer, given an integer value $n \ge 2$. [*Hint:* If A is a sufficiently large integer, the binomial coefficients $\binom{m}{k} = m!/(m-k)!\,k!$ can be computed readily from the value of $(A+1)^m$.]

b) Show how to compute a number $f(n)$ in $O(\log n)$ steps on such a computer, given an integer value $n \ge 2$, having the following properties: $f(n) = n$ if n is prime, otherwise $f(n)$ is a proper (but not necessarily prime) divisor of n. [*Hint:* If $n \neq 4$, one such function $f(n)$ is $\gcd(m(n), n)$, where $m(n) = \min\{\, m \mid m! \bmod n = 0 \,\}$.]

(As a consequence of (b), we can completely factor a given number n by doing only $O(\log n)^2$ arithmetic operations on arbitrarily large integers: Given a partial factorization $n = n_1 \ldots n_r$, each nonprime n_i can be replaced by $f(n_i) \cdot (n_i / f(n_i))$ in a total of $\sum O(\log n_i) = O(\log n)$ steps, and this refinement operation can be repeated until all n_i are prime.)

The problem of distinguishing prime numbers from composites,
and of resolving composite numbers into their prime factors,
is one of the most important and useful in all of arithmetic.
... The dignity of science seems to demand that every aid to the solution
of such an elegant and celebrated problem be zealously cultivated.

—K. F. GAUSS, *Disquisitiones Arithmeticæ*, Art. 329 (1801)

4.6. POLYNOMIAL ARITHMETIC

THE TECHNIQUES we have been studying apply in a natural way to many different types of mathematical quantities, not simply to numbers. In this section we shall deal with polynomials, which are the next step up from numbers. Formally speaking, a *polynomial over* S is an expression of the form

$$u(x) = u_n x^n + \cdots + u_1 x + u_0, \tag{1}$$

where the "coefficients" $u_n, \ldots, u_1, u_0$ are elements of some algebraic system S, and the "variable" x may be regarded as a formal symbol with an indeterminate meaning. We will assume that the algebraic system S is a *commutative ring with identity*; this means that S admits the operations of addition, subtraction, and multiplication, satisfying the customary properties: Addition and multiplication are associative and commutative binary operations defined on S, where multiplication distributes over addition; and subtraction is the inverse of addition. There is an additive identity element 0 such that $a + 0 = a$, and a multiplicative identity element 1 such that $a \cdot 1 = a$, for all a in S. The polynomial $0x^{n+m} + \cdots + 0x^{n+1} + u_n x^n + \cdots + u_1 x + u_0$ is regarded as the same polynomial as (1), although its expression is formally different.

We say that (1) is a polynomial of *degree* n and *leading coefficient* u_n if $u_n \neq 0$; and in this case we write

$$\deg(u) = n, \qquad \ell(u) = u_n. \tag{2}$$

By convention, we also set

$$\deg(0) = -\infty, \qquad \ell(0) = 0, \tag{3}$$

where "0" denotes the zero polynomial whose coefficients are all zero. We say that $u(x)$ is a *monic polynomial* if its leading coefficient $\ell(u)$ is 1.

Arithmetic on polynomials consists primarily of addition, subtraction, and multiplication; in some cases, further operations such as division, exponentiation, factoring, and taking the greatest common divisor are important. The processes of addition, subtraction, and multiplication are defined in a natural way, as though the variable x were an element of S: Addition and subtraction are done by adding or subtracting the coefficients of like powers of x. Multiplication is done by the rule

$$(u_r x^r + \cdots + u_0)(v_s x^s + \cdots + v_0) = (w_{r+s} x^{r+s} + \cdots + w_0),$$

where

$$w_k = u_0 v_k + u_1 v_{k-1} + \cdots + u_{k-1} v_1 + u_k v_0. \tag{4}$$

In the latter formula u_i or v_j are treated as zero if $i > r$ or $j > s$.

The algebraic system S is usually the set of integers, or the rational numbers; or it may itself be a set of polynomials (in variables other than x); in the latter

situation (1) is a *multivariate* polynomial, a polynomial in several variables. Another important case occurs when the algebraic system S consists of the integers $0, 1, \ldots, m-1$, with addition, subtraction, and multiplication performed mod m (cf. Eq. 4.3.2–11); this is called *polynomial arithmetic modulo* m. The special case of polynomial arithmetic modulo 2, when each of the coefficients is 0 or 1, is especially important.

The reader should note the similarity between polynomial arithmetic and multiple-precision arithmetic (Section 4.3.1), where the radix b is substituted for x. The chief difference is that the coefficient u_k of x^k in polynomial arithmetic bears little or no essential relation to its neighboring coefficients $u_{k\pm1}$, so the idea of "carrying" from one place to the next is absent. In fact, polynomial arithmetic modulo b is essentially identical to multiple-precision arithmetic with radix b, except that all carries are suppressed. For example, compare the multiplication of $(1101)_2$ by $(1011)_2$ in the binary number system with the analogous multiplication of x^3+x^2+1 by x^3+x+1 modulo 2:

Binary system	Polynomials modulo 2
1101	1101
$\times$ 1011	$\times$ 1011
1101	1101
1101	1101
1101	1101
10001111	1111111

The product of these polynomials modulo 2 is obtained by suppressing all carries, and it is $x^6+x^5+x^4+x^3+x^2+x+1$. If we had multiplied the same polynomials over the integers, without taking residues modulo 2, the result would have been $x^6+x^5+x^4+3x^3+x^2+x+1$; again carries are suppressed, but in this case the coefficients can get arbitrarily large.

In view of this strong analogy with multiple-precision arithmetic, it is unnecessary to discuss polynomial addition, subtraction, and multiplication much further in this section. However, we should point out some factors that often make polynomial arithmetic somewhat different from multiple-precision arithmetic in practice: There is often a tendency to have a large number of zero coefficients, and polynomials of huge degrees, so special forms of representation are desirable; see Section 2.2.4. Furthermore, arithmetic on polynomials in several variables leads to routines that are best understood in a recursive framework; this situation is discussed in Chapter 8.

Although the techniques of polynomial addition, subtraction, and multiplication are comparatively straightforward, there are several other important aspects of polynomial arithmetic that deserve special examination. The following subsections therefore discuss *division* of polynomials, with associated techniques such as finding greatest common divisors and factoring. We shall also discuss the problem of efficient *evaluation* of polynomials, i.e., the task of finding the value of $u(x)$ when x is a given element of S, using as few operations as possible.

The special case of evaluating x^n rapidly when n is large is quite important by itself, so it is discussed in detail in Section 4.6.3.

The first major set of computer subroutines for doing polynomial arithmetic was the ALPAK system [W. S. Brown, J. P. Hyde, and B. A. Tague, *Bell System Tech. J.* **42** (1963), 2081–2119; **43** (1964), 785–804, 1547–1562]. Another early landmark in this field was the PM system of George Collins [*CACM* **9** (1966), 578–589]; see also C. L. Hamblin, *Comp. J.* **10** (1967), 168–171.

EXERCISES

1. [*10*] If we are doing polynomial arithmetic modulo 10, what is $7x + 2$ minus $x^2 + 3$? What is $6x^2 + x + 3$ times $5x^2 + 2$?

2. [*17*] True or false: (a) The product of monic polynomials is monic. (b) The product of polynomials of respective degrees m and n has degree $m + n$. (c) The sum of polynomials of respective degrees m and n has degree $\max(m, n)$.

3. [*M20*] If each of the coefficients $u_\tau, \ldots, u_0, v_s, \ldots, v_0$ in (4) is an integer satisfying the conditions $|u_i| \leq m_1$, $|v_j| \leq m_2$, what is the maximum absolute value of the product coefficients w_k?

▶ **4.** [*21*] Can the multiplication of polynomials modulo 2 be facilitated by using the ordinary arithmetic operations on a binary computer, if coefficients are packed into computer words?

▶ **5.** [*M21*] Show how to multiply two polynomials of degree $\leq n$, modulo 2, with an execution time proportional to $O(n^{\lg 3})$ when n is large, by adapting Karatsuba's method (cf. Section 4.3.3).

4.6.1. Division of Polynomials

It is possible to divide one polynomial by another in essentially the same way that we divide one multiple-precision integer by another, when arithmetic is being done on polynomials over a "field." A field S is a commutative ring with identity, in which exact division is possible as well as the operations of addition, subtraction, and multiplication; this means as usual that whenever u and v are elements of S, and $v \neq 0$, there is an element w in S such that $u = vw$. The most important fields of coefficients that arise in applications are

a) the rational numbers (represented as fractions, see Section 4.5.1);
b) the real or complex numbers (represented within a computer by means of floating point approximations; see Section 4.2);
c) the integers modulo p where p is prime (where division can be implemented as suggested in exercise 4.5.2–15);
d) "rational functions" over a field (namely, quotients of two polynomials whose coefficients are in that field, the denominator being monic).

Of special importance is the field of integers modulo 2, when the two values 0 and 1 are the only elements of the field. Polynomials over this field (namely polynomials modulo 2) have many analogies to integers expressed in binary notation; and rational functions over this field have striking analogies to rational numbers whose numerator and denominator are represented in binary notation.

Given two polynomials $u(x)$ and $v(x)$ over a field, with $v(x) \neq 0$, we can divide $u(x)$ by $v(x)$ to obtain a quotient polynomial $q(x)$ and a remainder polynomial $r(x)$ satisfying the conditions

$$u(x) = q(x) \cdot v(x) + r(x), \qquad \deg(r) < \deg(v). \tag{1}$$

It is easy to see that there is at most one pair of polynomials $\big(q(x), r(x)\big)$ satisfying these relations; for if (1) holds for both $\big(q_1(x), r_1(x)\big)$ and $\big(q_2(x), r_2(x)\big)$ and for the same polynomials $u(x), v(x)$, then $q_1(x)v(x) + r_1(x) = q_2(x)v(x) + r_2(x)$, so $\big(q_1(x) - q_2(x)\big)v(x) = r_2(x) - r_1(x)$. Now if $q_1(x) - q_2(x)$ is nonzero, we have $\deg\big((q_1 - q_2) \cdot v\big) = \deg(q_1 - q_2) + \deg(v) \geq \deg(v) > \deg(r_2 - r_1)$, a contradiction; hence $q_1(x) - q_2(x) = 0$ and $r_1(x) = 0$. ·

The following algorithm, which is essentially the same as Algorithm 4.3.1D for multiple-precision division but without any concerns of carries, may be used to determine $q(x)$ and $r(x)$:

Algorithm D (*Division of polynomials over a field*). Given polynomials

$$u(x) = u_m x^m + \cdots + u_1 x + u_0, \qquad v(x) = v_n x^n + \cdots + v_1 x + v_0$$

over a field S, where $v_n \neq 0$ and $m \geq n \geq 0$, this algorithm finds the polynomials

$$q(x) = q_{m-n} x^{m-n} + \cdots + q_0, \qquad r(x) = r_{n-1} x^{n-1} + \cdots + r_0$$

over S that satisfy (1).

D1. [Iterate on k.] Do step D2 for $k = m - n, m - n - 1, \ldots, 0$; then the algorithm terminates with $(r_{n-1}, \ldots, r_0) \leftarrow (u_{n-1}, \ldots, u_0)$.

D2. [Division loop.] Set $q_k \leftarrow u_{n+k}/v_n$, and then set $u_j \leftarrow u_j - q_k v_{j-k}$ for $j = n+k-1, n+k-2, \ldots, k$. (The latter operation amounts to replacing $u(x)$ by $u(x) - q_k x^k v(x)$, a polynomial of degree $< n + k$.) ∎

An example of Algorithm D appears below in (5). The number of arithmetic operations is essentially proportional to $n(m - n + 1)$. For some reason this procedure has become known as "synthetic division" of polynomials. Note that explicit division of coefficients is done only at the beginning of step D2, and the divisor is always v_n; thus if $v(x)$ is a monic polynomial (with $v_n = 1$), there is no actual division at all. If multiplication is easier to perform than division it will be preferable to compute $1/v_n$ at the beginning of the algorithm and to multiply by this quantity in step D2.

We shall often write $u(x) \bmod v(x)$ for the remainder $r(x)$ in (1).

Unique factorization domains. If we restrict consideration to polynomials over a field, we are not coming to grips with many important cases, such as polynomials over the integers or polynomials in several variables. Let us therefore now consider the more general situation that the algebraic system S of coefficients is a *unique factorization domain*, not necessarily a field. This means that S is a commutative ring with identity, and that

i) $uv \neq 0$, whenever u and v are nonzero elements of S;

ii) every nonzero element u of S is either a "unit" or has a "unique" representation of the form

$$u = p_1 \dots p_t, \qquad t \geq 1, \tag{2}$$

where $p_1, \dots, p_t$ are "primes."

Here a "unit" u is an element that has a reciprocal, i.e., an element such that $uv = 1$ for some v in S; and a "prime" p is a nonunit element such that the equation $p = qr$ can be true only if either q or r is a unit. The representation (2) is to be unique in the sense that if $p_1 \dots p_t = q_1 \dots q_s$, where all the p's and q's are primes, then $s = t$ and there is a permutation $\pi_1 \dots \pi_t$ of $\{1, \dots, t\}$ such that $p_1 = a_1 q_{\pi_1}, \dots, p_t = a_t q_{\pi_t}$ for some units $a_1, \dots, a_t$. In other words, factorization into primes is unique, except for unit multiples and except for the order of the factors.

Any field is a unique factorization domain, in which each nonzero element is a unit and there are no primes. The integers form a unique factorization domain in which the units are $+1$ and -1, and the primes are $\pm 2, \pm 3, \pm 5, \pm 7, \pm 11$, etc. The case that S is the set of all integers is of principal importance, because it is often preferable to work with integer coefficients instead of arbitrary rational coefficients.

One of the key facts about polynomials (see exercise 10) is that *the polynomials over a unique factorization domain form a unique factorization domain.* A polynomial that is "prime" in this domain is usually called an *irreducible polynomial.* By using the unique factorization theorem repeatedly, we can prove that multivariate polynomials over the integers, or over any field, in any number of variables, can be uniquely factored into irreducible polynomials. For example, the multivariate polynomial $90x^3 - 120x^2y + 18x^2yz - 24xy^2z$ over the integers is the product of five irreducible polynomials $2 \cdot 3 \cdot x \cdot (3x - 4y) \cdot (5x + yz)$. The same polynomial, as a polynomial over the rationals, is the product of three irreducible polynomials $(6x) \cdot (3x - 4y) \cdot (5x + yz)$; this factorization can also be written $x \cdot (90x - 120y) \cdot (x + \frac{1}{6}yz)$ and in infinitely many other ways, although the factorization is essentially unique.

As usual, we say that $u(x)$ is a multiple of $v(x)$, and that $v(x)$ is a divisor of $u(x)$, if $u(x) = v(x)q(x)$ for some polynomial $q(x)$. If we have an algorithm to tell whether or not u is a multiple of v for arbitrary nonzero elements u and v of a unique factorization domain S, and to determine w if $u = v \cdot w$, then Algorithm D gives us a method to tell whether or not $u(x)$ is a multiple of $v(x)$ for arbitrary nonzero polynomials $u(x)$ and $v(x)$ over S. For if $u(x)$ is a multiple

of $v(x)$, it is easy to see that u_{n+k} must be a multiple of v_n each time we get to step D2, hence the quotient $u(x)/v(x)$ will be found. (Applying this observation repeatedly, we obtain an algorithm that decides if a given polynomial over S, in any number of variables, is a multiple of another given polynomial over S, and the algorithm will find the quotient when it exists.)

A set of elements of a unique factorization domain is said to be *relatively prime* if no prime of that unique factorization domain divides all of them. A polynomial over a unique factorization domain is called *primitive* if its coefficients are relatively prime. (This concept should not be confused with the quite different idea of "primitive polynomials modulo p" discussed in Section 3.2.2.) The following fact, introduced for the case of polynomials over the integers by K. F. Gauss in article 42 of his celebrated book *Disquisitiones Arithmeticæ* (Leipzig: 1801), is of prime importance:

Lemma G (Gauss's Lemma). *The product of primitive polynomials over a unique factorization domain is primitive.*

Proof. Let $u(x) = u_m x^m + \cdots + u_0$ and $v(x) = v_n x^n + \cdots + v_0$ be primitive polynomials. If p is any prime of the domain, we must show that p does not divide all the coefficients of $u(x)v(x)$. By assumption, there is an index j such that u_j is not divisible by p, and an index k such that v_k is not divisible by p. Let j and k be as small as possible; then the coefficient of x^{j+k} in $u(x)v(x)$ is $u_j v_k + u_{j+1}v_{k-1} + \cdots + u_{j+k}v_0 + u_{j-1}v_{k+1} + \cdots + u_0 v_{k+j}$, and it is easy to see that this is not a multiple of p (since its first term isn't, but all of its other terms are). ∎

If a nonzero polynomial $u(x)$ over a unique factorization domain S is not primitive, we can write $u(x) = p_1 \cdot u_1(x)$, where p_1 is a prime of S dividing all the coefficients of $u(x)$, and where $u_1(x)$ is another nonzero polynomial over S. All of the coefficients of $u_1(x)$ have one less prime factor than the corresponding coefficients of $u(x)$. Now if $u_1(x)$ is not primitive, we can write $u_1(x) = p_2 \cdot u_2(x)$, etc.; this process must ultimately terminate in a representation $u(x) = c \cdot u_k(x)$, where c is an element of S and $u_k(x)$ is primitive. In fact, we have the following companion to Lemma G:

Lemma H. *Any nonzero polynomial $u(x)$ over a unique factorization domain S can be factored in the form $u(x) = c \cdot v(x)$, where c is in S and $v(x)$ is primitive. Furthermore, this representation is unique, in the sense that if $u = c_1 \cdot v_1(x) = c_2 \cdot v_2(x)$, then $c_1 = ac_2$ and $v_2(x) = av_1(x)$ where a is a unit of S.*

Proof. We have shown that such a representation exists, so only the uniqueness needs to be proved. Assume that $c_1 \cdot v_1(x) = c_2 \cdot v_2(x)$, where $v_1(x)$ and $v_2(x)$ are primitive and c_1 is not a unit multiple of c_2. By unique factorization there is a prime p of S and an exponent k such that p^k divides one of $\{c_1, c_2\}$ but not the other, say p^k divides c_1 but not c_2. Then p^k divides all of the coefficients of $c_2 \cdot v_2(x)$, so p divides all the coefficients of $v_2(x)$, contradicting the assumption that $v_2(x)$ is primitive. Hence $c_1 = ac_2$, where a is a unit; and $0 = ac_2 \cdot v_1(x) - c_2 \cdot v_2(x) = c_2 \cdot \big(av_1(x) - v_2(x)\big)$, so $av_1(x) - v_2(x) = 0$. ∎

Therefore we may write any nonzero polynomial $u(x)$ as

$$u(x) = \operatorname{cont}(u) \cdot \operatorname{pp}(u(x)), \tag{3}$$

where $\operatorname{cont}(u)$, the "content" of u, is an element of S, and $\operatorname{pp}(u(x))$, the "primitive part" of $u(x)$, is a primitive polynomial over S. When $u(x) = 0$, it is convenient to define $\operatorname{cont}(u) = \operatorname{pp}(u(x)) = 0$. Combining Lemmas G and H gives us the relations

$$\begin{aligned} \operatorname{cont}(u \cdot v) &= a \operatorname{cont}(u) \operatorname{cont}(v), \\ \operatorname{pp}(u(x) \cdot v(x)) &= b \operatorname{pp}(u(x)) \operatorname{pp}(v(x)), \end{aligned} \tag{4}$$

where a and b are units, depending on u and v, with $ab = 1$. When we are working with polynomials over the integers, the only units are $+1$ and -1, and it is conventional to define $\operatorname{pp}(u(x))$ so that its leading coefficient is positive; then (4) is true with $a = b = 1$. When working with polynomials over a field we may take $\operatorname{cont}(u) = \ell(u)$, so that $\operatorname{pp}(u(x))$ is monic; in this case again (4) holds with $a = b = 1$, for all $u(x)$ and $v(x)$.

For example, if we are dealing with polynomials over the integers, let $u(x) = -26x^2 + 39$ and $v(x) = 21x + 14$. Then

$$\begin{aligned} \operatorname{cont}(u) &= -13, & \operatorname{pp}(u(x)) &= 2x^2 - 3, \\ \operatorname{cont}(v) &= +7, & \operatorname{pp}(v(x)) &= 3x + 2, \\ \operatorname{cont}(u \cdot v) &= -91, & \operatorname{pp}(u(x) \cdot v(x)) &= 6x^3 + 4x^2 - 9x - 6. \end{aligned}$$

Greatest common divisors. When there is unique factorization, it makes sense to speak of a "greatest common divisor" of two elements; this is a common divisor that is divisible by as many primes as possible. (Cf. Eq. 4.5.2–6.) Since a unique factorization domain may have many units, however, there is a certain amount of ambiguity in this definition of greatest common divisor; if w is a greatest common divisor of u and v, so is $a \cdot w$, when a is any unit. Conversely, the assumption of unique factorization implies that if w_1 and w_2 are both greatest common divisors of u and v, then $w_1 = a \cdot w_2$ for some unit a. In other words it does not make sense, in general, to speak of "the" greatest common divisor of u and v; there is a set of greatest common divisors, each one being a unit multiple of the others.

Let us now consider the problem of finding a greatest common divisor of two given polynomials over an algebraic system S. If S is a field, the problem is relatively simple; our division algorithm, Algorithm D, can be extended to an algorithm that computes greatest common divisors, just as Euclid's algorithm (Algorithm 4.5.2A) yields the greatest common divisor of two given integers based on a division algorithm for integers: If $v(x) = 0$, then $\gcd(u(x), v(x)) = u(x)$; otherwise $\gcd(u(x), v(x)) = \gcd(v(x), r(x))$, where $r(x)$ is given by (1). This procedure is called Euclid's algorithm for polynomials over a field; it was first used by Simon Stevin in 1585 [*Les œuvres mathématiques de Simon Stevin*, ed. by A. Girard, **1** (Leyden, 1634), 56].

For example, let us determine the gcd of $x^8 + x^6 + 10x^4 + 10x^3 + 8x^2 + 2x + 8$ and $3x^6 + 5x^4 + 9x^2 + 4x + 8$, mod 13, by using Euclid's algorithm for polynomials over the integers modulo 13. First, writing only the coefficients to show the steps of Algorithm D, we have

$$\begin{array}{rrrrrrrrrr}
 & & & & & & & 9 & 0 & 7 \\
3 & 0 & 5 & 0 & 9 & 4 & 8 \;)\; & 1 & 0 & 1 & 0 & 10 & 10 & 8 & 2 & 8 \\
 & & & & & & & 1 & 0 & 6 & 0 & 3 & 10 & 7 & & \\
\cline{4-14}
 & & & & & & & 0 & 8 & 0 & 7 & 0 & 1 & 2 & 8 & \\
 & & & & & & & 8 & 0 & 9 & 0 & 11 & 2 & 4 & & \\
\cline{5-14}
 & & & & & & & & 0 & 11 & 0 & 3 & 0 & 4 & &
\end{array} \tag{5}$$

and hence

$$\begin{aligned}
x^8 + x^6 + 10x^4 + 10x^3 + 8x^2 + 2x + 8 \\
\qquad = (9x^2 + 7)(3x^6 + 5x^4 + 9x^2 + 4x + 8) \;+\; (11x^4 + 3x^2 + 4).
\end{aligned}$$

Similarly,

$$\begin{aligned}
3x^6 + 5x^4 + 9x^2 + 4x + 8 &= (5x^2 + 5)(11x^4 + 3x^2 + 4) \;+\; (4x + 1); \\
11x^4 + 3x^2 + 4 &= (6x^3 + 5x^2 + 6x + 5)(4x + 1) \;+\; 12; \\
4x + 1 &= (9x + 12) \cdot 12 \;+\; 0.
\end{aligned} \tag{6}$$

(The equality sign here means congruence modulo 13, since all arithmetic on the coefficients has been done mod 13.) This computation shows that 12 is a greatest common divisor of the two original polynomials. Now any nonzero element of a field is a unit of the domain of polynomials over that field, so it is conventional in the case of fields to divide the result of the algorithm by its leading coefficient, producing a *monic* polynomial that is called *the* greatest common divisor of the two given polynomials. The gcd computed in (6) is accordingly taken to be 1, not 12. The last step in (6) could have been omitted, for if $\deg(v) = 0$, then $\gcd(u(x), v(x)) = 1$, no matter what polynomial is chosen for $u(x)$. Exercise 4 determines the average running time for Euclid's algorithm on random polynomials modulo p.

Let us now turn to the more general situation in which our polynomials are given over a unique factorization domain that is not a field. From Eqs. (4) we can deduce the important relations

$$\begin{aligned}
\operatorname{cont}(\gcd(u, v)) &= a \cdot \gcd(\operatorname{cont}(u), \operatorname{cont}(v)), \\
\operatorname{pp}(\gcd(u(x), v(x))) &= b \cdot \gcd(\operatorname{pp}(u(x)), \operatorname{pp}(v(x))),
\end{aligned} \tag{7}$$

where a and b are units. Here $\gcd(u(x), v(x))$ denotes any particular polynomial in x that is a greatest common divisor of $u(x)$ and $v(x)$. Equations (7) reduce the problem of finding greatest common divisors of arbitrary polynomials to the problem of finding greatest common divisors of *primitive* polynomials.

Algorithm D for division of polynomials over a field can be generalized to a pseudo-division of polynomials over any algebraic system that is a commutative ring with identity. We can observe that Algorithm D requires explicit division only by $\ell(v)$, the leading coefficient of $v(x)$, and that step D2 is carried out exactly $m-n+1$ times; thus if $u(x)$ and $v(x)$ start with integer coefficients, and if we are working over the rational numbers, then the only denominators that appear in the coefficients of $q(x)$ and $r(x)$ are divisors of $\ell(v)^{m-n+1}$. This suggests that we can always find polynomials $q(x)$ and $r(x)$ such that

$$\ell(v)^{m-n+1}u(x) = q(x)v(x) + r(x), \qquad \deg(r) < n, \tag{8}$$

where $m = \deg(u)$ and $n = \deg(v)$, for any polynomials $u(x)$ and $v(x) \neq 0$, provided that $m \geq n$.

Algorithm R (*Pseudo-division of polynomials*). Given polynomials

$$u(x) = u_m x^m + \cdots + u_1 x + u_0, \qquad v(x) = v_n x^n + \cdots + v_1(x) + v_0,$$

where $v_n \neq 0$ and $m \geq n \geq 0$, this algorithm finds polynomials $q(x) = q_{m-n}x^{m-n} + \cdots + q_0$ and $r(x) = r_{n-1}x^{n-1} + \cdots + r_0$ satisfying (8).

R1. [Iterate on k.] Do step R2 for $k = m-n, m-n-1, \ldots, 0$; then the algorithm terminates with $(r_{n-1}, \ldots, r_0) = (u_{n-1}, \ldots, u_0)$.

R2. [Multiplication loop.] Set $q_k \leftarrow u_{n+k}v_n^k$, and set $u_j \leftarrow v_n u_j - u_{n+k}v_{j-k}$ for $j = n+k-1, n+k-2, \ldots, 0$. (When $j < k$ this means that $u_j \leftarrow v_n u_j$, since we treat $v_{-1}, v_{-2}, \ldots$ as zero. These multiplications could have been avoided if we had started the algorithm by replacing u_t by $v_n^{m-n-t}u_t$, for $0 \leq t < m-n$.) ∎

An example calculation appears below in (10). It is easy to prove the validity of Algorithm R by induction on $m-n$, since each execution of step R2 essentially replaces $u(x)$ by $\ell(v)u(x) - \ell(u)x^k v(x)$, where $k = \deg(u) - \deg(v)$. Note that no division whatever is used in this algorithm; the coefficients of $q(x)$ and $r(x)$ are themselves certain polynomial functions of the coefficients of $u(x)$ and $v(x)$. If $v_n = 1$, the algorithm is identical to Algorithm D. If $u(x)$ and $v(x)$ are polynomials over a unique factorization domain, we can prove as before that the polynomials $q(x)$ and $r(x)$ are unique; therefore another way to do the pseudo-division over a unique factorization domain is to multiply $u(x)$ by v_n^{m-n+1} and apply Algorithm D, knowing that all the quotients in step D2 will exist.

Algorithm R can be extended to a "generalized Euclidean algorithm" for primitive polynomials over a unique factorization domain, in the following way: Let $u(x)$ and $v(x)$ be primitive polynomials with $\deg(u) \geq \deg(v)$, and determine the polynomial $r(x)$ satisfying (8) by means of Algorithm R. Now we can prove that $\gcd\big(u(x), v(x)\big) = \gcd\big(v(x), r(x)\big)$: Any common divisor of $u(x)$ and $v(x)$ divides $v(x)$ and $r(x)$; conversely, any common divisor of $v(x)$ and $r(x)$ divides $\ell(v)^{m-n+1}u(x)$, and it must be primitive (since $v(x)$ is primitive) so it divides $u(x)$. If $r(x) = 0$, we therefore have $\gcd\big(u(x), v(x)\big) = v(x)$; on the other hand if $r(x) \neq 0$, we have $\gcd\big(v(x), r(x)\big) = \gcd\big(v(x), \mathrm{pp}\big(r(x)\big)\big)$ since $v(x)$ is primitive, so the process can be iterated.

Algorithm E (*Generalized Euclidean algorithm*). Given nonzero polynomials $u(x)$ and $v(x)$ over a unique factorization domain S, this algorithm calculates a greatest common divisor of $u(x)$ and $v(x)$. We assume that auxiliary algorithms exist to calculate greatest common divisors of elements of S, and to divide a by b in S when $b \neq 0$ and a is a multiple of b.

E1. [Reduce to primitive.] Set $d \leftarrow \gcd(\text{cont}(u), \text{cont}(v))$, using the assumed algorithm for calculating greatest common divisors in S. (Note that $\text{cont}(u)$ is a greatest common divisor of the coefficients of $u(x)$.) Replace $u(x)$ by the polynomial $u(x)/\text{cont}(u) = \text{pp}(u(x))$; similarly, replace $v(x)$ by $\text{pp}(v(x))$.

E2. [Pseudo-division.] Calculate $r(x)$ using Algorithm R. (It is unnecessary to calculate the quotient polynomial $q(x)$.) If $r(x) = 0$, go to E4. If $\deg(r) = 0$, replace $v(x)$ by the constant polynomial "1" and go to E4.

E3. [Make remainder primitive.] Replace $u(x)$ by $v(x)$ and replace $v(x)$ by $\text{pp}(r(x))$. Go back to step E2. (This is the "Euclidean step," analogous to the other instances of Euclid's algorithm that we have seen.)

E4. [Attach the content.] The algorithm terminates, with $d \cdot v(x)$ as the desired answer. ∎

As an example of Algorithm E, let us calculate the gcd of the polynomials

$$\begin{aligned} u(x) &= x^8 + x^6 - 3x^4 - 3x^3 + 8x^2 + 2x - 5, \\ v(x) &= 3x^6 + 5x^4 - 4x^2 - 9x + 21, \end{aligned} \tag{9}$$

over the integers. These polynomials are primitive, so step E1 sets $d \leftarrow 1$. In step E2 we have the pseudo-division

$$\begin{array}{rrrrrrrrrr}
 & & & & & & & 1 & 0 & -6 \\
3\ 0\ 5\ 0\ -4\ -9\ 21\ ) & 1 & 0 & 1 & 0 & -3 & -3 & 8 & 2 & -5 \\
 & 3 & 0 & 3 & 0 & -9 & -9 & 24 & 6 & -15 \\
\cline{2-10}
 & 3 & 0 & 5 & 0 & -4 & -9 & 21 & & \\
\cline{2-10}
 & & 0 & -2 & 0 & -5 & 0 & 3 & 6 & -15 \\
 & & 0 & -6 & 0 & -15 & 0 & 9 & 18 & -45 \\
 & & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
\cline{2-10}
 & & & -6 & 0 & -15 & 0 & 9 & 18 & -45 \\
 & & & -18 & 0 & -45 & 0 & 27 & 54 & -135 \\
 & & & -18 & 0 & -30 & 0 & 24 & 54 & -126 \\
\cline{2-10}
 & & & & & -15 & 0 & 3 & 0 & -9
\end{array} \tag{10}$$

Here the quotient $q(x)$ is $1 \cdot 3^2x^2 + 0 \cdot 3^1x + -6 \cdot 3^0$; we have

$$27u(x) = v(x)(9x^2 - 6) + (-15x^4 + 3x^2 - 9). \tag{11}$$

Now step E3 replaces $u(x)$ by $v(x)$ and $v(x)$ by $\text{pp}(r(x)) = 5x^4 - x^2 + 3$. The subsequent calculation is summarized in the following table, where only the

coefficients are shown:

$u(x)$	$v(x)$	$r(x)$	
$1,0,1,0,-3,-3,8,2,-5$	$3,0,5,0,-4,-9,21$	$-15,0,3,0,-9$	
$3,0,5,0,-4,-9,21$	$5,0,-1,0,3$	$-585,-1125,2205$	
$5,0,-1,0,3$	$13,25,-49$	$-233150,307500$	
$13,25,-49$	$4663,-6150$	143193869	(12)

It is instructive to compare this calculation with the computation of the same greatest common divisor over the *rational* numbers, instead of over the integers, by using Euclid's algorithm for polynomials over a field as described earlier in this section. The following surprisingly complicated sequence appears:

$u(x)$	$v(x)$	
$1,0,1,0,-3,-3,8,2,-5$	$3,0,5,0,-4,-9,21$	
$3,0,5,0,-4,-9,21$	$-\frac{5}{9},0,\frac{1}{9},0,-\frac{1}{3}$	
$-\frac{5}{9},0,\frac{1}{9},0,-\frac{1}{3}$	$-\frac{117}{25},-9,\frac{441}{25}$	
$-\frac{117}{25},-9,\frac{441}{25}$	$\frac{233150}{19773},-\frac{102500}{6591}$	
$\frac{233150}{19773},-\frac{102500}{6591}$	$-\frac{1288744821}{543589225}$	(13)

To improve that algorithm, we can reduce $u(x)$ and $v(x)$ to monic polynomials at each step, since this removes "unit" factors that make the coefficients more complicated than necessary; this is actually Algorithm E over the rationals:

$u(x)$	$v(x)$	
$1,0,1,0,-3,-3,8,2,-5$	$1,0,\frac{5}{3},0,-\frac{4}{3},-3,7$	
$1,0,\frac{5}{3},0,-\frac{4}{3},-3,7$	$1,0,-\frac{1}{5},0,\frac{3}{5}$	
$1,0,-\frac{1}{5},0,\frac{3}{5}$	$1,\frac{25}{13},-\frac{49}{13}$	
$1,\frac{25}{13},-\frac{49}{13}$	$1,-\frac{6150}{4663}$	
$1,-\frac{6150}{4663}$	1	(14)

In both (13) and (14) the sequence of polynomials is essentially the same as (12), which was obtained by Algorithm E over the integers; the only difference is that the polynomials have been multiplied by certain rational numbers. Whether we have $5x^4-x^2+3$ or $-\frac{5}{9}x^4+\frac{1}{9}x^2-\frac{1}{3}$ or $x^4-\frac{1}{5}x^2+\frac{3}{5}$, the computations are essentially the same. But either algorithm using rational arithmetic will run noticeably slower than the all-integer Algorithm E, since rational arithmetic requires many more evaluations of gcd's of integers within each step. Therefore it is definitely better to use the all-integer algorithm.

It is also instructive to compare the above calculations with (6) above, where we determined the gcd of the same polynomials $u(x)$ and $v(x)$ modulo 13 with considerably less labor. Since $\ell(u)$ and $\ell(v)$ are not multiples of 13, the fact that $\gcd(u(x),v(x))=1$ modulo 13 is sufficient to prove that $u(x)$ and $v(x)$ are relatively prime over the integers (and therefore over the rational numbers); we will return to this time-saving observation at the close of Section 4.6.2.

The subresultant algorithm. An ingenious algorithm that is generally superior to Algorithm E, and that gives us further information about Algorithm E's behavior, was discovered by George E. Collins [*JACM* **14** (1967), 128–142] and subsequently improved by W. S. Brown and J. F. Traub [*JACM* **18** (1971), 505–514; see also W. S. Brown, *ACM Trans. Math. Software* **4** (1978), 237–249]. This algorithm avoids the calculation of primitive parts in step E3, dividing instead by an element of S that is known to be a factor of $r(x)$:

Algorithm C (*Greatest common divisor over a unique factorization domain*). This algorithm has the same input and output assumptions as Algorithm E, and has the advantage that fewer calculations of greatest common divisors of coefficients are needed.

C1. [Reduce to primitive.] As in step E1 of Algorithm E, set $d \leftarrow \gcd(\mathrm{cont}(u), \mathrm{cont}(v))$, and replace $\big(u(x), v(x)\big)$ by $\big(\mathrm{pp}(u(x)), \mathrm{pp}(v(x))\big)$. Set $g \leftarrow h \leftarrow 1$.

C2. [Pseudo-division.] Set $\delta \leftarrow \deg(u) - \deg(v)$. Calculate $r(x)$ using Algorithm R. If $r(x) = 0$, go to C4. If $\deg(r) = 0$, replace $v(x)$ by the constant polynomial "1" and go to C4.

C3. [Adjust remainder.] Replace the polynomial $u(x)$ by $v(x)$, and replace $v(x)$ by $r(x)/gh^{\delta}$. (At this point all coefficients of $r(x)$ are multiples of gh^{δ}.) Then set $g \leftarrow \ell(u)$, $h \leftarrow h^{1-\delta}g^{\delta}$ and return to C2. (The new value of h will be in the domain S, even if $\delta > 1$.)

C4. [Attach the content.] Return $d \cdot \mathrm{pp}(v(x))$ as the answer. ∎

If we apply this algorithm to the polynomials (9) considered earlier, the following sequence of results is obtained at the beginning of step C2:

$u(x)$	$v(x)$	g	h	
$1, 0, 1, 0, -3, -3, 8, 2, -5$	$3, 0, 5, 0, -4, -9, 21$	1	1	
$3, 0, 5, 0, -4, -9, 21$	$-15, 0, 3, 0, -9$	3	9	
$-15, 0, 3, 0, -9$	$65, 125, -245$	-15	25	
$65, 125, -245$	$-9326, 12300$	65	169	(15)

At the conclusion of the algorithm, $r(x)/gh^{\delta} = 260708$.

The sequence of polynomials consists of integral multiples of the polynomials in the sequence produced by Algorithm E. In spite of the fact that the polynomials are not reduced to primitive form, the coefficients are kept to a reasonable size because of the reduction factor in step C3.

In order to analyze Algorithm C and to prove that it is valid, let us call the sequence of polynomials it produces $u_1(x)$, $u_2(x)$, $u_3(x)$, ..., where $u_1(x) = u(x)$ and $u_2(x) = v(x)$. Let $\delta_j = n_j - n_{j+1}$ for $j \geq 1$, where $n_j = \deg(u_j)$; and let $g_1 = h_1 = 1$, $g_j = \ell(u_j)$, $h_j = h_{j-1}^{1-\delta_{j-1}} g_j^{\delta_{j-1}}$ for $j \geq 2$. Then we have

$$\begin{aligned} g_2^{\delta_1+1}u_1(x) &= u_2(x)q_1(x) + g_1h_1^{\delta_1}u_3(x), && n_3 < n_2; \\ g_3^{\delta_2+1}u_2(x) &= u_3(x)q_2(x) + g_2h_2^{\delta_2}u_4(x), && n_4 < n_3; \\ g_4^{\delta_3+1}u_3(x) &= u_4(x)q_3(x) + g_3h_3^{\delta_3}u_5(x), && n_5 < n_4; \end{aligned} \tag{16}$$

Table 1

COEFFICIENTS IN ALGORITHM C

and so on. The process terminates when $n_{k+1} = \deg(u_{k+1}) \leq 0$. We must show that $u_3(x)$, $u_4(x)$, ..., have coefficients in S, i.e., that the factors $g_j h_j^{\delta_j}$ evenly divide the remainders, and we must also show that the h_j values all belong to S. The proof is rather involved, and it can be most easily understood by considering an example.

Suppose, as in (15), that $n_1 = 8$, $n_2 = 6$, $n_3 = 4$, $n_4 = 2$, $n_5 = 1$, $n_6 = 0$, so that $\delta_1 = \delta_2 = \delta_3 = 2$, $\delta_4 = \delta_5 = 1$. Let us write $u_1(x) = a_8x^8 + a_7x^7 + \cdots + a_0$, $u_2(x) = b_6x^6 + b_5x^5 + \cdots + b_0$, ..., $u_5(x) = e_1x + e_0$, $u_6(x) = f_0$, so that $h_1 = 1$, $h_2 = b_6^2$, $h_3 = c_4^2/b_6^2$, $h_4 = d_2^2b_6^2/c_4^2$. In these terms it is helpful to consider the array shown in Table 1. For concreteness, let us assume that the coefficients of the polynomials are integers. We have $b_6^3u_1(x) = u_2(x)q_1(x) + u_3(x)$; so if we multiply row A_5 by b_6^3 and subtract appropriate multiples of rows B_7, B_6, and B_5 (corresponding to the coefficients of $q_1(x)$) we will get row C_5. If we also multiply row A_4 by b_6^3 and subtract multiples of rows B_6, B_5, and B_4, we get row C_4. In a similar way, we have $c_4^3u_2(x) = u_3(x)q_2(x) + b_6^5u_4(x)$; so we

can multiply row B_3 by c_4^3, subtract integer multiples of rows C_5, C_4, and C_3, then divide by b_6^5 to obtain row D_3.

In order to prove that $u_4(x)$ has integer coefficients, let us consider the matrix

$$\begin{matrix} A_2 \\ A_1 \\ A_0 \\ B_4 \\ B_3 \\ B_2 \\ B_1 \\ B_0 \end{matrix} \begin{pmatrix} a_8 & a_7 & a_6 & a_5 & a_4 & a_3 & a_2 & a_1 & a_0 & 0 & 0 \\ 0 & a_8 & a_7 & a_6 & a_5 & a_4 & a_3 & a_2 & a_1 & a_0 & 0 \\ 0 & 0 & a_8 & a_7 & a_6 & a_5 & a_4 & a_3 & a_2 & a_1 & a_0 \\ b_6 & b_5 & b_4 & b_3 & b_2 & b_1 & b_0 & 0 & 0 & 0 & 0 \\ 0 & b_6 & b_5 & b_4 & b_3 & b_2 & b_1 & b_0 & 0 & 0 & 0 \\ 0 & 0 & b_6 & b_5 & b_4 & b_3 & b_2 & b_1 & b_0 & 0 & 0 \\ 0 & 0 & 0 & b_6 & b_5 & b_4 & b_3 & b_2 & b_1 & b_0 & 0 \\ 0 & 0 & 0 & 0 & b_6 & b_5 & b_4 & b_3 & b_2 & b_1 & b_0 \end{pmatrix} = M. \tag{17}$$

The indicated row operations and a permutation of rows will transform M into

$$\begin{matrix} B_4 \\ B_3 \\ B_2 \\ B_1 \\ C_2 \\ C_1 \\ C_0 \\ D_0 \end{matrix} \begin{pmatrix} b_6 & b_5 & b_4 & b_3 & b_2 & b_1 & b_0 & 0 & 0 & 0 & 0 \\ 0 & b_6 & b_5 & b_4 & b_3 & b_2 & b_1 & b_0 & 0 & 0 & 0 \\ 0 & 0 & b_6 & b_5 & b_4 & b_3 & b_2 & b_1 & b_0 & 0 & 0 \\ 0 & 0 & 0 & b_6 & b_5 & b_4 & b_3 & b_2 & b_1 & b_0 & 0 \\ 0 & 0 & 0 & 0 & c_4 & c_3 & c_2 & c_1 & c_0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & c_4 & c_3 & c_2 & c_1 & c_0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & c_4 & c_3 & c_2 & c_1 & c_0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & d_2 & d_1 & d_0 \end{pmatrix} = M'. \tag{18}$$

Because of the way M' has been derived from M, we must have

$$b_6^3 \cdot b_6^3 \cdot b_6^3 \cdot (c_4^3/b_6^5) \cdot \det M_0 = \pm \det M_0',$$

if M_0 and M_0' represent any square matrices obtained by selecting eight corresponding columns from M and M'. For example, let us select the first seven columns and the column containing d_1; then

$$b_6^3 \cdot b_6^3 \cdot b_6^3 \cdot (c_4^3/b_6^5) \cdot \det \begin{pmatrix} a_8 & a_7 & a_6 & a_5 & a_4 & a_3 & a_2 & 0 \\ 0 & a_8 & a_7 & a_6 & a_5 & a_4 & a_3 & a_0 \\ 0 & 0 & a_8 & a_7 & a_6 & a_5 & a_4 & a_1 \\ b_6 & b_5 & b_4 & b_3 & b_2 & b_1 & b_0 & 0 \\ 0 & b_6 & b_5 & b_4 & b_3 & b_2 & b_1 & 0 \\ 0 & 0 & b_6 & b_5 & b_4 & b_3 & b_2 & 0 \\ 0 & 0 & 0 & b_6 & b_5 & b_4 & b_3 & b_0 \\ 0 & 0 & 0 & 0 & b_6 & b_5 & b_4 & b_1 \end{pmatrix} = \pm b_6^4 \cdot c_4^3 \cdot d_1.$$

Since $b_6 c_4 \neq 0$, this proves that d_1 is an integer. Similarly, d_2 and d_0 are integers.

In general, we can show that $u_{j+1}(x)$ has integer coefficients in a similar manner. If we start with the matrix M consisting of rows $A_{n_2-n_j}$ through A_0 and $B_{n_1-n_j}$ through B_0, and if we perform the row operations indicated in Table 1, we will obtain a matrix M' consisting in some order of rows $B_{n_1-n_j}$

through $B_{n_3-n_j+1}$, $C_{n_2-n_j}$ through $C_{n_4-n_j+1}$, $\ldots$, $P_{n_{j-2}-n_j}$ through P_1, $Q_{n_{j-1}-n_j}$ through Q_0, and finally R_0 (a row containing the coefficients of $u_{j+1}(x)$). Extracting appropriate columns shows that

$$(g_2^{\delta_1+1}/g_1h_1^{\delta_1})^{n_2-n_j+1}(g_3^{\delta_2+1}/g_2h_2^{\delta_2})^{n_3-n_j+1}\ldots(g_j^{\delta_{j-1}+1}/g_{j-1}h_{j-1}^{\delta_{j-1}})^{n_j-n_j+1}$$
$$\times \det M_0 \;=\; \pm g_2^{n_1-n_3}g_3^{n_2-n_4}\ldots g_{j-1}^{n_{j-2}-n_j}g_j^{n_{j-1}-n_j+1}r_t, \quad (19)$$

where r_t is a given coefficient of $u_{j+1}(x)$ and M_0 is a submatrix of M. The h's have been chosen very cleverly so that this equation simplifies to

$$\det M_0 = \pm r_t \quad (20)$$

(see exercise 24). Therefore *every coefficient of $u_{j+1}(x)$ can be expressed as the determinant of an $(n_1+n_2-2n_j+2)\times(n_1+n_2-2n_j+2)$ matrix whose elements are coefficients of $u(x)$ and $v(x)$.*

It remains to be shown that the cleverly chosen h's also are integers. A similar technique applies: Let's look, for example, at the matrix

$$\begin{array}{c} A_1 \\ A_0 \\ B_3 \\ B_2 \\ B_1 \\ B_0 \end{array}\begin{pmatrix} a_8 & a_7 & a_6 & a_5 & a_4 & a_3 & a_2 & a_1 & a_0 & 0 \\ 0 & a_8 & a_7 & a_6 & a_5 & a_4 & a_3 & a_2 & a_1 & a_0 \\ b_6 & b_5 & b_4 & b_3 & b_2 & b_1 & b_0 & 0 & 0 & 0 \\ 0 & b_6 & b_5 & b_4 & b_3 & b_2 & b_1 & b_0 & 0 & 0 \\ 0 & 0 & b_6 & b_5 & b_4 & b_3 & b_2 & b_1 & b_0 & 0 \\ 0 & 0 & 0 & b_6 & b_5 & b_4 & b_3 & b_2 & b_1 & b_0 \end{pmatrix} = M. \quad (21)$$

Row operations as specified in Table 1, and permutation of rows, leads to

$$\begin{array}{c} B_3 \\ B_2 \\ B_1 \\ B_0 \\ C_1 \\ C_0 \end{array}\begin{pmatrix} b_6 & b_5 & b_4 & b_3 & b_2 & b_1 & b_0 & 0 & 0 & 0 \\ 0 & b_6 & b_5 & b_4 & b_3 & b_2 & b_1 & b_0 & 0 & 0 \\ 0 & 0 & b_6 & b_5 & b_4 & b_3 & b_2 & b_1 & b_0 & 0 \\ 0 & 0 & 0 & b_6 & b_5 & b_4 & b_3 & b_2 & b_1 & b_0 \\ 0 & 0 & 0 & 0 & c_4 & c_3 & c_2 & c_1 & c_0 & 0 \\ 0 & 0 & 0 & 0 & 0 & c_4 & c_3 & c_2 & c_1 & c_0 \end{pmatrix} = M'; \quad (22)$$

hence if we consider any submatrices M_0 and M_0' obtained by selecting six corresponding columns of M and M' we have

$$b_6^3 \cdot b_6^3 \cdot b_6^3 \cdot \det M_0 = \pm \det M_0'.$$

When M_0 is chosen to be the first six columns of M, we find that $\det M_0 = \pm c_4^2/b_6^2 = \pm h_3$, so h_3 is an integer.

In general, to show that h_j is an integer for $j \geq 3$, we start with the matrix M consisting of rows $A_{n_2-n_j-1}$ through A_0 and $B_{n_1-n_j-1}$ through B_0; then we perform appropriate row operations until obtaining a matrix M' consisting of rows $B_{n_1-n_j-1}$ through $B_{n_3-n_j}$, $C_{n_2+n_j-1}$ through $C_{n_4-n_j}$, $\ldots$, $P_{n_{j-2}-n_j-1}$

through P_0, $Q_{n_{j-1}-n_j-1}$ through Q_0. Letting M_0 be the first $n_1+n_2-2n_j$ columns of M, we obtain

$$(g_2^{\delta_1+1}/g_1h_1^{\delta_1})^{n_2-n_j}(g_3^{\delta_2+1}/g_2h_2^{\delta_2})^{n_3-n_j}\dots(g_j^{\delta_{j-1}+1}/g_{j-1}h_{j-1}^{\delta_{j-1}})^{n_j-n_j}\det M_0 = \pm g_2^{n_1-n_3}g_3^{n_2-n_4}\dots g_{j-1}^{n_{j-2}-n_j}g_j^{n_{j-1}-n_j}, \quad (23)$$

an equation that neatly simplifies to

$$\det M_0 = \pm h_j. \quad (24)$$

(This proof, although stated for the domain of integers, obviously applies to any unique factorization domain.)

In the process of verifying Algorithm C, we have also learned that every element of S dealt with by the algorithm can be expressed as a determinant whose entries are the coefficients of the primitive parts of the original polynomials. A well-known theorem of Hadamard (see exercise 15) states that

$$|\det(a_{ij})| \le \prod_{1\le i\le n}\left(\sum_{1\le j\le n}a_{ij}^2\right)^{1/2}; \quad (25)$$

therefore an upper bound for the maximum coefficient appearing in the polynomials computed by Algorithm C is

$$N^{m+n}(m+1)^{n/2}(n+1)^{m/2}, \quad (26)$$

if all coefficients of the given polynomials $u(x)$ and $v(x)$ are bounded by N in absolute value. This same upper bound applies to the coefficients of all polynomials $u(x)$ and $v(x)$ computed during the execution of Algorithm E, since the polynomials obtained in Algorithm E are always divisors of the polynomials obtained in Algorithm C.

This upper bound on the coefficients is extremely gratifying, because it is much better than we would ordinarily have a right to expect. For example, consider what happens if we avoid the corrections in steps E3 and C3, merely replacing $v(x)$ by $r(x)$. This is the simplest gcd algorithm, and it is the one that traditionally appears in textbooks on algebra (for theoretical purposes, not intended for practical calculations). If we suppose that $\delta_1=\delta_2=\cdots=1$, we find that the coefficients of $u_3(x)$ are bounded by N^3, the coefficients of $u_4(x)$ are bounded by N^7, those of $u_5(x)$ by N^{17}, ...; the coefficients of $u_k(x)$ are bounded by N^{a_k}, where $a_k=2a_{k-1}+a_{k-2}$. Thus the upper bound, in place of (25) for $m=n+1$, would be approximately

$$N^{0.5(2.414)^n}, \quad (27)$$

and experiments show that the simple algorithm does in fact have this behavior; the number of digits in the coefficients grows exponentially at each step! In

Algorithm E, by contrast, the growth in the number of digits is only slightly more than linear at most.

Another byproduct of our proof of Algorithm C is the fact that the degrees of the polynomials will almost always decrease by 1 at each step, so that the number of iterations of step C2 (or E2) will usually be $\deg(v)$ if the given polynomials are "random." In order to see why this happens, note for example that we could have chosen the first eight columns of M and M' in (16) and (17), and then we would have found that $u_4(x)$ has degree less than 3 if and only if $d_3 = 0$, that is, if and only if

$$\det\begin{pmatrix} a_8 & a_7 & a_6 & a_5 & a_4 & a_3 & a_2 & a_1 \\ 0 & a_8 & a_7 & a_6 & a_5 & a_4 & a_3 & a_2 \\ 0 & 0 & a_8 & a_7 & a_6 & a_5 & a_4 & a_3 \\ b_6 & b_5 & b_4 & b_3 & b_2 & b_1 & b_0 & 0 \\ 0 & b_6 & b_5 & b_4 & b_3 & b_2 & b_1 & b_0 \\ 0 & 0 & b_6 & b_5 & b_4 & b_3 & b_2 & b_1 \\ 0 & 0 & 0 & b_6 & b_5 & b_4 & b_3 & b_2 \\ 0 & 0 & 0 & 0 & b_6 & b_5 & b_4 & b_3 \end{pmatrix} = 0.$$

In general, δ_j will be greater than 1 for $j > 1$ if and only if a similar determinant in the coefficients of $u(x)$ and $v(x)$ is zero. Since such a determinant is a nonzero multivariate polynomial in the coefficients, it will be nonzero "almost always," or "with probability 1." (See exercise 16 for a more precise formulation of this statement, and see exercise 4 for a related proof.) The example polynomials in (15) have both δ_2 and δ_3 equal to 2, so they are exceptional indeed.

The considerations above can be used to derive the well-known fact that two polynomials are relatively prime if and only if their "resultant" is nonzero; the resultant is a determinant having the form of rows A_5 through A_0 and B_7 through B_0 in Table 1. (This is "Sylvester's determinant"; see exercise 12. Further properties of resultants are discussed in B. L. van der Waerden, *Modern Algebra*, tr. by Fred Blum (New York: Ungar, 1949), Sections 27–28.) From the standpoint discussed above, we could say that the gcd is "almost always" of degree zero, since Sylvester's determinant is almost never zero. But many calculations of practical interest would never be undertaken if there weren't some reasonable chance that the gcd would be a polynomial of positive degree.

We can see exactly what happens during Algorithms E and C when the gcd is not 1 by considering $u(x) = w(x)u_1(x)$ and $v(x) = w(x)u_2(x)$, where $u_1(x)$ and $u_2(x)$ are relatively prime and $w(x)$ is primitive. Then if the polynomials $u_1(x)$, $u_2(x)$, $u_3(x)$, ... are obtained when Algorithm E works on $u(x) = u_1(x)$ and $v(x) = u_2(x)$, it is easy to show that the sequence obtained for $u(x) = w(x)u_1(x)$ and $v(x) = w(x)u_2(x)$ is simply $w(x)u_1(x)$, $w(x)u_2(x)$, $w(x)u_3(x)$, $w(x)u_4(x)$, ... With Algorithm C the behavior is different; if the polynomials $u_1(x)$, $u_2(x)$, $u_3(x)$, ... are obtained when Algorithm C is applied to $u(x) = u_1(x)$ and $v(x) = u_2(x)$, and if we assume that $\deg(u_{j+1}) = \deg(u_j) - 1$ (which is almost always true when $j > 1$), then the sequence

$$w(x)u_1(x),\ w(x)u_2(x),\ \ell^2 w(x)u_3(x),\ \ell^4 w(x)u_4(x),\ \ell^6 w(x)u_5(x),\ \ldots \tag{28}$$

is obtained when Algorithm C is applied to $u(x) = w(x)u_1(x)$ and $v(x) = w(x)u_2(x)$, where $\ell = \ell(w)$. (See exercise 13.) Even though these additional ℓ-factors are present, Algorithm C will be superior to Algorithm E, because it is easier to deal with slightly larger polynomials than to calculate primitive parts repeatedly.

Polynomial remainder sequences such as those in Algorithms C and E are not useful merely for finding greatest common divisors; another important application is to the enumeration of real roots, for a given polynomial in a given interval, according to the famous theorem of J. Sturm [*Mém. présentes par divers savants* **6** (Paris, 1835), 271–318]. Let $u(x)$ be a polynomial over the real numbers, having distinct roots. We shall see in the next section that this is the same as saying $\gcd(u(x), u'(x)) = 1$, where $u'(x)$ is the derivative of $u(x)$; accordingly, there is a polynomial remainder sequence proving that $u(x)$ is relatively prime to $u'(x)$. We set $u_0(x) = u(x)$, $u_1(x) = u'(x)$, and (following Sturm) we negate the sign of all remainders:

$$\begin{aligned} c_1 u_0(x) &= u_1(x)q_1(x) - d_1 u_2(x), \\ c_2 u_1(x) &= u_2(x)q_2(x) - d_2 u_3(x), \\ &\vdots \\ c_k u_{k-1}(x) &= u_k(x)q_k(x) - d_k u_{k+1}(x), \end{aligned} \tag{29}$$

for some positive constants c_j and d_j, where $\deg(u_{k+1}) = 0$. We say that the *variation* $V(u, a)$ of $u(x)$ at a is the number of changes of sign in the sequence $u_0(a)$, $u_1(a)$, $\ldots$, $u_{k+1}(a)$, not counting zeros. For example, if the sequence of signs is 0, +, −, −, 0, +, +, −, we have $V(u, a) = 3$. Sturm's theorem asserts that the number of roots of $u(x)$ in the interval $a < x \le b$ is $V(u, a) - V(u, b)$; and the proof is surprisingly short (see exercise 22).

Although Algorithms C and E are interesting, they aren't the whole story. Important alternative ways to calculate polynomial gcd's over the integers are discussed at the end of Section 4.6.2. There is also a general determinant-evaluation algorithm that may be said to include Algorithm C as a special case; see E. H. Bareiss, *Math. Comp.* **22** (1968), 565–578.

EXERCISES

1. [*10*] Compute the pseudo-quotient $q(x)$ and pseudo-remainder $r(x)$, namely, the polynomials satisfying (8), when $u(x) = x^6 + x^5 - x^4 + 2x^3 + 3x^2 - x + 2$ and $v(x) = 2x^3 + 2x^2 - x + 3$, over the integers.

2. [*15*] What is the greatest common divisor of $3x^6 + x^5 + 4x^4 + 4x^3 + 3x^2 + 4x + 2$ and its "reverse" $2x^6 + 4x^5 + 3x^4 + 4x^3 + 4x^2 + x + 3$, modulo 7?

▶ **3.** [*M25*] Show that Euclid's algorithm for polynomials over a field S can be extended to find polynomials $U(x)$ and $V(x)$ over S such that

$$u(x)V(x) + U(x)v(x) = \gcd(u(x), v(x)).$$

(Cf. Algorithm 4.5.2X.) What are the degrees of the polynomials $U(x)$ and $V(x)$ that are computed by this extended algorithm? Prove that if S is the field of rational numbers, and if $u(x) = x^m - 1$ and $v(x) = x^n - 1$, then the extended algorithm yields polynomials $U(x)$ and $V(x)$ having *integer* coefficients. Find $U(x)$ and $V(x)$ when $u(x) = x^{21} - 1$ and $v(x) = x^{13} - 1$.

▶ **4.** [*M30*] Let p be prime, and suppose that Euclid's algorithm applied to the polynomials $u(x)$ and $v(x)$ modulo p yields a sequence of polynomials having respective degrees $m, n, n_1, \ldots, n_t, -\infty$, where $m = \deg(u)$, $n = \deg(v)$, and $n_t \geq 0$. Assume that $m \geq n$. If $u(x)$ and $v(x)$ are monic polynomials, independently and uniformly distributed over all the p^{m+n} pairs of monic polynomials having respective degrees m and n, what are the average values of the three quantities t, $n_1 + \cdots + n_t$, and $(n - n_1)n_1 + \cdots + (n_{t-1} - n_t)n_t$, as functions of m, n, and p? (These three quantities are the fundamental factors in the running time of Euclid's algorithm applied to polynomials modulo p, assuming that division is done by Algorithm D.) [*Hint:* Show that $u(x) \bmod v(x)$ is uniformly distributed and independent of $v(x)$.]

5. [*M22*] What is the probability that $u(x)$ and $v(x)$ are relatively prime modulo p, if $u(x)$ and $v(x)$ are independently and uniformly distributed monic polynomials of degree n?

6. [*M23*] We have seen that Euclid's Algorithm 4.5.2A for integers can be directly adapted to an algorithm for the greatest common divisor of polynomials. Can the "binary gcd algorithm," Algorithm 4.5.2B, be adapted in an analogous way to an algorithm that applies to polynomials?

7. [*M10*] What are the units in the domain of all polynomials over a unique factorization domain S?

▶ **8.** [*M22*] Show that if a polynomial with integer coefficients is irreducible over the domain of integers, it is irreducible when considered as a polynomial over the field of rational numbers.

9. [*M25*] Let $u(x)$ and $v(x)$ be primitive polynomials over a unique factorization domain S. Prove that $u(x)$ and $v(x)$ are relatively prime if and only if there are polynomials $U(x)$ and $V(x)$ over S such that $u(x)V(x) + U(x)v(x)$ is a polynomial of degree zero. [*Hint:* Extend Algorithm E, as Algorithm 4.5.2E is extended in exercise 3.]

10. [*M28*] Prove that the polynomials over a unique factorization domain form a unique factorization domain. [*Hint:* Use the result of exercise 9 to help show that there is at most one kind of factorization possible.]

11. [*M22*] What row names would have appeared in Table 1 if the sequence of degrees had been 9, 6, 5, 2, $-\infty$ instead of 8, 6, 4, 2, 1, 0?

▶ **12.** [*M24*] Let $u_1(x), u_2(x), u_3(x), \ldots$ be a sequence of polynomials obtained during a run of Algorithm C. "Sylvester's matrix" is the square matrix formed from rows A_{n_2-1} through A_0 and B_{n_1-1} through B_0 (in a notation analogous to that of Table 1). Show that if $u_1(x)$ and $u_2(x)$ have a common factor of positive degree, then the determinant of Sylvester's matrix is zero; conversely, given that $\deg(u_k) = 0$ for some k, show that the determinant of Sylvester's matrix is nonzero by deriving a formula for its absolute value in terms of $\ell(u_j)$ and $\deg(u_j)$, $1 \leq j \leq k$.

13. [*M22*] Show that the leading coefficient ℓ of the primitive part of $\gcd(u(x), v(x))$ enters into Algorithm C's polynomial sequence as shown in (28), when $\delta_1 = \delta_2 = \cdots = \delta_{k-1} = 1$. What is the behavior for general δ_j?

14. [*M29*] Let $r(x)$ be the pseudo-remainder when $u(x)$ is pseudo-divided by $v(x)$. If $\deg(u) \geq \deg(v) + 2$ and $\deg(v) \geq \deg(r) + 2$, show that $r(x)$ is a multiple of $\ell(v)$.

15. [*M26*] Prove Hadamard's inequality (25). [*Hint:* Consider the matrix AA^T.]

16. [*HM22*] Let $f(x_1, \ldots, x_n)$ be a multivariate polynomial with real coefficients not all zero, and let a_N be the number of solutions to the equation $f(x_1, \ldots, x_n) = 0$ such that $|x_1| \leq N$, ..., $|x_n| \leq N$, and such that each x_j is an integer. Prove that the roots have zero density, i.e., that $\lim_{N\to\infty} a_N/(2N+1)^n = 0$.

17. [*M32*] (*P. M. Cohn's algorithm for division of string polynomials.*) Let A be an "alphabet," i.e., a set of symbols. A *string* α on A is a sequence of $n \geq 0$ symbols, $\alpha = a_1 \ldots a_n$, where each a_j is in A. The length of α, denoted by $|\alpha|$, is the number n of symbols. A *string polynomial* on A is a finite sum $U = \sum_k r_k \alpha_k$, where each r_k is a nonzero rational number and each α_k is a string on A. The *degree* of U, $\deg(U)$, is defined to be $-\infty$ if $U = 0$ (i.e., if the sum is empty), otherwise $\deg(u) = \max|\alpha_k|$. The sum and product of string polynomials are defined in an obvious manner, e.g., $(\sum_j r_j\alpha_j)(\sum_k s_k\beta_k) = \sum_{j,k} r_j s_k \alpha_j \beta_k$, where the product of two strings is obtained by simply juxtaposing them. For example, if $A = \{a, b\}$, $U = ab + ba - 2a - 2b$, and $V = a + b - 1$, then $\deg(U) = 2$, $\deg(V) = 1$, $V^2 = aa + ab + ba + bb - 2a - 2b + 1$, and $V^2 - U = aa + bb + 1$. Clearly, $\deg(UV) = \deg(U) + \deg(V)$, and $\deg(U+V) \leq \max(\deg(U), \deg(V))$, with equality in the latter formula if $\deg(U) \neq \deg(V)$. (String polynomials may be regarded as ordinary multivariate polynomials over the field of rational numbers, except that the variables are *not commutative* under multiplication. In the conventional language of pure mathematics, the set of string polynomials with the operations defined here is the "free associative algebra" generated by A over the rationals.)

a) Let Q_1, Q_2, U, V be string polynomials with $\deg(U) \geq \deg(V)$ and such that $\deg(Q_1U - Q_2V) < \deg(Q_1U)$. Give an algorithm to find a string polynomial Q such that $\deg(U - QV) < \deg(U)$. (Thus if we are given U and V such that $Q_1U = Q_2V + R$ and $\deg(R) < \deg(Q_1U)$, for some Q_1 and Q_2, then there is a solution to these conditions with $Q_1 = 1$.)

b) Given that U and V are string polynomials with $\deg(V) > \deg(Q_1U - Q_2V)$ for some Q_1 and Q_2, show that the result of (a) can be improved to find a quotient Q such that $U = QV + R$, $\deg(R) < \deg(V)$. (This is the analog of (1) for string polynomials; part (a) showed that we can make $\deg(R) < \deg(U)$, under weaker hypotheses.)

c) A "homogeneous" polynomial is one whose terms all have the same degree (length). If U_1, U_2, V_1, V_2 are homogeneous string polynomials with $U_1V_1 = U_2V_2$ and $\deg(V_1) \geq \deg(V_2)$, show that there is a homogeneous string polynomial U such that $U_2 = U_1U$ and $V_1 = UV_2$.

d) Given that U and V are homogeneous string polynomials with $UV = VU$, prove that there is a homogeneous string polynomial W such that $U = rW^m$, $V = sW^n$ for some integers m, n and rational numbers r, s. Give an algorithm to compute such a W having the largest possible degree. (This algorithm is of interest, for example, when $U = \alpha$ and $V = \beta$ are strings satisfying $\alpha\beta = \beta\alpha$; then W is simply a string γ. When $U = x^m$ and $V = x^n$, the solution of largest degree is

the string $W = x^{\gcd(m,n)}$, so this algorithm includes a gcd algorithm for integers as a special case.)

▶ **18.** [*M24*] (*Euclidean algorithm for string polynomials.*) Let V_1 and V_2 be string polynomials, not both zero, having a "common left multiple." (This means that there exist string polynomials U_1 and U_2, not both zero, such that $U_1V_1 = U_2V_2$.) The purpose of this exercise is to find an algorithm to compute their "greatest common right divisor" $\operatorname{gcrd}(V_1, V_2)$ as well as their "least common left multiple" $\operatorname{lclm}(V_1, V_2)$. The latter quantities are defined as follows: $\operatorname{gcrd}(V_1, V_2)$ is a common right divisor of V_1 and V_2 (that is, $V_1 = W_1 \operatorname{gcrd}(V_1, V_2)$ and $V_2 = W_2 \operatorname{gcrd}(V_1, V_2)$ for some W_1 and W_2), and any common right divisor of V_1 and V_2 is a right divisor of $\operatorname{gcrd}(V_1, V_2)$; $\operatorname{lclm}(V_1, V_2) = Z_1V_1 = Z_2V_2$ for some Z_1 and Z_2, and any common left multiple of V_1 and V_2 is a left multiple of $\operatorname{lclm}(V_1, V_2)$.

For example, let $U_1 = abbbab + abbab - bbab + ab - 1$, $V_1 = babab + abab + ab - b$; $U_2 = abb + ab - b$, $V_2 = babbabab + bababab + babab + abab - babb - 1$. Then we have $U_1V_1 = U_2V_2 = abbbabbabab + abbabbabab + abbbababab + abbababab - bbabbabab + abbbabab - bbababab + 2abbabab - abbbabb + ababab - abbabb - bbabab - babab + bbabb - abb - ab + b$. For these string polynomials it can be shown that $\operatorname{gcrd}(V_1, V_2) = ab + 1$, and $\operatorname{lclm}(V_1, V_2) = U_1V_1$.

The division algorithm of exercise 17 may be restated thus: If V_1 and V_2 are string polynomials, with $V_2 \neq 0$, and if $U_1 \neq 0$ and U_2 satisfy the equation $U_1V_1 = U_2V_2$, then there exist string polynomials Q and R such that

$$V_1 = QV_2 + R, \qquad \text{where } \deg(R) < \deg(V_2).$$

It follows readily that Q and R are uniquely determined; they do not depend on the given U_1 and U_2. Furthermore the result is right-left symmetric, in the sense that

$$U_2 = U_1Q + R', \qquad \text{where } \deg(R') = \deg(U_1) - \deg(V_2) + \deg(R) < \deg(U_1).$$

Show that this division algorithm can be extended to an algorithm that computes $\operatorname{lclm}(V_1, V_2)$ and $\operatorname{gcrd}(V_1, V_2)$; in fact, the extended algorithm finds string polynomials Z_1 and Z_2 such that $Z_1V_1 + Z_2V_2 = \operatorname{gcrd}(V_1, V_2)$. [*Hint:* Use auxiliary variables u_1, u_2, v_1, v_2, w_1, w_2, w_1', w_2', z_1, z_2, z_1', z_2', whose values are string polynomials; start by setting $u_1 \leftarrow U_1$, $u_2 \leftarrow U_2$, $v_1 \leftarrow V_1$, $v_2 \leftarrow V_2$, and throughout the algorithm maintain the conditions

$$\begin{aligned} U_1w_1 + U_2w_2 &= u_1, & z_1V_1 + z_2V_2 &= v_1, \\ U_1w_1' + U_2w_2' &= u_2, & z_1'V_1 + z_2'V_2 &= v_2, \\ u_1z_1 - u_2z_1' &= (-1)^nU_1, & w_1v_1 - w_1'v_2 &= (-1)^nV_1, \\ -u_1z_2 + u_2z_2' &= (-1)^nU_2, & -w_2v_1 + w_2'v_2 &= (-1)^nV_2 \end{aligned}$$

at the nth iteration. This might be regarded as the "ultimate" extension of Euclid's algorithm.]

19. [*M39*] (*Common divisors of square matrices.*) Exercise 18 shows that the concept of greatest common right divisor can be meaningful when multiplication is not commutative. Prove that any two $n \times n$ matrices A and B of integers have a greatest common right matrix divisor D. [*Suggestion:* Design an algorithm whose inputs are A and B, and whose outputs are integer matrices D, P, Q, X, Y, where $A = PD$, $B = QD$, and $D = XA + YB$.] Find a greatest common right divisor of the matrices $\left(\begin{smallmatrix} 1 & 2 \\ 3 & 4 \end{smallmatrix}\right)$ and $\left(\begin{smallmatrix} 4 & 3 \\ 2 & 1 \end{smallmatrix}\right)$.

20. [*M40*] Investigate the accuracy of Euclid's algorithm: What can be said about calculation of the greatest common divisor of polynomials whose coefficients are floating point numbers?

21. [*M25*] Prove that the computation time required by Algorithm C to compute the gcd of two nth degree polynomials over the integers is $O(n^4(\log Nn)^2)$, if the coefficients of the given polynomials are bounded by N in absolute value.

22. [*M23*] Prove Sturm's theorem. [*Hint:* Some sign sequences are impossible.]

23. [*M22*] Prove that if $u(x)$ in (29) has $\deg(u)$ real roots, then we have $\deg(u_{j+1}) = \deg(u_j) - 1$ for $0 \le j \le k$.

24. [*M21*] Show that (19) simplifies to (20) and (23) simplifies to (24).

25. [*M24*] (W. S. Brown.) Prove that all the polynomials $u_j(x)$ in (16) for $j \ge 3$ are multiples of $\gcd(\ell(u), \ell(v))$, and explain how to improve Algorithm C accordingly.

▶ **26.** [*M26*] The purpose of this exercise is to give an analog for polynomials of the fact that continued fractions with positive integer entries give the best approximations to real numbers (exercise 4.5.3-42).

Let $u(x)$ and $v(x)$ be polynomials over a field, with $\deg(u) > \deg(v)$, and let $a_1(x)$, $a_2(x)$, ... be the quotient polynomials when Euclid's algorithm is applied to $u(x)$ and $v(x)$. For example, the sequence of quotients in (5) and (6) is $9x^2 + 7$, $5x^2 + 5$, $6x^3 + 5x^2 + 6x + 5$, $9x + 12$. We wish to show that the convergents $p_n(x)/q_n(x)$ of the continued fraction $/a_1(x), a_2(x), \ldots/$ are the "best approximations" of low degree to the rational function $v(x)/u(x)$, where we have $p_n(x) = Q_{n-1}(a_2(x), \ldots, a_n(x))$ and $q_n(x) = Q_n(a_1(x), \ldots, a_n(x))$ in terms of the continuant polynomials of Eq. 4.5.3–4. By convention, we let $p_0(x) = q_{-1}(x) = 0$, $p_{-1}(x) = q_0(x) = 1$.

Prove that if $p(x)$ and $q(x)$ are polynomials such that $\deg(q) < \deg(q_n)$ and $\deg(pu - qv) \le \deg(p_{n-1}u - q_{n-1}v)$, for some $n \ge 1$, then $p(x) = cp_{n-1}(x)$ and $q(x) = cq_{n-1}(x)$ for some constant c. In particular, each $q_n(x)$ is a "record-breaking" polynomial in the sense that no nonzero polynomial $q(x)$ of smaller degree can make the quantity $p(x)u(x) - q(x)v(x)$, for any polynomial $p(x)$, achieve a degree as small as $p_n(x)u(x) - q_n(x)v(x)$.

*4.6.2. Factorization of Polynomials

Let us now consider the problem of *factoring* polynomials, not merely finding the greatest common divisor of two or more of them.

Factoring modulo p. As in the case of integer numbers (Sections 4.5.2, 4.5.4), the problem of factoring seems to be more difficult than finding the greatest common divisor. But factorization of polynomials modulo a prime integer p is not as hard to do as we might expect. It is much easier to find the factors of an arbitrary polynomial of degree n, modulo 2, than to use any known method to find the factors of an arbitrary n-bit binary number. This surprising situation is a consequence of an instructive factorization algorithm discovered in 1967 by Elwyn R. Berlekamp [*Bell System Technical J.* **46** (1967), 1853–1859].

Let p be a prime number; all arithmetic on polynomials in the following discussion will be done modulo p. Suppose that someone has given us a polynomial $u(x)$, whose coefficients are chosen from the set $\{0, 1, \ldots, p-1\}$; we may assume

that $u(x)$ is monic. Our goal is to express $u(x)$ in the form

$$u(x) = p_1(x)^{e_1} \dots p_r(x)^{e_r}, \tag{1}$$

where $p_1(x), \dots, p_r(x)$ are distinct, monic, irreducible polynomials.

As a first step, we can use a standard technique to determine whether any of the exponents $e_1, \dots, e_r$ are greater than unity. If

$$u(x) = u_n x^n + \cdots + u_0 = v(x)^2 w(x), \tag{2}$$

then its "derivative" formed in the usual way (but modulo p) is

$$u'(x) = n u_n x^{n-1} + \cdots + u_1 = 2v(x)v'(x)w(x) + v(x)^2 w'(x), \tag{3}$$

and this is a multiple of the squared factor $v(x)$. Therefore our first step in factoring $u(x)$ is to form

$$\gcd\big(u(x), u'(x)\big) = d(x). \tag{4}$$

If $d(x)$ is equal to 1, we know that $u(x)$ is "squarefree," the product of distinct primes $p_1(x) \dots p_r(x)$. If $d(x)$ is not equal to 1 and $d(x) \neq u(x)$, then $d(x)$ is a proper factor of $u(x)$; the relation between the factors of $d(x)$ and the factors of $u(x)/d(x)$ speeds up the factorization process nicely in this case (see exercise 34). Finally, if $d(x) = u(x)$, we must have $u'(x) = 0$; hence the coefficient u_k of x^k is nonzero only when k is a multiple of p. This means that $u(x)$ can be written as a polynomial of the form $v(x^p)$, and in such a case we have

$$u(x) = v(x^p) = \big(v(x)\big)^p; \tag{5}$$

the factorization process can be completed by finding the irreducible factors of $v(x)$ and raising them to the pth power.

Identity (5) may appear somewhat strange to the reader; it is an important fact that is basic to Berlekamp's algorithm and to several other methods we shall discuss. We can prove it as follows: If $v_1(x)$ and $v_2(x)$ are any polynomials modulo p, then

$$\begin{aligned}\big(v_1(x) + v_2(x)\big)^p &= v_1(x)^p + \tbinom{p}{1} v_1(x)^{p-1} v_2(x) \\ &\qquad + \cdots + \tbinom{p}{p-1} v_1(x) v_2(x)^{p-1} + v_2(x)^p \\ &= v_1(x)^p + v_2(x)^p,\end{aligned}$$

since the binomial coefficients $\binom{p}{1}, \dots, \binom{p}{p-1}$ are all multiples of p. Furthermore if a is any integer, we have $a^p \equiv a$ (modulo p) by Fermat's theorem. Therefore when $v(x) = v_m x^m + v_{m-1} x^{m-1} + \cdots + v_0$, we find that

$$\begin{aligned}v(x)^p &= (v_m x^m)^p + (v_{m-1} x^{m-1})^p + \cdots + (v_0)^p \\ &= v_m x^{mp} + v_{m-1} x^{(m-1)p} + \cdots + v_0 \;=\; v(x^p).\end{aligned}$$

The above remarks show that the problem of factoring a polynomial reduces to the problem of factoring a squarefree polynomial. Let us therefore assume that

$$u(x) = p_1(x)p_2(x)\dots p_r(x) \tag{6}$$

is the product of distinct primes. How can we be clever enough to discover the $p_j(x)$'s when only $u(x)$ is given? Berlekamp's idea is to make use of the Chinese remainder theorem, which is valid for polynomials just as it is valid for integers (see exercise 3). If $(s_1, s_2, \dots, s_r)$ is any r-tuple of integers mod p, the Chinese remainder theorem implies that *there is a unique polynomial* $v(x)$ *such that*

$$\begin{gathered} v(x) \equiv s_1 \ \big(\text{modulo } p_1(x)\big), \quad \dots, \quad v(x) \equiv s_r \ \big(\text{modulo } p_r(x)\big), \\ \deg(v) < \deg(p_1) + \deg(p_2) + \cdots + \deg(p_r) = \deg(u). \end{gathered} \tag{7}$$

The notation $g(x) \equiv h(x) \ \big(\text{modulo } f(x)\big)$ that appears here is the same as "$g(x) \equiv h(x)$ (modulo $f(x)$ and p)" in exercise 3.2.2–11, since we are considering polynomial arithmetic modulo p. The polynomial $v(x)$ in (7) gives us a way to get at the factors of $u(x)$, for if $r \geq 2$ and $s_1 \neq s_2$, we will have $\gcd\big(u(x), v(x) - s_1\big)$ divisible by $p_1(x)$ but not by $p_2(x)$.

Since this observation shows that we can get information about the factors of $u(x)$ from appropriate solutions $v(x)$ of (7), let us analyze (7) more closely. In the first place we can observe that the polynomial $v(x)$ satisfies the condition $v(x)^p \equiv s_j^p = s_j \equiv v(x) \ \big(\text{modulo } p_j(x)\big)$ for $1 \leq j \leq r$, therefore

$$v(x)^p \equiv v(x) \ \big(\text{modulo } u(x)\big), \qquad \deg(v) < \deg(u). \tag{8}$$

In the second place we have the basic polynomial identity

$$x^p - x \equiv (x-0)(x-1)\dots\big(x-(p-1)\big) \quad (\text{modulo } p) \tag{9}$$

(see exercise 6); hence

$$v(x)^p - v(x) = \big(v(x)-0\big)\big(v(x)-1\big)\dots\big(v(x)-(p-1)\big) \tag{10}$$

is an identity for any polynomial $v(x)$, when we are working modulo p. If $v(x)$ satisfies (8), it follows that $u(x)$ divides the left-hand side of (10), so every irreducible factor of $u(x)$ must divide one of the p relatively prime factors of the right-hand side of (10). In other words, *all* solutions of (8) must have the form of (7), for some $s_1, s_2, \dots, s_r$; *there are exactly* p^r *solutions of* (8).

The solutions $v(x)$ to congruence (8) therefore provide a key to the factorization of $u(x)$. It may seem harder to find all solutions to (8) than to factor $u(x)$ in the first place, but in fact this is not true, since the set of solutions to (8) is closed under addition. Let $\deg(u) = n$; we can construct the $n \times n$ matrix

$$Q = \begin{pmatrix} q_{0,0} & q_{0,1} & \cdots & q_{0,n-1} \\ \vdots & \vdots & & \vdots \\ q_{n-1,0} & q_{n-1,1} & \cdots & q_{n-1,n-1} \end{pmatrix} \tag{11}$$

where

$$x^{pk} \equiv q_{k,n-1}x^{n-1} + \cdots + q_{k,1}x + q_{k,0} \pmod{u(x)}. \tag{12}$$

Then $v(x) = v_{n-1}x^{n-1} + \cdots + v_1x + v_0$ is a solution to (8) if and only if

$$(v_0, v_1, \ldots, v_{n-1})Q = (v_0, v_1, \ldots, v_{n-1}); \tag{13}$$

for the latter equation holds if and only if

$$v(x) = \sum_j v_j x^j = \sum_j \sum_k v_k q_{k,j} x^j \equiv \sum_k v_k x^{pk} = v(x^p) \equiv v(x)^p \pmod{u(x)}.$$

Berlekamp's factoring algorithm therefore proceeds as follows:

B1. Ensure that $u(x)$ is squarefree; i.e., if $\gcd(u(x), u'(x)) \neq 1$, reduce the problem of factoring $u(x)$, as stated earlier in this section.

B2. Form the matrix Q defined by (11) and (12). This can be done in one of two ways, depending on whether or not p is very large, as explained below.

B3. "Triangularize" the matrix $Q - I$, where $I = (\delta_{ij})$ is the $n \times n$ identity matrix, finding its rank $n - r$ and finding linearly independent vectors $v^{[1]}$, $\ldots$, $v^{[r]}$ such that $v^{[j]}(Q-I) = (0, 0, \ldots, 0)$ for $1 \leq j \leq r$. (The first vector $v^{[1]}$ may always be taken as $(1, 0, \ldots, 0)$, representing the trivial solution $v^{[1]}(x) = 1$ to (8). The "triangularization" needed in this step can be done using appropriate column operations, as explained in Algorithm N below.) *At this point, r is the number of irreducible factors of $u(x)$,* because the solutions to (8) are the p^r polynomials corresponding to the vectors $t_1v^{[1]} + \cdots + t_rv^{[r]}$ for all choices of integers $0 \leq t_1, \ldots, t_r < p$. Therefore if $r = 1$ we know that $u(x)$ is irreducible, and the procedure terminates.

B4. Calculate $\gcd(u(x), v^{[2]}(x)-s)$ for $0 \leq s < p$, where $v^{[2]}(x)$ is the polynomial represented by vector $v^{[2]}$. The result will be a nontrivial factorization of $u(x)$, because $v^{[2]}(x) - s$ is nonzero and has degree less than $\deg(u)$, and by exercise 7 we have

$$u(x) = \prod_{0 \leq s < p} \gcd(v(x) - s, u(x)) \tag{14}$$

whenever $v(x)$ satisfies (8).

If the use of $v^{[2]}(x)$ does not succeed in splitting $u(x)$ into r factors, further factors can be obtained by calculating $\gcd(v^{[k]}(x) - s, w(x))$ for $0 \leq s < p$ and all factors $w(x)$ found so far, for $k = 3, 4, \ldots$, until r factors are obtained. (If we choose $s_i \neq s_j$ in (7), we obtain a solution $v(x)$ to (8) that distinguishes $p_i(x)$ from $p_j(x)$; some $v^{[k]}(x) - s$ will be divisible by $p_i(x)$ and not by $p_j(x)$, so this procedure will eventually find all of the factors.)

If p is 2 or 3, the calculations of this step are quite efficient; but if p is more than 25, say, there is a much better way to proceed, as we shall see later. ∎

As an example of this procedure, let us now determine the factorization of

$$u(x) = x^8 + x^6 + 10x^4 + 10x^3 + 8x^2 + 2x + 8 \tag{15}$$

modulo 13. (This polynomial appears in several of the examples in Section 4.6.1.) A quick calculation using Algorithm 4.6.1E shows that $\gcd(u(x), u'(x)) = 1$; therefore $u(x)$ is squarefree, and we turn to step B2. Step B2 involves calculating the Q matrix, which in this case is an 8×8 array. The first row of Q is always $(1, 0, 0, \ldots, 0)$, representing the polynomial $x^0 \bmod u(x) = 1$. The second row represents $x^{13} \bmod u(x)$, and, in general, $x^k \bmod u(x)$ may readily be determined as follows (for relatively small values of k): If

$$u(x) = x^n + u_{n-1}x^{n-1} + \cdots + u_1 x + u_0$$

and if

$$x^k \equiv a_{k,n-1}x^{n-1} + \cdots + a_{k,1}x + a_{k,0} \ \ (\text{modulo } u(x)),$$

then

$$\begin{aligned} x^{k+1} &\equiv a_{k,n-1}x^n + \cdots + a_{k,1}x^2 + a_{k,0}x \\ &\equiv a_{k,n-1}(-u_{n-1}x^{n-1} - \cdots - u_1 x - u_0) + a_{k,n-2}x^{n-1} + \cdots + a_{k,0}x \\ &= a_{k+1,n-1}x^{n-1} + \cdots + a_{k+1,1}x + a_{k+1,0}, \end{aligned}$$

where

$$a_{k+1,j} = a_{k,j-1} - a_{k,n-1}u_j. \tag{16}$$

In this formula $a_{k,-1}$ is treated as zero, so that $a_{k+1,0} = -a_{k,n-1}u_0$. The simple "shift register" recurrence (16) makes it easy to calculate x^1, x^2, x^3, ... mod $u(x)$. Inside a computer, this calculation is of course generally done by maintaining a one-dimensional array $(a_{n-1}, \ldots, a_1, a_0)$ and repeatedly setting $t \leftarrow a_{n-1}$, $a_{n-1} \leftarrow (a_{n-2} - tu_{n-1}) \bmod p$, ..., $a_1 \leftarrow (a_0 - tu_1) \bmod p$, and $a_0 \leftarrow (-tu_0) \bmod p$. (We have seen similar procedures in connection with random number generation; cf. Eq. 3.2.2–10.) For the example polynomial $u(x)$ in (15), we obtain the following sequence of coefficients of $x^k \bmod u(x)$, using arithmetic modulo 13:

k	$a_{k,7}$	$a_{k,6}$	$a_{k,5}$	$a_{k,4}$	$a_{k,3}$	$a_{k,2}$	$a_{k,1}$	$a_{k,0}$
0	0	0	0	0	0	0	0	1
1	0	0	0	0	0	0	1	0
2	0	0	0	0	0	1	0	0
3	0	0	0	0	1	0	0	0
4	0	0	0	1	0	0	0	0
5	0	0	1	0	0	0	0	0
6	0	1	0	0	0	0	0	0
7	1	0	0	0	0	0	0	0
8	0	12	0	3	3	5	11	5
9	12	0	3	3	5	11	5	0
10	0	4	3	2	8	0	2	8
11	4	3	2	8	0	2	8	0
12	3	11	8	12	1	2	5	7
13	11	5	12	10	11	7	1	2

Therefore the second row of Q is $(2,1,7,11,10,12,5,11)$. Similarly we may determine $x^{26} \bmod u(x)$, ..., $x^{91} \bmod u(x)$, and we find that

$$Q = \begin{pmatrix} 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 2 & 1 & 7 & 11 & 10 & 12 & 5 & 11 \\ 3 & 6 & 4 & 3 & 0 & 4 & 7 & 2 \\ 4 & 3 & 6 & 5 & 1 & 6 & 2 & 3 \\ 2 & 11 & 8 & 8 & 3 & 1 & 3 & 11 \\ 6 & 11 & 8 & 6 & 2 & 7 & 10 & 9 \\ 5 & 11 & 7 & 10 & 0 & 11 & 7 & 12 \\ 3 & 3 & 12 & 5 & 0 & 11 & 9 & 12 \end{pmatrix},$$

$$Q - I = \begin{pmatrix} 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 2 & 0 & 7 & 11 & 10 & 12 & 5 & 11 \\ 3 & 6 & 3 & 3 & 0 & 4 & 7 & 2 \\ 4 & 3 & 6 & 4 & 1 & 6 & 2 & 3 \\ 2 & 11 & 8 & 8 & 2 & 1 & 3 & 11 \\ 6 & 11 & 8 & 6 & 2 & 6 & 10 & 9 \\ 5 & 11 & 7 & 10 & 0 & 11 & 6 & 12 \\ 3 & 3 & 12 & 5 & 0 & 11 & 9 & 11 \end{pmatrix}. \tag{17}$$

That finishes step B2; the next step of Berlekamp's procedure requires finding the "null space" of $Q - I$. In general, suppose that A is an $n \times n$ matrix over a field, whose rank $n - r$ is to be determined; suppose further that we wish to determine linearly independent vectors $v^{[1]}$, $v^{[2]}$, ..., $v^{[r]}$ such that $v^{[1]}A = v^{[2]}A = \cdots = v^{[r]}A = (0, \ldots, 0)$. An algorithm for this calculation can be based on the observation that any column of A may be multiplied by a nonzero quantity, and any multiple of one of its columns may be added to a different column, without changing the rank or the vectors $v^{[1]}, \ldots, v^{[r]}$. (These transformations amount to replacing A by AB, where B is a nonsingular matrix.) The following well-known "triangularization" procedure may therefore be used.

Algorithm N (*Null space algorithm*). Let A be an $n \times n$ matrix, whose elements a_{ij} belong to a field and have subscripts in the range $0 \le i, j < n$. This algorithm outputs r vectors $v^{[1]}$, ..., $v^{[r]}$, which are linearly independent over the field and satisfy $v^{[j]}A = (0, \ldots, 0)$, where $n - r$ is the rank of A.

N1. [Initialize.] Set $c_0 \leftarrow c_1 \leftarrow \cdots \leftarrow c_{n-1} \leftarrow -1$, $r \leftarrow 0$. (During the calculation we will have $c_j \ge 0$ only if $a_{c_j j} = -1$ and all other entries of row c_j are zero.)

N2. [Loop on k.] Do step N3 for $k = 0$, 1, ..., $n - 1$, and then terminate the algorithm.

N3. [Scan row for dependence.] If there is some j in the range $0 \le j < n$ such that $a_{kj} \ne 0$ and $c_j < 0$, then do the following: Multiply column j of A by $-1/a_{kj}$ (so that a_{kj} becomes equal to -1); then add a_{ki} times column j to column i for all $i \ne j$; finally set $c_j \leftarrow k$. (Since it is not difficult to show that $a_{sj} = 0$ for all $s < k$, these operations have no effect on rows 0, 1, ..., $k - 1$ of A.)

On the other hand, if there is no j in the range $0 \le j < n$ such that $a_{kj} \neq 0$ and $c_j < 0$, then set $r \leftarrow r + 1$ and output the vector

$$v^{[r]} = (v_0, v_1, \ldots, v_{n-1})$$

defined by the rule

$$v_j = \begin{cases} a_{ks}, & \text{if } c_s = j \ge 0; \\ 1, & \text{if } j = k; \\ 0, & \text{otherwise.} \end{cases} \tag{18}$$

∎

An example will reveal the mechanism of this algorithm. Let A be the matrix $Q - I$ of (17) over the field of integers modulo 13. When $k = 0$, we output the vector $v^{[1]} = (1, 0, 0, 0, 0, 0, 0, 0)$. When $k = 1$, we may take j in step N3 to be either 0, 2, 3, 4, 5, 6, or 7; the choice here is completely arbitrary, although it affects the particular vectors that are chosen to be output by the algorithm. For hand calculation, it is most convenient to pick $j = 5$, since $a_{15} = 12 = -1$ already; the column operations of step N3 then change A to the matrix

$$\begin{pmatrix} 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & \textcircled{12} & 0 & 0 \\ 11 & 6 & 5 & 8 & 1 & 4 & 1 & 7 \\ 3 & 3 & 9 & 5 & 9 & 6 & 6 & 4 \\ 4 & 11 & 2 & 6 & 12 & 1 & 8 & 9 \\ 5 & 11 & 11 & 7 & 10 & 6 & 1 & 10 \\ 1 & 11 & 6 & 1 & 6 & 11 & 9 & 3 \\ 12 & 3 & 11 & 9 & 6 & 11 & 12 & 2 \end{pmatrix}.$$

(The circled element in column "5", row "1", is used here to indicate that $c_5 = 1$. Remember that Algorithm N numbers the rows and columns of the matrix starting with 0, not 1.) When $k = 2$, we may choose $j = 4$ and proceed in a similar way, obtaining the following matrices, which all have the same null space as $Q - I$:

$k = 2$

$$\begin{pmatrix} 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & \textcircled{12} & 0 & 0 \\ 0 & 0 & 0 & 0 & \textcircled{12} & 0 & 0 & 0 \\ 8 & 1 & 3 & 11 & 4 & 9 & 10 & 6 \\ 2 & 4 & 7 & 1 & 1 & 5 & 9 & 3 \\ 12 & 3 & 0 & 5 & 3 & 5 & 4 & 5 \\ 0 & 1 & 2 & 5 & 7 & 0 & 3 & 0 \\ 11 & 6 & 7 & 0 & 7 & 0 & 6 & 12 \end{pmatrix}$$

$k = 3$

$$\begin{pmatrix} 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & \textcircled{12} & 0 & 0 \\ 0 & 0 & 0 & 0 & \textcircled{12} & 0 & 0 & 0 \\ 0 & \textcircled{12} & 0 & 0 & 0 & 0 & 0 & 0 \\ 9 & 9 & 8 & 9 & 11 & 8 & 8 & 5 \\ 1 & 10 & 4 & 11 & 4 & 4 & 0 & 0 \\ 5 & 12 & 12 & 7 & 3 & 4 & 6 & 7 \\ 2 & 7 & 2 & 12 & 9 & 11 & 11 & 2 \end{pmatrix}$$

$k = 4$

$$\begin{pmatrix} 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & (12) & 0 & 0 \\ 0 & 0 & 0 & 0 & (12) & 0 & 0 & 0 \\ 0 & (12) & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & (12) \\ 1 & 10 & 4 & 11 & 4 & 4 & 0 & 0 \\ 8 & 2 & 6 & 10 & 11 & 11 & 0 & 9 \\ 1 & 6 & 4 & 11 & 2 & 0 & 0 & 10 \end{pmatrix}$$

$k = 5$

$$\begin{pmatrix} 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & (12) & 0 & 0 \\ 0 & 0 & 0 & 0 & (12) & 0 & 0 & 0 \\ 0 & (12) & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & (12) \\ (12) & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 5 & 0 & 0 & 0 & 5 & 5 & 0 & 9 \\ 12 & 9 & 0 & 0 & 11 & 9 & 0 & 10 \end{pmatrix}$$

Now every column that has no circled entry is completely zero; so when $k = 6$ and $k = 7$ the algorithm outputs two more vectors, namely

$$v^{[2]} = (0, 5, 5, 0, 9, 5, 1, 0), \qquad v^{[3]} = (0, 9, 11, 9, 10, 12, 0, 1).$$

From the form of matrix A after $k = 5$, it is evident that these vectors satisfy the equation $vA = (0, \ldots, 0)$. Since the computation has produced three linearly independent vectors, $u(x)$ must have exactly three irreducible factors.

Finally we can go to step B4 of the factoring procedure. The calculation of $\gcd\big(u(x), v^{[2]}(x) - s\big)$ for $0 \le s < 13$, where $v^{[2]}(x) = x^6 + 5x^5 + 9x^4 + 5x^2 + 5x$, gives $x^5 + 5x^4 + 9x^3 + 5x + 5$ as the answer when $s = 0$, and $x^3 + 8x^2 + 4x + 12$ when $s = 2$; the gcd is unity for other values of s. Therefore $v^{[2]}(x)$ gives us only two of the three factors. Turning to $\gcd\big(v^{[3]}(x) - s,\ x^5 + 5x^4 + 9x^3 + 5x + 5\big)$, where $v^{[3]}(x) = x^7 + 12x^5 + 10x^4 + 9x^3 + 11x^2 + 9x$, we obtain the value $x^4 + 2x^3 + 3x^2 + 4x + 6$ when $s = 6$, $x + 3$ when $s = 8$, and unity otherwise. Thus the complete factorization is

$$u(x) = (x^4 + 2x^3 + 3x^2 + 4x + 6)(x^3 + 8x^2 + 4x + 12)(x + 3). \tag{19}$$

Let us now estimate the running time of Berlekamp's method when an nth degree polynomial is factored modulo p. First assume that p is relatively small, so that the four arithmetic operations can be done modulo p in essentially a fixed length of time. (Division modulo p can be converted to multiplication, by storing a table of reciprocals as suggested in exercise 9; for example, when working modulo 13, we have $\frac{1}{2} = 7$, $\frac{1}{3} = 9$, etc.) The computation in step B1 takes $O(n^2)$ units of time; step B2 takes $O(pn^2)$. For step B3 we use Algorithm N, which requires $O(n^3)$ units of time at most. Finally, in step B4 we can observe that the calculation of $\gcd\big(f(x), g(x)\big)$ by Euclid's algorithm takes $O\big(\deg(f)\deg(q)\big)$ units of time; hence the calculation of $\gcd\big(v^{[j]}(x) - s,\ w(x)\big)$ for fixed j and s and for all factors $w(x)$ of $u(x)$ found so far takes $O(n^2)$ units. Step B4 therefore requires $O(prn^2)$ units of time at most. *Berlekamp's procedure factors an arbitrary polynomial of degree n, modulo p, in $O(n^3 + prn^2)$ steps*, when p is a small prime; and exercise 5 shows that the average number of factors, r, is approximately $\ln n$.

Thus the algorithm is much faster than any known methods of factoring n-digit numbers in the p-ary number system.

Of course, when n and p are small, a trial-and-error factorization procedure analogous to Algorithm 4.5.4A will be even faster than Berlekamp's method. Exercise 1 implies that it is a good idea to cast out factors of small degree first when p is small, before going to any more complicated procedure, even when n is large.

When p is large, a different implementation of Berlekamp's procedure would be used for the calculations. Division modulo p would not be done with an auxiliary table of reciprocals; instead the method of exercise 4.5.2–15, which takes $O((\log p)^2)$ steps, would probably be used. Then step B1 would take $O(n^2(\log p)^2)$ units of time; similarly, step B3 takes $O(n^3(\log p)^2)$. In step B2, we can form $x^p \bmod u(x)$ in a more efficient way than (16) when p is large: Section 4.6.3 shows that this value can essentially be obtained by using $O(\log p)$ operations of "squaring $\bmod u(x)$," i.e., going from $x^k \bmod u(x)$ to $x^{2k} \bmod u(x)$. The squaring operation is relatively easy to perform if we first make an auxiliary table of $x^m \bmod u(x)$ for $m = n, n+1, \ldots, 2n-2$; if

$$x^k \bmod u(x) = c_{n-1}x^{n-1} + \cdots + c_1 x + c_0,$$

then

$$x^{2k} \bmod u(x) = \left(c_{n-1}^2 x^{2n-2} + \cdots + (c_1c_0 + c_1c_0)x + c_0^2\right) \bmod u(x),$$

where $x^{2n-2}, \ldots, x^n$ can be replaced by polynomials in the auxiliary table. The total time to compute $x^p \bmod u(x)$ comes to $O(n^2(\log p)^3)$ units, and we obtain the second row of Q. To get further rows of Q, we can compute $x^{2p} \bmod u(x)$, $x^{3p} \bmod u(x)$, ..., simply by multiplying repeatedly by $x^p \bmod u(x)$, in a fashion analogous to squaring $\bmod u(x)$; step B2 is completed in $O(n^2(\log p)^3)$ units of time. Thus steps B1, B2, and B3 take a total of $O(n^2(\log p)^3 + n^3(\log p)^2)$ units of time; these three steps tell us the number of factors of $u(x)$.

But when p is large and we get to step B4, we are asked to calculate a greatest common divisor for p different values of s, and that is out of the question if p is even moderately large. This hurdle was first surmounted by Hans Zassenhaus [*J. Number Theory* **1** (1969), 291–311], who showed how to determine all of the "useful" values of s (see exercise 14); but an even better way to proceed was found by Zassenhaus and Cantor in 1980. If $v(x)$ is any solution to (8), we know that $u(x)$ divides $v(x)^p - v(x) = v(x) \cdot \left(v(x)^{(p-1)/2} + 1\right) \cdot \left(v(x)^{(p-1)/2} - 1\right)$. This suggests that we calculate

$$\gcd\left(u(x), v(x)^{(p-1)/2} - 1\right); \tag{20}$$

with a little bit of luck, (20) will be a nontrivial factor of $u(x)$. In fact, we can determine exactly how much luck is involved, by considering (7). Let $v(x) \equiv s_j$ (modulo $p_j(x)$) for $1 \le j \le r$; then $p_j(x)$ divides $v(x)^{(p-1)/2} - 1$ if and only if

$s_j^{(p-1)/2} \equiv 1$ (modulo p). We know that exactly $(p-1)/2$ of the integers s in the range $0 \le s < p$ satisfy $s^{(p-1)/2} \equiv 1$ (modulo p), hence about half of the $p_j(x)$ will appear in the gcd (20). More precisely, if $v(x)$ is a random solution of (8), where all p^r solutions are equally likely, the probability that the gcd (20) equals $u(x)$ is exactly

$$\big((p-1)/2p\big)^r,$$

and the probability that it equals 1 is $\big((p+1)/2p\big)^r$. The probability that a nontrivial factor will be obtained is therefore

$$1-\left(\frac{p-1}{2p}\right)^r-\left(\frac{p+1}{2p}\right)^r = 1-\frac{1}{2^{r-1}}\left(1+\binom{r}{2}p^{-2}+\binom{r}{4}p^{-4}+\cdots\right) \ge \frac{4}{9},$$

for all $r \ge 2$ and $p \ge 3$.

It is therefore a good idea to replace step B4 by the following procedure, unless p is quite small: Set $v(x) \leftarrow a_1 v^{[1]}(x) + a_2 v^{[2]}(x) + \cdots + a_r v^{[r]}(x)$, where the coefficients a_j are randomly chosen in the range $0 \le a_j < p$. Let the current partial factorization of $u(x)$ be $u_1(x)\ldots u_t(x)$ where t is initially 1. Compute

$$g_i(x) = \gcd\big(u_i(x), v(x)^{(p-1)/2} - 1\big)$$

for all i such that $\deg(u_i) > 1$; replace $u_i(x)$ by $g_i(x)\cdot\big(u_i(x)/g_i(x)\big)$ and increase the value of t, whenever a nontrivial gcd is found. Repeat this process for different choices of $v(x)$ until $t = r$.

If we assume (as we may) that only $O(\log r)$ random solutions $v(x)$ to (8) will be needed, we can give an upper bound on the time required to perform this alternative to step B4. It takes $O\big(r(\log p)^2\big)$ steps to compute $v(x)$; and if $\deg(u_i) = d$, it takes $O\big(d^2(\log p)^3\big)$ steps to compute $v(x)^{(p-1)/2} \bmod u_i(x)$ and $O\big(d^2(\log p)^2\big)$ further steps to compute $\gcd\big(u_i(x), v(x)^{(p-1)/2} - 1\big)$. Thus the total time is $O(n^2(\log p)^3 \log r)$.

For further discussion, see the articles by E. R. Berlekamp, *Math. Comp.* **24** (1970), 713–735, and Robert T. Moenck, *Math. Comp.* **31** (1977), 235–250.

Distinct-degree factorization. We shall now turn to a somewhat simpler way to find factors modulo p. The ideas we have studied so far in this section involve many instructive insights into computational algebra, so the author does not apologize to the reader for presenting them; but it turns out that the problem of factorization modulo p can actually be solved without relying on so many concepts.

In the first place we can make use of the fact that an irreducible polynomial $q(x)$ of degree d is a divisor of $x^{p^d} - x$, and it is not a divisor of $x^{p^c} - x$ for $c < d$; see exercise 16. We can therefore cast out the irreducible factors of each degree separately, by adopting the following strategy.

D1. Rule out squared factors, as in Berlekamp's method. Also set $v(x) \leftarrow u(x)$, $w(x) \leftarrow$ "x", and $d \leftarrow 0$. (Here $v(x)$ and $w(x)$ are variables that have polynomials as values.)

D2. (At this point $w(x) = x^{p^d} \bmod v(x)$; all of the irreducible factors of $v(x)$ are distinct and have degree $> d$.) If $d+1 > \frac{1}{2}\deg(v)$, the procedure terminates since we either have $v(x) = 1$ or $v(x)$ is irreducible. Otherwise increase d by 1 and replace $w(x)$ by $w(x)^p \bmod v(x)$.

D3. Find $g_d(x) = \gcd\big(w(x) - x, v(x)\big)$. (This is the product of all the irreducible factors of $u(x)$ whose degree is d.) If $g_d(x) \neq 1$, replace $v(x)$ by $v(x)/g_d(x)$ and $w(x)$ by $w(x) \bmod v(x)$; and if the degree of $g_d(x)$ is greater than d, use the algorithm below to find its factors. Return to step D2. ∎

This procedure determines the product of all irreducible factors of each degree d, and therefore it tells us how many factors there are of each degree. Since the three factors of our example polynomial (19) have different degrees, they would all be discovered without any need to factorize the polynomials $g_d(x)$.

The distinct degree factorization technique was known to several people in 1960 [cf. S. W. Golomb, L. R. Welch, A. Hales, "On the factorization of trinomials over GF(2)," Jet Propulsion Laboratory memo 20–189 (July 14, 1959)], but there seem to be no references to it in the "open literature." Previous work by Š. Schwarz, *Quart. J. Math.*, Oxford (2) **7** (1956), 110–124, had shown how to determine the number of irreducible factors of each degree, but not their product, using the matrix Q.

To complete the method, we need a way to split the polynomial $g_d(x)$ into its irreducible factors when $\deg(g_d) > d$. Michael Rabin pointed out in 1976 that this can be done by doing arithmetic in the field of p^d elements. David G. Cantor and Hans Zassenhaus discovered in 1979 that there is an even simpler way to proceed, based on the following identity: If p is any odd prime, we have

$$g_d(x) = \gcd\big(g_d(x), t(x)\big) \cdot \gcd\big(g_d(x), t(x)^{(p^d-1)/2} + 1\big) \cdot \gcd\big(g_d(x), t(x)^{(p^d-1)/2} - 1\big) \tag{21}$$

for all polynomials $t(x)$, since $t(x)^{p^d} - t(x)$ is a multiple of all irreducible polynomials of degree d. (We may regard $t(x)$ as an element of the field of size p^d, when that field consists of all polynomials modulo an irreducible $f(x)$ as in exercise 16.) Now exercise 29 shows that $\gcd\big(g_d(x), t(x)^{(p^d-1)/2}\big)$ will be a nontrivial factor of $g_d(x)$ about 50 per cent of the time, when $t(x)$ is a random polynomial of degree $\leq 2d - 1$; hence it will not take long to discover all of the factors. We may assume without loss of generality that $t(x)$ is monic, since integer multiples of $t(x)$ make no difference except possibly to change $t(x)^{(p^d-1)/2}$ into its negative. Thus in the case $d = 1$, we can take $t(x) = x + s$, where s is chosen at random. [See *SIAM J. Computing* **9** (1980), 273–280; *Math. Comp.*, to appear.]

Sometimes this procedure will in fact succeed for $d > 1$ when only linear polynomials $t(x)$ are used. For example, there are eight irreducible polynomials $f(x)$ of degree 3, modulo 3, and they will all be distinguished by calculating

$\gcd\big(f(x), (x+s)^{13}-1\big)$ for $0 \le s < 3$:

$f(x)$	$s=0$	$s=1$	$s=2$
x^3+2x+1	1	1	1
x^3+2x+2	$f(x)$	$f(x)$	$f(x)$
x^3+x^2+2	$f(x)$	$f(x)$	1
x^3+x^2+x+2	$f(x)$	1	$f(x)$
x^3+x^2+2x+1	1	$f(x)$	$f(x)$
x^3+2x^2+1	1	$f(x)$	1
x^3+2x^2+x+1	1	1	$f(x)$
x^3+2x^2+2x+2	$f(x)$	1	1

Exercise 31 contains a partial explanation of why linear polynomials can be effective; however, when the number of irreducible polynomials of degree d exceeds 2^p, it is clear that there will exist irreducibles that cannot be distinguished by linear choices of $t(x)$.

An alternative to (21) that works when $p = 2$ is discussed in exercise 30.

Factoring over the integers. It is somewhat more difficult to find the complete factorization of polynomials with integer coefficients when we are *not* working modulo p, but some reasonably efficient methods are available for this purpose.

Isaac Newton gave a method for finding linear and quadratic factors of polynomials with integer coefficients in his *Arithmetica Universalis* (1707). This method was extended by an astronomer named Friedrich von Schubert in 1793, who showed how to find all factors of degree n in a finite number of steps; see M. Cantor, *Geschichte der Mathematik* **4** (Leipzig: Teubner, 1908), 136–137. L. Kronecker rediscovered von Schubert's method independently about 90 years later; but unfortunately the method is very inefficient when n is five or more. Much better results can be obtained with the help of the "mod p" factorization methods presented above.

Suppose that we want to find the irreducible factors of a given polynomial

$$u(x) = u_n x^n + u_{n-1}x^{n-1} + \cdots + u_0, \qquad u_n \neq 0,$$

over the integers. As a first step, we can divide by the greatest common divisor of the coefficients; this leaves us with a *primitive* polynomial. We may also assume that $u(x)$ is squarefree, by dividing out $\gcd(u(x), u'(x))$ as in exercise 34.

Now if $u(x) = v(x)w(x)$, where each of these polynomials has integer coefficients, we obviously have $u(x) \equiv v(x)w(x)$ (modulo p) for all primes p, so there is a nontrivial factorization modulo p unless p divides $\ell(u)$. An efficient algorithm for factoring $u(x)$ modulo p can therefore be used in an attempt to reconstruct possible factorizations of $u(x)$ over the integers.

For example, let

$$u(x) = x^8 + x^6 - 3x^4 - 3x^3 + 8x^2 + 2x - 5. \tag{22}$$

We have seen above in (19) that

$$u(x) \equiv (x^4+2x^3+3x^2+4x+6)(x^3+8x^2+4x+12)(x+3) \text{ (modulo 13)}; \quad (23)$$

and the complete factorization of $u(x)$ modulo 2 shows one factor of degree 6 and another of degree 2 (see exercise 10). From (23) we can see that $u(x)$ has no factor of degree 2, so it must be irreducible over the integers.

This particular example was perhaps too simple; experience shows that most irreducible polynomials can be recognized as such by examining their factors modulo a few primes, but it is *not* always so easy to establish irreducibility. For example, there are polynomials that can be properly factored modulo p for all primes p, with consistent degrees of the factors, yet they are irreducible over the integers (see exercise 12).

Almost all polynomials are irreducible over the integers, as shown in exercise 27. But we usually aren't trying to factor a random polynomial; there is probably some reason to expect a nontrivial factor or else the calculation would not have been attempted in the first place. We need a method that identifies factors when they are there.

In general if we try to find the factors of $u(x)$ by considering its behavior modulo different primes, the results will not be easy to combine; for example, if $u(x)$ actually is the product of four quadratic polynomials, it will be hard to match up their images with respect to different prime moduli. Therefore it is desirable to stick to a single prime and to see how much mileage we can get out of it, once we feel that the factors modulo this prime have the right degrees.

One idea is to work modulo a very *large* prime p, big enough so that the coefficients in any true factorization $u(x) = v(x)w(x)$ over the integers must actually lie between $-p/2$ and $p/2$. Then all possible integer factors can be "read off" from the mod p factors we know how to compute.

Exercise 20 shows how to obtain fairly good bounds on the coefficients of polynomial factors. For example, if (22) were reducible it would have a factor $v(x)$ of degree ≤ 4, and the coefficients of v would be at most 34 in magnitude by the results of that exercise. So all potential factors of $u(x)$ will be fairly evident if we work modulo any prime $p > 68$. Indeed, the complete factorization modulo 71 is

$$(x+12)(x+25)(x^2-13-7)(x^4-24x^3-16x^2+31x-12),$$

and we see immediately that none of these polynomials are factors of (22) over the integers since their constant terms do not divide 5; furthermore there is no way to obtain a divisor of (22) by grouping two of these factors, since none of the conceivable constant terms 12×25, -12×7, $12 \times (-12)$ is congruent to ± 1 or ± 5 (modulo 71).

Incidentally, it is not trivial to obtain good bounds on the coefficients of polynomial factors, since a lot of cancellation can occur when polynomials are multiplied. For example, the innocuous-looking polynomial $x^n - 1$ has irreducible

factors whose coefficients exceed $\exp(n^{1/\lg\lg n})$ for infinitely many n. [See R. C. Vaughan, *Michigan Math. J.* **21** (1974), 289–295.] The factorization of $x^n - 1$ is discussed in exercise 32.

Instead of using a large prime p, which might have to be truly enormous if $u(x)$ has large degree or large coefficients, we can also make use of small p, provided that $u(x)$ is squarefree mod p. For in this case, an important construction introduced by K. Hensel [*Theorie der Algebraischen Zahlen* (Leipzig: Teubner, 1908), Chapter 4] can be used to extend a factorization modulo p in a unique way to a factorization modulo p^e for arbitrarily high e. Hensel's method is described in exercise 22; if we apply it to (23) with $p = 13$ and $e = 2$, we obtain the unique factorization

$$u(x) \equiv (x - 36)(x^3 - 18x^2 + 82x - 66)(x^4 + 54x^3 - 10x^2 + 69x + 84)$$

(modulo 169). Calling these factors $v_1(x)v_3(x)v_4(x)$, we see that $v_1(x)$ and $v_3(x)$ are not factors of $u(x)$ over the integers, nor is their product $v_1(x)v_3(x)$ when the coefficients have been reduced modulo 169 to the range $(-\frac{169}{2}, \frac{169}{2})$. Thus we have exhausted all possibilities, proving once again that $u(x)$ is irreducible over the integers—this time using only its factorization modulo 13.

The example we have been considering is atypical in one important respect: We have been factoring the *monic* polynomial $u(x)$ in (22), so we could assume that all its factors were monic. What should we do if $u_n > 1$? In such a case, the leading coefficients of all but one of the polynomial factors can be varied almost arbitrarily modulo p^e; we certainly don't want to try all possibilities. Perhaps the reader has already noticed this problem. Fortunately there is a simple way out: the factorization $u(x) = v(x)w(x)$ implies a factorization $u_n u(x) = v_1(x)w_1(x)$ where $\ell(v_1) = \ell(w_1) = u_n = \ell(u)$. ("Do you mind if I multiply your polynomial by its leading coefficient before factoring it?") We can proceed essentially as above, but using $p^e > 2B$ where B now bounds the maximum coefficient for factors of $u_n u(x)$ instead of $u(x)$.

Putting these observations all together results in the following procedure:

F1. Find the unique squarefree factorization

$$u(x) \equiv \ell(u)v_1(x)\dots v_r(x) \text{ (modulo } p^e),$$

where p^e is sufficiently large as explained above, and where the $v_j(x)$ are monic. (This will be possible for all but a few primes p, see exercise 23.) Also set $d \leftarrow 1$.

F2. For every combination of factors $v(x) = v_{i_1}(x)\dots v_{i_d}(x)$, with $i_1 = 1$ if $d = \frac{1}{2}r$, form the unique polynomial $\bar{v}(x) \equiv \ell(u)v(x)$ (modulo p^e) whose coefficients all lie in the interval $[-\frac{1}{2}p^e, \frac{1}{2}p^e)$. If $\bar{v}(x)$ divides $\ell(u)u(x)$, output the factor $\mathrm{pp}(\bar{v}(x))$, divide $u(x)$ by this factor, and remove the corresponding $v_i(x)$ from the list of factors modulo p^e; decrease r by the number of factors removed, and terminate the algorithm if $d > \frac{1}{2}r$.

F3. Increase d by 1, and return to F2 if $d > \frac{1}{2}r$. ∎

At the conclusion of this process, the current value of $u(x)$ will be the final irreducible factor of the originally given polynomial. Note that if $|u_0| < |u_n|$, it is preferable to do all of the work with the reverse polynomial $u_0x^n + \cdots + u_n$, whose factors are the reverses of the factors of $u(x)$.

The procedure as stated requires $p^e > 2B$, where B is a bound on the coefficients of *any* divisor of $u_n u(x)$, but we can use a much smaller value of B if we only guarantee it to be valid for divisors of degree $\leq \frac{1}{2}\deg(u)$. In this case the divisibility test in step F2 should be applied to $w(x) = v_1(x)\ldots v_r(x)/v(x)$ instead of $v(x)$, whenever $\deg(v) > \frac{1}{2}\deg(u)$.

The above algorithm contains an obvious bottleneck: We may have to test as many as 2^{r-1} potential factors $v(x)$. The average value of 2^r in a random situation is about n, or perhaps $n^{1.5}$ (see exercise 5), but in nonrandom situations we will want to speed up this part of the routine as much as we can. One way to rule out spurious factors quickly is to compute the trailing coefficient $\bar{v}(0)$ first, continuing only if this divides $\ell(u)u(0)$; the complication explained in the preceding paragraph does not have to be considered unless this divisibility condition is satisfied, since such a test is valid even when $\deg(v) > \frac{1}{2}\deg(u)$.

Another important way to speed up the procedure is to reduce r so that it tends to reflect the true number of factors. The distinct degree factorization algorithm above can be applied for various small primes p_j, thus obtaining for each prime a set D_j of possible degrees of factors modulo p_j; see exercise 26. We can represent D_j as a string of n binary bits. Now we compute the intersection $\bigcap D_j$, namely the logical "and" of these bit strings, and we perform step F2 only for $i_1 + \cdots + i_d \in \bigcap D_j$. Furthermore p is chosen to be that p_j having the smallest value of r. This technique is due to David R. Musser, whose experience suggests trying about five primes p_j (see *JACM* **25** (1978), 271–282). Of course we would stop immediately if the current $\bigcap D_j$ shows that $u(x)$ is irreducible.

Musser has given a complete discussion of a factorization method similar to the steps above, in *JACM* **22** (1975), 291–308. The procedure above incorporates an improvement suggested in 1978 by G. E. Collins, namely to look for trial divisors by taking combinations of d factors at a time rather than combinations of total degree d. This improvement is important because of the statistical behavior of the modulo-p factors of polynomials that are irreducible over the rationals (cf. exercise 37).

Greatest common divisors. Similar techniques can be used to calculate greatest common divisors of polynomials: If $\gcd\bigl(u(x), v(x)\bigr) = d(x)$ over the integers, and if $\gcd\bigl(u(x), v(x)\bigr) = q(x)$ (modulo p) where $q(x)$ is monic, then $d(x)$ is a common divisor of $u(x)$ and $v(x)$ modulo p; hence

$$d(x) \text{ divides } q(x) \quad (\text{modulo } p). \tag{24}$$

If p does not divide the leading coefficients of both u and v, it does not divide the leading coefficient of d; in such a case $\deg(d) \leq \deg(q)$. When $q(x) = 1$ for such a prime p, we must therefore have $\deg(d) = 0$, and $d(x) = \gcd\bigl(\mathrm{cont}(u), \mathrm{cont}(v)\bigr)$. This justifies the remark made in Section 4.6.1 that the simple computation

of $\gcd(u(x), v(x))$ modulo 13 in 4.6.1–6 is enough to prove that $u(x)$ and $v(x)$ are relatively prime over the integers; the comparatively laborious calculations of Algorithm 4.6.1E or Algorithm 4.6.1C are unnecessary. Since two random primitive polynomials are almost always relatively prime over the integers, and since they are relatively prime modulo p with probability $1 - 1/p$, it is usually a good idea to do the computations modulo p.

As remarked before, we need good methods also for the nonrandom polynomials that arise in practice. Therefore we wish to sharpen our techniques and discover how to find $\gcd(u(x), v(x))$ in general, over the integers, based entirely on information that we obtain working modulo primes p. We may assume that $u(x)$ and $v(x)$ are primitive.

Instead of calculating $\gcd(u(x), v(x))$ directly, it will be convenient to search instead for the polynomial

$$\bar{d}(x) = c \cdot \gcd(u(x), v(x)), \tag{25}$$

where the constant c is chosen so that

$$\ell(\bar{d}) = \gcd(\ell(u), \ell(v)). \tag{26}$$

This condition will always hold for suitable c, since the leading coefficient of any common divisor of $u(x)$ and $v(x)$ must be a divisor of $\gcd(\ell(u), \ell(v))$. Once $\bar{d}(x)$ has been found satisfying these conditions, we can readily compute $\operatorname{pp}(\bar{d}(x))$, which is the true greatest common divisor of $u(x)$ and $v(x)$. Condition (26) is convenient since it avoids the uncertainty of unit multiples of the gcd; we have used essentially the same idea to control the leading coefficients in our factorization routine.

If p is a sufficiently large prime, based on the bounds for coefficients in exercise 20 applied either to $\ell(\bar{d})u(x)$ or $\ell(\bar{d})v(x)$, let us compute the unique polynomial $\bar{q}(x) \equiv \ell(\bar{d})q(x)$ (modulo p) having all coefficients in $[-\frac{1}{2}p, \frac{1}{2}p)$. When $\operatorname{pp}(\bar{q}(x))$ divides both $u(x)$ and $v(x)$, it must equal $\gcd(u(x), v(x))$ because of (24). On the other hand if it does not divide both $u(x)$ and $v(x)$ we must have $\deg(q) > \deg(d)$. A study of Algorithm 4.6.1E reveals that this will be the case only if p divides the leading coefficient of one of the nonzero remainders computed by that algorithm with exact integer arithmetic; otherwise Euclid's algorithm modulo p deals with precisely the same sequence of polynomials as Algorithm 4.6.1E except for nonzero constant multiples (modulo p). So only a small number of "unlucky" primes can cause us to miss the gcd, and we will soon find a lucky prime if we keep trying.

If the bound on coefficients is so large that single-precision primes p are insufficient, we can compute $\bar{d}(x)$ modulo several primes p until it has been determined via the Chinese remainder algorithm of Section 4.3.2. This approach, which is due to W. S. Brown and G. E. Collins, has been described in detail by Brown in *JACM* **18** (1971), 478–504. Alternatively, as suggested by J. Moses and D. Y. Y. Yun [*Proc. ACM Conf.* **28** (1973), 159–166], we can use Hensel's

method to determine $\bar{d}(x)$ modulo p^e for sufficiently large e. Hensel's construction appears to be computationally superior to the Chinese remainder approach; but it is valid directly only when

$$\gcd\big(d(x),\, u(x)/d(x)\big) = 1 \qquad \text{or} \qquad \gcd\big(d(x),\, v(x)/d(x)\big) = 1, \tag{27}$$

since the idea is to apply the techniques of exercise 22 to one of the factorizations $\ell(\bar{d})u(x) \equiv \bar{q}(x)u_1(x)$ or $\ell(\bar{d})v(x) \equiv \bar{q}(x)v_1(x)$ (modulo p). Exercises 34 and 35 show that it is possible to arrange things so that (27) holds whenever necessary.

The gcd algorithms sketched here are significantly faster than those of Section 4.6.1 except when the polynomial remainder sequence is very short. Perhaps the best general procedure would be to start with the computation of $\gcd\big(u(x), v(x)\big)$ modulo a fairly small prime p, not a divisor of both $\ell(u)$ and $\ell(v)$. If the result $q(x)$ is 1, we're done; if it has high degree, we use Algorithm 4.6.1C; otherwise we use one of the above methods, first computing a bound for the coefficients of $\bar{d}(x)$ based on the coefficients of $u(x)$ and $v(x)$, and on the (small) degree of $q(x)$. As in the factorization problem, we should apply this procedure to the reverses of $u(x), v(x)$ and reverse the result, if the trailing coefficients are simpler than the leading ones.

Multivariate polynomials. Similar techniques lead to useful algorithms for factorization or gcd calculations on multivariate polynomials with integer coefficients. It is convenient to deal with the polynomial $u(x_1, \ldots, x_t)$ by working modulo the irreducible polynomials $x_2 - a_2, \ldots, x_t - a_t$, which play the rôle of p in the above discussion. Since $v(x) \bmod (x - a) = v(a)$, the value of $u(x_1, \ldots, x_t)$ is the univariate polynomial $u(x_1, a_2, \ldots, a_t)$. When the integers $a_2, \ldots, a_t$ have been chosen so that $u(x_1, a_2, \ldots, a_t)$ has the same degree in x_1 as $u(x_1, x_2, \ldots, x_t)$, an appropriate generalization of Hensel's construction will "lift" squarefree factorizations of this univariate polynomial to factorizations modulo $(x_2 - a_2)^{n_2}$, $\ldots$, $(x_t - a_t)^{n_t}$, where n_j is the degree of x_j in u; at the same time we can also work modulo an appropriate integer prime p. As many as possible of the a_j should be zero, so that sparseness of the intermediate results is retained. For details, see P. S. Wang, *Math. Comp.* **32** (1978), 1215–1231, in addition to the papers by Musser and by Moses and Yun cited earlier.

EXERCISES

▶ **1.** [*M24*] Let p be prime. What is the probability that a random polynomial of degree n has a linear factor (a factor of degree 1), when $n \geq p$? Show that this probability is more than $\frac{1}{2}$. (Assume that each of the p^n monic polynomials modulo p is equally likely.) What is the average number of linear factors?

▶ **2.** [*M25*] (a) Show that any monic polynomial $u(x)$, over a unique factorization domain, may be expressed uniquely in the form

$$u(x) = v(x)^2 w(x),$$

where $w(x)$ is squarefree (has no factor of positive degree of the form $d(x)^2$) and both $v(x)$ and $w(x)$ are monic. (b) (E. R. Berlekamp.) How many monic polynomials of degree n are squarefree modulo p, when p is prime?

3. [*M25*] Let $u_1(x), \ldots, u_r(x)$ be polynomials over a field S, with $u_j(x)$ relatively prime to $u_k(x)$ for all $j \neq k$. For any given polynomials $w_1(x), \ldots, w_r(x)$ over S, prove that there is a unique polynomial $v(x)$ over S such that

$$\deg(v) < \deg(u_1) + \cdots + \deg(u_r)$$

and

$$v(x) \equiv w_j(x) \pmod{u_j(x)}$$

for $1 \leq j \leq r$. (Compare with Theorem 4.3.2C.)

4. [*HM28*] Let a_{np} be the number of monic irreducible polynomials of degree n, modulo a prime p. Find a formula for the generating function $G_p(z) = \sum_n a_{np} z^n$. [*Hint:* Prove the following identity connecting power series: $f(z) = \sum_{j \geq 1} g(z^j)/j^t$ if and only if $g(z) = \sum_{n \geq 1} \mu(n) f(z^n)/n^t$.] What is $\lim_{p \to \infty} a_{np}/p^n$?

5. [*HM30*] Let A_{np} be the average number of factors of a randomly selected polynomial of degree n, modulo a prime p. Show that $\lim_{p \to \infty} A_{np} = H_n$. What is the limiting average value of 2^r, when there are r factors?

6. [*M21*] (J. L. Lagrange, 1771.) Prove the congruence (9). [*Hint:* Factor $x^p - x$ in the field of p elements.]

7. [*M22*] Prove Eq. (14).

8. [*HM20*] How can we be sure that the vectors output by Algorithm N are linearly independent?

9. [*20*] Explain how to construct a table of reciprocals mod 101 in a simple way, given that 2 is a primitive root of 101.

▶ **10.** [*21*] Find the complete factorization of the polynomial $u(x)$ in (22), modulo 2, using Berlekamp's procedure.

11. [*22*] Find the complete factorization of the polynomial $u(x)$ in (22), modulo 5.

▶ **12.** [*M22*] Use Berlekamp's algorithm to determine the number of factors of $u(x) = x^4 + 1$, modulo p, for all primes p. [*Hint:* Consider the cases $p = 2$, $p = 8k + 1$, $p = 8k + 3$, $p = 8k + 5$, $p = 8k + 7$ separately; what is the matrix Q? You need not discover the factors; just determine how many there are.]

13. [*M25*] Give an explicit formula for the factors of $x^4 + 1$, modulo p, for all odd primes p, in terms of the quantities $\sqrt{-1}$, $\sqrt{2}$, $\sqrt{-2}$ (if such square roots exist modulo p).

14. [*M25*] (H. Zassenhaus.) Let $v(x)$ be a solution to (8), and let $w(x) = \prod(x - s)$ where the product is over all $0 \leq s < p$ such that $\gcd(u(x), v(x) - s) \neq 1$. Explain how to compute $w(x)$, given $u(x)$ and $v(x)$. [*Hint:* Eq. (14) implies that $w(x)$ is the polynomial of least degree such that $u(x)$ divides $w(v(x))$.]

▶ **15.** [*M27*] Design an algorithm to calculate the "square root" of a given integer u modulo a given prime p, i.e., to find an integer v such that $v^2 \equiv u \pmod{p}$ whenever such a v exists. Your algorithm should be efficient even for very large primes p. (Note that a solution to this problem leads to a procedure for solving any given quadratic equation modulo p, using the quadratic formula in the usual way.)

16. [*M30*] (a) Given that $f(x)$ is an irreducible polynomial modulo a prime p, of degree n, prove that the p^n polynomials of degree less than n form a field under arithmetic modulo $f(x)$ and p. (*Note:* The existence of irreducible polynomials of each degree is proved in exercise 4; therefore fields with p^n elements exist for all primes p and all $n \geq 1$.) (b) Show that any field with p^n elements has a "primitive root" element ξ such that the elements of the field are $\{0, 1, \xi, \xi^2, \ldots, \xi^{p^n-2}\}$. [*Hint:* Exercise 3.2.1.2–16 provides a proof in the special case $n = 1$.] (c) If $f(x)$ is an irreducible polynomial modulo p, of degree n, prove that $x^{p^m} - x$ is divisible by $f(x)$ if and only if m is a multiple of n. (It follows that we can test irreducibility rather quickly: A given nth degree polynomial $f(x)$ is irreducible modulo p if and only if $x^{p^n} - x$ is divisible by $f(x)$ and $\gcd(x^{p^{n/q}} - x,\ f(x)) = 1$ for all primes q dividing n.)

17. [*M23*] Let F be a field with 13^2 elements. How many elements of F have order f, for each integer f with $1 \leq f < 13^2$? (The "order" of an element a is the least positive integer m such that $a^m = 1$.)

▶ **18.** [*M25*] Let $u(x) = u_n x^n + \cdots + u_0, u_n \neq 0$, be a primitive polynomial with integer coefficients, and let $v(x)$ be the monic polynomial defined by

$$v(x) = u_n^{n-1} \cdot u(x/u_n) = x^n + u_{n-1}x^{n-1} + u_{n-2}u_n x^{n-2} + \cdots u_0 u_n^{n-1}.$$

(a) Given that $v(x)$ has the complete factorization $p_1(x) \ldots p_r(x)$ over the integers, where each $p_j(x)$ is monic, what is the complete factorization of $u(x)$ over the integers? (b) If $w(x) = x^m + w_{m-1}x^{m-1} + \cdots + w_0$ is a factor of $v(x)$, prove that w_k is a multiple of u_n^{m-1-k} for $0 \leq k < m$.

19. [*M20*] (*Eisenstein's criterion.*) Perhaps the best-known class of irreducible polynomials over the integers was introduced by G. Eisenstein in *J. für die reine und angew. Math.* **39** (1850), 166–167: Let p be prime and let $u(x) = u_n x^n + \cdots + u_0$ have the following properties: (i) u_n is not divisible by p; (ii) $u_{n-1}, \ldots, u_0$ are divisible by p; (iii) u_0 is not divisible by p^2. Show that $u(x)$ is irreducible over the integers.

20. [*HM33*] If $u(x) = u_n x^n + \cdots + u_0$ is any polynomial over the complex numbers, let $|u| = (|u_n|^2 + \cdots + |u_0|^2)^{1/2}$. (a) Let $g(x) = (x - \alpha)u(x)$ and $h(x) = (\bar{\alpha}x - 1)u(x)$, where α is any complex number and $\bar{\alpha}$ is its complex conjugate. Prove that $|g| = |h|$. (b) Let the complete factorization of $u(x)$ over the complex numbers be $u_n(x - \alpha_1)\ldots(x - \alpha_n)$, and write $M(u) = \prod_{1 \leq j \leq n} \max(1, |\alpha_j|)$. Prove that $M(u) \leq |u|/|u_n|$. (c) Show that $|u_j| \leq |u_n|\left(\binom{n-1}{j} M(u) + \binom{n-1}{j-1}\right)$ for $0 \leq j \leq n$. (d) Combine these results to prove that if $u(x) = v(x)w(x)$ and $v(x) = v_m x^m + \cdots + v_0$, where u, v, w all have integer coefficients, then the coefficients of v are bounded by

$$|v_j| \leq \binom{m-1}{j}|u| + \binom{m-1}{j-1}|u_n|.$$

21. [*HM30*] The purpose of this exercise is to obtain useful bounds on the coefficients of *multivariate* polynomial factors over the integers. Given a polynomial $u(x_1, \ldots, x_t)$ over the complex numbers, let $|u|$ be $(\sum |u_{j_1 \ldots j_t}|^2)^{1/2}$ summed over all the coefficients. Let $e(x) = e^{2\pi i x}$. (a) Prove that

$$|u|^2 = \int_0^1 \cdots \int_0^1 \left|u(e(\theta_1), \ldots, e(\theta_t))\right|^2 d\theta_t \ldots d\theta_1.$$

(b) Let $u(x) = v(x)w(x)$, where $\deg(v) = m$ and $\deg(w) = k$. Use the results proved in exercise 20 to show that we always have $|v||w| \le f(m,k)^{1/2}|u|$, where $f(m,k) = \binom{2m}{m}\binom{2k}{k}$. (c) Let $u(x_1,\ldots,x_t) = v(x_1,\ldots,x_t)w(x_1,\ldots,x_t)$, where v and w have the respective degrees m_j and k_j in x_j. Prove that

$$|v||w| \le \big(f(m_1,k_1)\ldots f(m_t,k_t)\big)^{1/2}|u|.$$

▶ **22.** [*M24*] (*Hensel's Lemma.*) Let $u(x)$, $v_e(x)$, $w_e(x)$, $a(x)$, $b(x)$ be polynomials with integer coefficients, satisfying the relations

$$u(x) \equiv v_e(x)w_e(x) \pmod{p^e}, \qquad a(x)v_e(x) + b(x)w_e(x) \equiv 1 \pmod{p},$$

where p is prime, $e \ge 1$, $v_e(x)$ is monic, $\deg(a) < \deg(w_e)$, $\deg(b) < \deg(v_e)$, and $\deg(u) = \deg(v_e) + \deg(w_e)$. Show how to compute polynomials $v_{e+1}(x) \equiv v_e(x)$ and $w_{e+1}(x) \equiv w_e(x) \pmod{p^e}$, satisfying the same conditions with e increased by 1. Furthermore, prove that $v_{e+1}(x)$ and $w_{e+1}(x)$ are unique, modulo p^{e+1}.

Use your method for $p = 2$ to prove that (22) is irreducible over the integers, starting with its factorization mod 2 found in exercise 10. (Note that Euclid's extended algorithm, exercise 4.6.1–3, will get the process started for $e = 1$.)

23. [*HM23*] Let $u(x)$ be a squarefree polynomial with integer coefficients. Prove that there are only finitely many primes p such that $u(x)$ is not squarefree modulo p.

24. [*M20*] The text speaks only of factorization over the integers, not over the field of rational numbers. Explain how to find the complete factorization of a polynomial with rational coefficients, over the field of rational numbers.

25. [*M25*] What is the complete factorization of $x^5 + x^4 + x^2 + x + 2$ over the field of rational numbers?

26. [*20*] Let $d_1, \ldots, d_r$ be the degrees of the irreducible factors of $u(x)$ modulo p, with proper multiplicity, so that $d_1 + \cdots + d_r = n = \deg(u)$. Explain how to compute the set $\{\deg(v) \mid u(x) \equiv v(x)w(x) \pmod{p} \text{ for some } v(x), w(x)\}$ by performing $O(r)$ operations on binary bit strings of length n.

27. [*HM30*] Prove that a random primitive polynomial over the integers is "almost always" irreducible, in some appropriate sense.

28. [*M25*] The distinct-degree factorization procedure is "lucky" when there is at most one irreducible polynomial of each degree d; then $g_d(x)$ never needs to be broken into factors. What is the probability of such a lucky circumstance, when factoring a random polynomial of degree n, modulo p, for fixed n as $p \to \infty$?

29. [*M22*] Let $g(x)$ be a product of two or more distinct irreducible polynomials of degree d, modulo an odd prime p. Prove that $\gcd(g(x), t(x)^{(p^d-1)/2} - 1)$ will be a proper factor of $g(x)$ with probability $\ge 1/2 - 1/(2p^d)$, for any fixed $g(x)$, when $t(x)$ is selected at random from among the p^{2d} polynomials of degree $< 2d$ modulo p.

30. [*M25*] Prove that if $q(x)$ is an irreducible polynomial of degree d, modulo p, and if $t(x)$ is any polynomial, then the value of $\big(t(x) + t(x)^p + t(x)^{p^2} + \cdots + t(x)^{p^{d-1}}\big) \bmod q(x)$ is an integer (i.e., a polynomial of degree ≤ 0). Use this fact to design a probabilistic algorithm for factoring a product $g_d(x)$ of degree-d irreducibles, analogous to (21), for the case $p = 2$.

31. [*HM30*] Let p be an odd prime and let $d \geq 1$. Show that there exists a number $n(p,d)$ having the following two properties: (a) For all integers t, exactly $n(p,d)$ irreducible polynomials $q(x)$ of degree d, modulo p, satisfy $(x+t)^{(p^d-1)/2} \bmod q(x) = 1$. (b) For all integers $0 \leq t_1 < t_2 < p$, exactly $n(p,d)$ irreducible polynomials $q(x)$ of degree d, modulo p, satisfy $(x+t_1)^{(p^d-1)/2} \bmod q(x) = (x+t_2)^{(p^d-1)/2} \bmod q(x)$.

▶ **32.** [*M30*] (*Cyclotomic polynomials.*) Let $\Psi_n(x) = \prod_{1\leq k\leq n,\, \gcd(k,n)=1}(x-\omega^k)$, where $\omega = e^{2\pi i/n}$; thus, the roots of $\Psi_n(x)$ are the complex nth roots of unity that aren't mth roots for $m < n$. (a) Prove that $\Psi_n(x)$ is a polynomial with integer coefficients, and that

$$x^n - 1 = \prod_{d\backslash n} \Psi_d(x); \qquad \Psi_n(x) = \prod_{d\backslash n} (x^d-1)^{\mu(n/d)}.$$

(Cf. exercises 4.5.2–10(b) and 4.5.3–28(c).) (b) Prove that $\Psi_n(x)$ is irreducible over the integers, hence the above formula is the complete factorization of $x^n - 1$ over the integers. [*Hint:* If $f(x)$ is an irreducible factor of $\Psi_n(x)$ over the integers, and if ζ is a complex number with $f(\zeta) = 0$, prove that $f(\zeta^p) = 0$ for all primes p not dividing n. It may help to use the fact that $x^n - 1$ is squarefree modulo p for all such primes.] (c) Discuss the calculation of $\Psi_n(x)$, and tabulate the values for $n \leq 15$.

33. [*M18*] True or false: If $u(x) \neq 0$ and the complete factorization of $u(x)$ modulo p is $p_1(x)^{e_1} \ldots p_r(x)^{e_r}$, then $u(x)/\gcd(u(x), u'(x)) = p_1(x) \ldots p_r(x)$.

▶ **34.** [*M25*] (*Squarefree factorization.*) It is clear that any primitive polynomial of a unique factorization domain can be expressed in the form $u(x) = u_1(x)u_2(x)^2u_3(x)^3\ldots$, where the polynomials $u_i(x)$ are squarefree and relatively prime to each other. This representation, in which $u_j(x)$ is the product of all the irreducible polynomials that divide $u(x)$ exactly j times, is unique except for unit multiples; and it is a useful way to represent polynomials that participate in multiplication, division, and gcd operations.

Let $\mathrm{GCD}(u(x), v(x))$ be a procedure that returns three answers:

$$\mathrm{GCD}(u(x), v(x)) = (d(x), u(x)/d(x), v(x)/d(x)), \quad \text{where } d(x) = \gcd(u(x), v(x)).$$

The modular method described in the text following Eq. (25) always ends with a trial division of $u(x)/d(x)$ and $v(x)/d(x)$, to make sure that no "unlucky prime" has been used, so the quantities $u(x)/d(x)$ and $v(x)/d(x)$ are byproducts of the gcd computation; thus we can compute $\mathrm{GCD}(u(x), v(x))$ essentially as fast as $\gcd(u(x), v(x))$ when we are using a modular method.

Devise a procedure that obtains the squarefree representation $(u_1(x), u_2(x), \ldots)$ of a given primitive polynomial $u(x)$ over the integers. Your algorithm should perform exactly e computations of a GCD, where e is the largest subscript with $u_e(x) \neq 1$; furthermore, each GCD calculation should satisfy (27), so that Hensel's construction can be used.

35. [*M22*] (D. Y. Y. Yun.) Design an algorithm that computes the squarefree representation $(w_1(x), w_2(x), \ldots)$ of $w(x) = \gcd(u(x), v(x))$ over the integers, given the squarefree representations $(u_1(x), u_2(x), \ldots)$ and $(v_1(x), v_2(x), \ldots)$ of $u(x)$ and $v(x)$.

36. [*M27*] Extend the procedure of exercise 34 so that it will obtain the squarefree representation $(u_1(x), u_2(x), \ldots)$ of a given polynomial $u(x)$ when the coefficient arithmetic is performed modulo p.

37. [*HM24*] (George E. Collins.) Let $d_1, \ldots, d_r$ be positive integers whose sum is n, and let p be prime. What is the probability that the irreducible factors of a random nth-degree integer polynomial $u(x)$ have degrees $d_1, \ldots, d_r$, when it is completely factored modulo p? Show that this probability is asymptotically the same as the probability that a random permutation on n elements has cycles of lengths $d_1, \ldots, d_r$.

38. [*M48*] (V. R. Pratt.) If possible, find a way to construct proofs of irreducibility for all polynomials that are irreducible over the integers, so that the length of proof is at most a polynomial in $\deg(u)$ and the length of its coefficients. (Only a bound on the *length* of proof is requested here, as in exercise 4.5.4–17, not a bound on the time needed to find such a proof.)

4.6.3. Evaluation of Powers

In this section we shall study the interesting problem of computing x^n efficiently, given x and n, where n is a positive integer. Suppose, for example, that we need to compute x^{16}; we could simply start with x and multiply by x fifteen times. But it is possible to obtain the same answer with only four multiplications, if we repeatedly take the square of each partial result, successively forming x^2, x^4, x^8, x^{16}.

The same idea applies, in general, to any value of n, in the following way: Write n in the binary number system (suppressing zeros at the left). Then replace each "1" by the pair of letters SX, replace each "0" by S, and cross off the "SX" that now appears at the left. The result is a rule for computing x^n, if "S" is interpreted as the operation of *squaring*, and if "X" is interpreted as the operation of *multiplying by* x. For example, if $n = 23$, its binary representation is 10111; so we form the sequence SX S SX SX SX and remove the leading SX to obtain the rule SSXSXSX. This rule states that we should "square, square, multiply by x, square, multiply by x, square, and multiply by x"; in other words, we should successively compute x^2, x^4, x^5, x^{10}, x^{11}, x^{22}, x^{23}.

This "binary method" is easily justified by a consideration of the sequence of exponents in the calculation: If we reinterpret "S" as the operation of multiplying by 2 and "X" as the operation of adding 1, and if we start with 1 instead of x, the rule will lead to a computation of n because of the properties of the binary number system. The method is quite ancient; it appeared before 200 B.C. in Pingala's Hindu classic Chandah-sûtra [see B. Datta and A. N. Singh, *History of Hindu Mathematics* **1** (Bombay: 1935), 76]; however, there seem to be no other references to this method outside of India during the next 1000 years. A clear discussion of how to compute 2^n efficiently for arbitrary n was given by al-Uqlîdisî of Damascus in 952 A.D.; see *The Arithmetic of al-Uqlîdisî* by A. S. Saidan (Dordrecht: D. Reidel, 1975), 341–342, where the general ideas are illustrated for $n = 51$. See also al-Bîrûnî's *Chronology of Ancient Nations*, ed. and translated by E. Sachau (London: 1879), 132–136; this eleventh-century Arabic work had great influence.

The S-and-X binary method for obtaining x^n requires no temporary storage except for x and the current partial result, so it is well suited for incorpora-

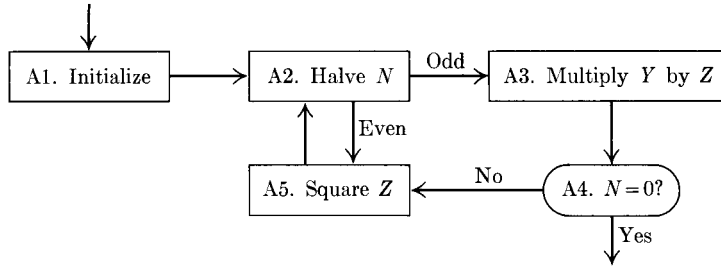

Fig. 12. Evaluation of x^n, based on a right-to-left scan of the binary notation for n.

tion in the hardware of a binary computer. The method can also be readily programmed for either binary or decimal computers; but it requires that the binary representation of n be scanned from left to right, while it is usually more convenient to do this from right to left. For example, with a binary computer we can shift the binary value of n to the right one bit at a time until zero is reached; with a decimal computer we can divide by 2 (or, equivalently, multiply by 5 or $\frac{1}{2}$) to deduce the binary representation from right to left. Therefore the following algorithm, based on a right-to-left scan of the number, is often more convenient:

Algorithm A (*Right-to-left binary method for exponentiation*). This algorithm evaluates x^n, where n is a positive integer. (Here x belongs to any algebraic system in which an associative multiplication, with identity element 1, has been defined.)

A1. [Initialize.] Set $N \leftarrow n$, $Y \leftarrow 1$, $Z \leftarrow x$.

A2. [Halve N.] (At this point, $x^n = Y \cdot Z^N$.) Set $N \leftarrow \lfloor N/2 \rfloor$, and at the same time determine whether N was even or odd. If N was even, skip to step A5.

A3. [Multiply Y by Z.] Set $Y \leftarrow Z$ times Y.

A4. [$N = 0$?] If $N = 0$, the algorithm terminates, with Y as the answer.

A5. [Square Z.] Set $Z \leftarrow Z$ times Z, and return to step A2. ∎

As an example of Algorithm A, consider the steps in the evaluation of x^{23}:

	N	Y	Z
After step A1	23	1	x
After step A4	11	x	x
After step A4	5	x^3	x^2
After step A4	2	x^7	x^4
After step A4	0	x^{23}	x^{16}

A MIX program corresponding to Algorithm A appears in exercise 2.

The great calculator al-Kashî stated Algorithm A about 1414 A.D. [*Istoriko-Mat. Issledovaniîa* **7** (1954), 256–257]. The method is closely related to a procedure for multiplication that was actually used by Egyptian mathematicians as early as 1800 B.C.; for if we change step A3 to "$Y \leftarrow Y + Z$" and step A5 to "$Z \leftarrow Z + Z$", and if we set Y to zero instead of unity in step A1, the algorithm terminates with $Y = nx$. This is a practical method for multiplication by hand, since it involves only the simple operations of doubling, halving, and adding. It is often called the "Russian peasant method" of multiplication, since Western visitors to Russia in the nineteenth century found the method in wide use there.

The number of multiplications required by Algorithm A is $\lfloor \lg n \rfloor + \nu(n)$, where $\nu(n)$ is the number of ones in the binary representation of n. This is one more multiplication than the left-to-right binary method mentioned at the beginning of this section would require, due to the fact that the first execution of step A3 is simply a multiplication by unity.

Because of the bookkeeping time required by this algorithm, the binary method is usually not of importance for small values of n, say $n \leq 10$, unless the time for a multiplication is comparatively large. If the value of n is known in advance, the left-to-right binary method is preferable. In some situations, such as the calculation of $x^n \bmod u(x)$ discussed in Section 4.6.2, it is much easier to multiply by x than to perform a general multiplication or to square a value, so binary methods for exponentiation are primarily suited for quite large n in such cases. If we wish to calculate the exact multiple-precision value of x^n, when x is an integer > 1, binary methods are no help unless n is so huge that the high-speed multiplication routines of Section 4.3.3 are involved; and such applications are rare. Similarly, binary methods are usually inappropriate for raising a polynomial to a power; see R. J. Fateman, *SIAM J. Computing* **3** (1974), 196–213, for a discussion of the extensive literature on polynomial exponentiation. The point of these remarks is that binary methods are nice, but not a panacea. They are most applicable when the time to multiply $x^j \cdot x^k$ is essentially independent of j and k (e.g., for floating point multiplication, or multiplication mod m); in such cases the running time is reduced from order n to order $\log n$.

Fewer multiplications. Several authors have published statements (without proof) that the binary method actually gives the *minimum* possible number of multiplications. But this is not true. The smallest counterexample is $n = 15$, when the binary method needs six multiplications, yet we can calculate $y = x^3$ in two multiplications and $x^{15} = y^5$ in three more, achieving the desired result with only five multiplications. Let us now discuss some other procedures for evaluating x^n, for applications when n is known in advance (e.g., within an optimizing compiler).

The *factor method* is based on a factorization of n. If $n = pq$, where p is the smallest prime factor of n and $q > 1$, we may calculate x^n by first calculating x^p and then raising this quantity to the qth power. If n is prime, we may calculate x^{n-1} and multiply by x. And, of course, if $n = 1$, we have x^n with no calculation at all. Repeated application of these rules gives a procedure for evaluating x^n,

given any value of n. For example, if we want to calculate x^{55}, we first evaluate $y = x^5 = x^4x = (x^2)^2x$; then we form $y^{11} = y^{10}y = (y^2)^5y$. The whole process takes eight multiplications, while the binary method would have required nine. The factor method is better than the binary method on the average, but there are cases ($n = 33$ is the smallest example) where the binary method excels.

The binary method can be generalized to an *m-ary method* as follows: Let $n = d_0m^t + d_1m^{t-1} + \cdots + d_t$, where $0 \le d_j < m$ for $0 \le j \le t$. The computation begins by forming x, x^2, x^3, ..., x^{m-1}. (Actually, only those powers x^{d_j} such that d_j appears in the representation of n are needed, and this observation often saves some of the work.) Then raise x^{d_0} to the mth power and multiply by x^{d_1}; we have computed $y_1 = x^{d_0m+d_1}$. Next, raise y_1 to the mth power and multiply by x^{d_2}, obtaining $y_2 = x^{d_0m^2+d_1m+d_2}$. The process continues in this way until $y_t = x^n$ has been computed. Whenever $d_j = 0$, it is, of course, unnecessary to multiply by x^{d_j}. Note that this method reduces to the left-to-right binary method discussed earlier, when $m = 2$; there is also a less obvious right-to-left m-ary method that takes more memory but only a few more steps (see exercise 9). If m is a small prime, the m-ary method will be particularly efficient for calculating powers of one polynomial modulo another, when the coefficients are treated modulo m (see Eq. 4.6.2–5).

A systematic method that gives the minimum number of multiplications for all of the relatively small values of n (in particular, for most n that occur in practical applications) is indicated in Fig. 13. To calculate x^n, find n in this tree, and the path from the root to n indicates the sequence of exponents that occur in an efficient evaluation of x^n. The rule for generating this "power tree" appears in exercise 5. Computer tests have shown that the power tree gives optimum results for all of the n listed in the figure. But for large enough values of n the power tree method is not always an optimum procedure; the smallest examples are $n = 77$, 154, 233. The first case for which the power tree is superior to both the binary method and the factor method is $n = 23$. The first case for which the factor method beats the power tree method is $n = 19879 = 103 \cdot 193$; such cases are quite rare. (For $n \le 100,000$ the power tree method is better than the factor method 88,803 times; it ties 11,191 times; and it loses only 6 times.)

Addition chains. The most economical way to compute x^n by multiplication is a mathematical problem with an interesting history. We shall now examine it in detail, not only because it is interesting in its own right, but because it is an excellent example of the theoretical questions that arise in the study of "optimum methods of computation."

Although we are concerned with multiplication of powers of x, the problem can easily be reduced to addition, since the exponents are additive. This leads us to the following abstract formulation: An *addition chain for n* is a sequence of integers

$$1 = a_0, \quad a_1, \quad a_2, \quad \ldots, \quad a_r = n \tag{1}$$

with the property that

$$a_i = a_j + a_k, \qquad \text{for some } k \le j < i, \tag{2}$$

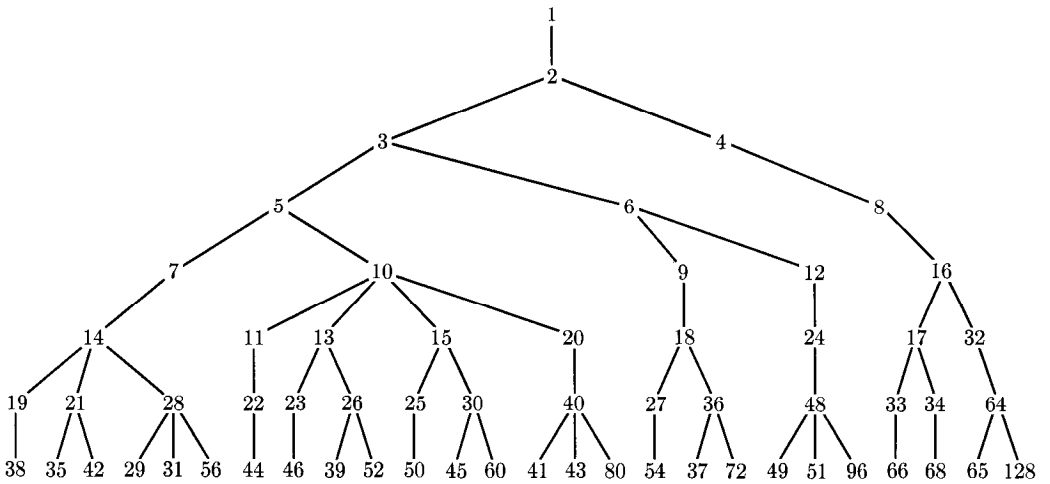

Fig. 13. The "power tree."

for all $i = 1, 2, \ldots, r$. One way of looking at this definition is to consider a simple computer that has an accumulator and is capable of the three operations LDA, STA, and ADD; the machine begins with the number 1 in its accumulator, and it proceeds to compute the number n by adding together previous results. Note that a_1 must equal 2, and a_2 is either 2, 3, or 4.

The shortest length, r, for which there exists an addition chain for n is denoted by $l(n)$. Our goal in the remainder of this section is to discover as much as we can about this function $l(n)$. The values of $l(n)$ for small n are displayed in tree form in Fig. 14, which shows how to calculate x^n with the fewest possible multiplications for all $n \leq 100$.

The problem of determining $l(n)$ was apparently first raised by H. Dellac in 1894, and a partial solution by E. de Jonquières mentioned the factor method [cf. *l'Intermédiaire des Mathématiciens* **1** (1894), 20, 162–164]. In his solution, de Jonquières listed what he felt were the values of $l(p)$ for all prime numbers $p < 200$, but his table entries for $p = 107, 149, 163, 179$ were one too high.

The factor method tells us immediately that

$$l(mn) \leq l(m) + l(n), \tag{3}$$

since we can take the chains $1, a_1, \ldots, a_r = m$ and $1, b_1, \ldots, b_s = n$ and form the chain $1, a_1, \ldots, a_r, a_r b_1, \ldots, a_r b_s = mn$.

We can also recast the m-ary method into addition-chain terminology. Consider the case $m = 2^k$, and write $n = d_0 m^t + d_1 m^{t-1} + \cdots + d_t$ in the m-ary number system; the corresponding addition chain takes the form

$$\begin{aligned} &1, 2, 3, \ldots, m-2, m-1, \\ &\quad 2d_0, 4d_0, \ldots, md_0, md_0 + d_1, \\ &\qquad 2(md_0+d_1), 4(md_0+d_1), \ldots, m(md_0+d_1), m^2 d_0 + md_1 + d_2, \\ &\qquad\quad \ldots, \qquad m^t d_0 + m^{t-1} d_1 + \cdots + d_t. \end{aligned} \tag{4}$$

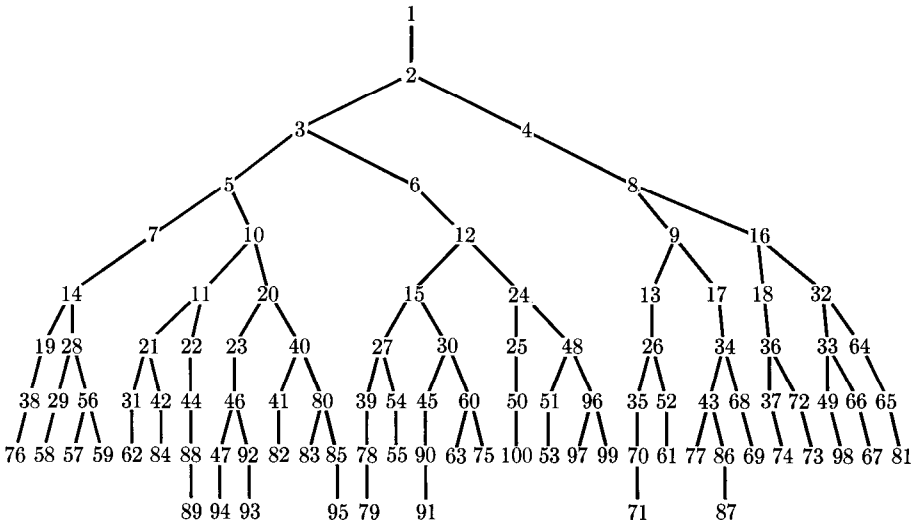

Fig. 14. A tree that minimizes the number of multiplications, for $n \leq 100$.

The length of this chain is $m - 2 + (k+1)t$; and it can often be reduced by deleting certain elements of the first row that do not occur among the coefficients d_j, plus elements among $2d_0$, $4d_0$, ... that already appear in the first row. Whenever digit d_j is zero, the step at the right end of the corresponding line may, of course, be dropped. Furthermore, as E. C. Thurber has observed [*Duke Math. J.* **40** (1973), 907–913], we can omit all the even numbers (except 2) in the first row, if we bring values of the form $d_j/2^e$ into the computation e steps earlier.

The simplest case of the m-ary method is the binary method ($m = 2$), when the general scheme (4) simplifies to the "S" and "X" rule mentioned at the beginning of this section: The binary addition chain for $2n$ is the binary chain for n followed by $2n$; for $2n+1$ it is the binary chain for $2n$ followed by $2n+1$. From the binary method we conclude that

$$l(2^{e_0} + 2^{e_1} + \cdots + 2^{e_t}) \leq e_0 + t, \qquad \text{if } e_0 > e_1 > \cdots > e_t \geq 0. \tag{5}$$

Let us now define two auxiliary functions for convenience in our subsequent discussion:

$$\lambda(n) = \lfloor \lg n \rfloor; \tag{6}$$

$$\nu(n) = \text{number of 1's in the binary representation of } n. \tag{7}$$

Thus $\lambda(17) = 4$, $\nu(17) = 2$; these functions may be defined by the recurrence relations

$$\lambda(1) = 0, \qquad \lambda(2n) = \lambda(2n+1) = \lambda(n) + 1; \tag{8}$$

$$\nu(1) = 1, \qquad \nu(2n) = \nu(n), \qquad \nu(2n+1) = \nu(n) + 1. \tag{9}$$

In terms of these functions, the binary addition chain for n requires exactly $\lambda(n) + \nu(n) - 1$ steps, and (5) becomes

$$l(n) \leq \lambda(n) + \nu(n) - 1. \tag{10}$$

Special classes of chains. We may assume without any loss of generality that an addition chain is "ascending,"

$$1 = a_0 < a_1 < a_2 < \cdots < a_r = n. \tag{11}$$

For if any two a's are equal, one of them may be dropped; and we can also rearrange the sequence (1) into ascending order and remove terms $> n$ without destroying the addition chain property (2). *From now on we shall consider only ascending chains,* without explicitly mentioning this assumption.

It is convenient at this point to define a few special terms relating to addition chains. By definition we have, for $1 \leq i \leq r$,

$$a_i = a_j + a_k \tag{12}$$

for some j and k, $0 \leq k \leq j < i$. Let us say that step i of (11) is a *doubling*, if $j = k = i - 1$; then a_i has the maximum possible value $2a_{i-1}$ that can follow the ascending chain $1, a_1, \ldots, a_{i-1}$. If j (but not necessarily k) equals $i - 1$, let us say that step i is a *star step*. The importance of star steps is explained below. Finally let us say that step i is a *small step* if $\lambda(a_i) = \lambda(a_{i-1})$. Since $a_{i-1} < a_i \leq 2a_{i-1}$, the quantity $\lambda(a_i)$ is always equal to either $\lambda(a_{i-1})$ or $\lambda(a_{i-1}) + 1$; it follows that, in any chain (11), *the length r is equal to $\lambda(n)$ plus the number of small steps.*

Several elementary relations hold between these types of steps: Step 1 is always a doubling. A doubling obviously is a star step, but never a small step. A doubling must be followed by a star step. Furthermore if step i is *not* a small step, then step $i + 1$ is either a small step or a star step, or both; putting this another way, if step $i + 1$ is neither small nor star, step i must be small.

A *star chain* is an addition chain that involves only star steps. This means that each term a_i is the sum of a_{i-1} and a previous a_k; the simple "computer" discussed above after Eq. (2) makes use only of the two operations STA and ADD (not LDA) in a star chain, since each new term of the sequence utilizes the preceding result in the accumulator. Most of the addition chains we have discussed so far are star chains. The minimum length of a star chain for n is denoted by $l^*(n)$; clearly

$$l(n) \leq l^*(n). \tag{13}$$

We are now ready to derive some nontrivial facts about addition chains. First we can show that there must be fairly many doublings if r is not far from $\lambda(n)$.

Theorem A. *If the addition chain* (11) *includes* d *doublings and* $f = r - d$ *nondoublings, then*

$$n \le 2^{d-1}F_{f+3}. \tag{14}$$

Proof. By induction on $r = d+f$, we see that (14) is certainly true when $r = 1$. When $r > 1$, there are three cases: If step r is a doubling, then $\frac{1}{2}n = a_{r-1} \le 2^{d-2}F_{f+3}$; hence (14) follows. If steps r and $r-1$ are both nondoublings, then $a_{r-1} \le 2^{d-1}F_{f+2}$ and $a_{r-2} \le 2^{d-1}F_{f+1}$; hence $n = a_r \le a_{r-1} + a_{r-2} \le 2^{d-1}(F_{f+2} + F_{f+1}) = 2^{d-1}F_{f+3}$ by the definition of the Fibonacci sequence. Finally, if step r is a nondoubling but step $r-1$ is a doubling, then $a_{r-2} \le 2^{d-2}F_{f+2}$ and $n = a_r \le a_{r-1} + a_{r-2} = 3a_{r-2}$. Now $2F_{f+3} - 3F_{f+2} = F_{f+1} - F_f \ge 0$; hence $n \le 2^{d-1}F_{f+3}$ in all cases. ∎

The method of proof we have used shows that inequality (14) is "best possible" under the stated assumptions; the addition chain

$$1, 2, \ldots, 2^{d-1}, 2^{d-1}F_3, 2^{d-1}F_4, \ldots, 2^{d-1}F_{f+3} \tag{15}$$

has d doublings and f nondoublings.

Corollary. *If the addition chain* (11) *includes* f *nondoublings and* s *small steps, then*

$$s \le f \le 3.271s. \tag{16}$$

Proof. Obviously $s \le f$. We have $2^{\lambda(n)} \le n \le 2^{d-1}F_{f+3} \le 2^d\phi^f = 2^{\lambda(n)+s}(\phi/2)^f$, since $d + f = \lambda(n) + s$, and since $F_{f+3} \le 2\phi^f$ when $f \ge 0$. Hence $0 \le s \ln 2 + f \ln(\phi/2)$, and (16) follows from the fact that

$$\ln 2 / \ln(2/\phi) \approx 3.2706. \quad ∎$$

Values of $l(n)$ for special n. It is easy to show by induction that $a_i \le 2^i$, and therefore $\lg n \le r$ in any addition chain (11). Hence

$$l(n) \ge \lceil \lg n \rceil. \tag{17}$$

This lower bound, together with the upper bound (10) given by the binary method, gives us the values

$$l(2^A) = A; \tag{18}$$

$$l(2^A + 2^B) = A + 1, \qquad \text{if } A > B. \tag{19}$$

In other words, the binary method is optimum when $\nu(n) \le 2$. With some further calculation we can extend these formulas to the case $\nu(n) = 3$:

Theorem B.

$$l(2^A + 2^B + 2^C) = A + 2, \qquad \text{if } A > B > C. \tag{20}$$

Proof. We can, in fact, prove a stronger result that will be of use to us later in this section: *All addition chains with exactly one small step have one of the following six types* (where all steps indicated by "..." represent doublings):

Type 1. $1, \ldots, 2^A, 2^A + 2^B, \ldots, 2^{A+C} + 2^{B+C}$; $A > B \geq 0$, $C \geq 0$.

Type 2. $1, \ldots, 2^A, 2^A + 2^B, 2^{A+1} + 2^B, \ldots, 2^{A+C+1} + 2^{B+C}$; $A > B \geq 0$, $C \geq 0$.

Type 3. $1, \ldots, 2^A, 2^A + 2^{A-1}, 2^{A+1} + 2^{A-1}, 2^{A+2}, \ldots, 2^{A+C}$; $A > 0$, $C \geq 2$.

Type 4. $1, \ldots, 2^A, 2^A + 2^{A-1}, 2^{A+1} + 2^A, 2^{A+2}, \ldots, 2^{A+C}$; $A > 0$, $C \geq 2$.

Type 5. $1, \ldots, 2^A, 2^A + 2^{A-1}, \ldots, 2^{A+C} + 2^{A+C-1}, 2^{A+C+1} + 2^{A+C-2}, \ldots, 2^{A+C+D+1} + 2^{A+C+D-2}$; $A > 0$, $C > 0$, $D \geq 0$.

Type 6. $1, \ldots, 2^A, 2^A + 2^B, 2^{A+1}, \ldots, 2^{A+C}$; $A > B \geq 0$, $C \geq 1$.

A straightforward hand calculation shows that these six types exhaust all possibilities. (Note that, by the corollary to Theorem A, there are at most three nondoublings when there is one small step; this maximum of three is attained only in sequences of Type 3. All of the above are star chains, except Type 6 when $B < A - 1$.)

The theorem now follows from the observation that $l(2^A + 2^B + 2^C) \leq A + 2$; and $l(2^A + 2^B + 2^C)$ must be greater than $A + 1$, since none of the six possible types have $\nu(n) > 2$. ∎

(E. de Jonquières stated without proof in 1894 that $l(n) \geq \lambda(n) + 2$ when $\nu(n) > 2$. The first published demonstration of Theorem B was by A. A. Gioia, M. V. Subbarao, and M. Sugunamma in *Duke Math. J.* **29** (1962), 481–487.)

The calculation of $l(2^A + 2^B + 2^C + 2^D)$, when $A > B > C > D$, is more involved; by the binary method it is at most $A + 3$, and by the proof of Theorem B it is at least $A + 2$. The value $A + 2$ is possible, since we know that the binary method is not optimal when $n = 15$ or $n = 23$. The complete behavior when $\nu(n) = 4$ can be determined, as we shall now see.

Theorem C. *If $\nu(n) \geq 4$ then $l(n) \geq \lambda(n) + 3$, except in the following circumstances when $A > B > C > D$ and $l(2^A + 2^B + 2^C + 2^D)$ equals $A + 2$:*

Case 1. $A - B = C - D$. (Example: $n = 15$.)
Case 2. $A - B = C - D + 1$. (Example: $n = 23$.)
Case 3. $A - B = 3$, $C - D = 1$. (Example: $n = 39$.)
Case 4. $A - B = 5$, $B - C = C - D = 1$. (Example: $n = 135$.)

Proof. When $l(n) = \lambda(n) + 2$, there is an addition chain for n having just two small steps; such an addition chain starts out as one of the six types in the proof of Theorem B, followed by a small step, followed by a sequence of nonsmall steps. Let us say that n is "special" if $n = 2^A + 2^B + 2^C + 2^D$ for one of the four

cases listed in the theorem. We can obtain addition chains of the required form for each special n, as shown in exercise 13; therefore it remains for us to prove that no chain with exactly two small steps contains any elements with $\nu(a_i) \geq 4$ except when a_i is special.

Let a "counterexample chain" be an addition chain with two small steps such that $\nu(a_r) \geq 4$, but a_r is not special. If counterexample chains exist, let $1 = a_0 < a_1 < \cdots < a_r = n$ be a counterexample chain of shortest possible length. Then step r is not a small step, since none of the six types in the proof of Theorem B can be followed by a small step with $\nu(n) \geq 4$ except when n is special. Furthermore, step r is not a doubling, otherwise $a_0, \ldots, a_{r-1}$ would be a shorter counterexample chain; and step r is a star step, otherwise $a_0, \ldots, a_{r-2}, a_r$ would be a shorter counterexample chain. Thus

$$a_r = a_{r-1} + a_{r-k}, \qquad k \geq 2; \qquad \text{and } \lambda(a_r) = \lambda(a_{r-1}) + 1. \tag{21}$$

Let c be the number of carries that occur when a_{r-1} is added to a_{r-k} in the binary number system by Algorithm 4.3.1A. Using the fundamental relation

$$\nu(a_r) = \nu(a_{r-1}) + \nu(a_{r-k}) - c, \tag{22}$$

we can prove that *step $r-1$ is not a small step* (see exercise 14).

Let $m = \lambda(a_{r-1})$. Since neither r nor $r-1$ is a small step, $c \geq 2$; and $c = 2$ can hold only when $a_{r-1} \geq 2^m + 2^{m-1}$.

Now let us suppose that $r-1$ is not a star step. Then $r-2$ is a small step, and $a_0, \ldots, a_{r-3}, a_{r-1}$ is a chain with only one small step; hence $\nu(a_{r-1}) \leq 2$ and $\nu(a_{r-2}) \leq 4$. The relation (22) can now hold only if $\nu(a_r) = 4$, $\nu(a_{r-1}) = 2$, $k = 2$, $c = 2$, $\nu(a_{r-2}) = 4$. From $c = 2$ we conclude that $a_{r-1} = 2^m + 2^{m-1}$; hence $a_0, a_1, \ldots, a_{r-3} = 2^{m-1} + 2^{m-2}$ is an addition chain with only one small step, and it must be of Type 1, so a_r belongs to Case 3. Thus $r-1$ *is a star step.*

Now assume that $a_{r-1} = 2^t a_{r-k}$ for some t. If $\nu(a_{r-1}) \leq 3$, then by (22), $c = 2$, $k = 2$, and we see that a_r must belong to Case 3. On the other hand, if $\nu(a_{r-1}) = 4$ then a_{r-1} is special, and it is easy to see by considering each case that a_r also belongs to one of the four cases. (Case 4 arises, for example, when $a_{r-1} = 90$, $a_{r-k} = 45$; or $a_{r-1} = 120$, $a_{r-k} = 15$.) Therefore we may conclude that $a_{r-1} \neq 2^t a_{r-k}$ for any t.

We have proved that $a_{r-1} = a_{r-2} + a_{r-q}$ for some $q \geq 2$. If $k = 2$, then $q > 2$, and $a_0, a_1, \ldots, a_{r-2}, 2a_{r-2}, 2a_{r-2} + a_{r-q} = a_r$ is a counterexample sequence in which $k > 2$; therefore we may assume that $k > 2$.

Let us now suppose that $\lambda(a_{r-k}) = m - 1$; the case $\lambda(a_{r-k}) < m - 1$ may be ruled out by similar arguments, as shown in exercise 14. If $k = 4$, both $r-2$ and $r-3$ are small steps; hence $a_{r-4} = 2^{m-1}$, and (22) is impossible. Therefore $k = 3$; step $r-2$ is small, $\nu(a_{r-3}) = 2$, $c = 2$, $a_{r-1} \geq 2^m + 2^{m-1}$, and $\nu(a_{r-1}) = 4$. There must be at least two carries when a_{r-2} is added to $a_{r-1} - a_{r-2}$; hence $\nu(a_{r-2}) = 4$, and a_{r-2} (being special and $\geq \frac{1}{2}a_{r-1}$) has the form $2^{m-1} + 2^{m-2} + 2^{d+1} + 2^d$ for some d. Now a_{r-1} is either $2^m + 2^{m+1} + 2^{d+1} + 2^d$ or $2^m + 2^{m-1} + 2^{d+2} + 2^{d+1}$, and in both cases a_{r-3} must be $2^{m-1} + 2^{m-2}$, so a_r belongs to Case 3. ∎

E. G. Thurber [*Pacific J. Math.* **49** (1973), 229–242] has extended Theorem C to show that $l(n) \geq \lambda(n) + 4$ when $\nu(n) > 8$. It seems reasonable to conjecture that $l(n) \geq \lambda(n) + \lg \nu(n)$ in general, since A. Schönhage has come very close to proving this (see exercise 29).

Asymptotic values. Theorem C indicates that it is probably quite difficult to get exact values of $l(n)$ for large n, when $\nu(n) > 4$; however, we can determine the approximate behavior in the limit as $n \to \infty$.

Theorem D (A. Brauer, *Bull. Amer. Math. Soc.* **45** (1939), 736–739).

$$\lim_{n\to\infty} l^*(n)/\lambda(n) = \lim_{n\to\infty} l(n)/\lambda(n) = 1. \tag{23}$$

Proof. The addition chain (4) for the 2^k-ary method is a star chain if we delete the second occurrence of any element that appears twice in the chain; for if a_i is the first element among $2d_0$, $4d_0$, ... of the second line that is not present in the first line, we have $a_i \leq 2(m-1)$; hence $a_i = (m-1) + a_j$ for some a_j in the first line. By totaling up the length of the chain, we have

$$\lambda(n) \leq l(n) \leq l^*(n) < \left(1 + \frac{1}{k}\right) \lg n + 2^k \tag{24}$$

for all $k \geq 1$. The theorem follows if we choose, say, $k = \lfloor \frac{1}{2} \lg \lambda(n) \rfloor$. ∎

If we let $k = \lambda\lambda(n) - 2\lambda\lambda\lambda(n)$ in (24) for large n, where $\lambda\lambda(n)$ denotes $\lambda(\lambda(n))$, we obtain the stronger asymptotic bound

$$l(n) \leq l^*(n) \leq \lambda(n) + \lambda(n)/\lambda\lambda(n) + O\big(\lambda(n)\lambda\lambda\lambda(n)/\lambda\lambda(n)^2\big). \tag{25}$$

The second term $\lambda(n)/\lambda\lambda(n)$ is essentially the best that can be obtained from (24). A much deeper analysis of lower bounds can be carried out, to show that this term $\lambda(n)/\lambda\lambda(n)$ is, in fact, essential in (25). In order to see why this is so, let us consider the following fact:

Theorem E (Paul Erdős, *Acta Arithmetica* **6** (1960), 77–81). *Let ϵ be a positive real number. The number of addition chains* (11) *such that*

$$\lambda(n) = m, \qquad r \leq m + (1-\epsilon)m/\lambda(m) \tag{26}$$

is less than α^m, for some $\alpha < 2$, for all suitably large m. (In other words, the number of addition chains so short that (26) is satisfied is substantially less than the number of values of n such that $\lambda(n) = m$, when m is large.)

Proof. We want to estimate the number of possible addition chains, and for this purpose our first goal is to get an improvement of Theorem A that enables us to deal more satisfactorily with nondoublings.

Lemma P. *Let $\delta < \sqrt{2} - 1$ be a fixed positive real number. Call step i of an addition chain a "ministep" if it is not a doubling and if $a_i < a_j(1+\delta)^{i-j}$ for some j, where $0 \le j < i$. If the addition chain contains s small steps and t ministeps, then*

$$t \le s/(1-\theta), \qquad \text{where } (1+\delta)^2 = 2^\theta. \tag{27}$$

Proof. For each ministep i_k, $1 \le k \le t$, we have $a_{i_k} < a_{j_k}(1+\delta)^{i_k - j_k}$ for some $j_k < i_k$. Let $I_1, \ldots, I_t$ be the intervals $(j_1, i_1], \ldots, (j_t, i_t]$, where the notation $(j, i]$ stands for the set of all integers k such that $j < k \le i$. It is possible (see exercise 17) to find nonoverlapping intervals $J_1, \ldots, J_h = (j'_1, i'_1], \ldots, (j'_h, i'_h]$ such that

$$\begin{aligned} I_1 \cup \cdots \cup I_t &= J_1 \cup \cdots \cup J_h, \\ a_{i'_k} < a_{j'_k}(1+\delta)^{2(i'_k - j'_k)}, &\qquad \text{for } 1 \le k \le h. \end{aligned} \tag{28}$$

Now for all steps i outside of the intervals $J_1, \ldots, J_h$ we have $a_i \le 2a_{i-1}$; hence if we let

$$q = (i'_1 - j'_1) + \cdots + (i'_h - j'_h),$$

we have

$$2^{\lambda(n)} \le n \le 2^{r-q}(1+\delta)^{2q} = 2^{\lambda(n)+s-(1-\theta)q} \le 2^{\lambda(n)+s-(1-\theta)t}. \quad \blacksquare$$

Returning to the proof of Theorem E, let us choose $\delta = 2^{\epsilon/4} - 1$, and let us divide the r steps of each addition chain into three classes:

$$t \text{ ministeps}, \qquad u \text{ doublings}, \qquad v \text{ other steps}, \qquad t + u + v = r. \tag{29}$$

Counting another way, we have s small steps, where $s + m = r$. By the hypotheses, Theorem A, and Lemma P, we obtain the relations

$$t \le s/(1-\epsilon/2), \qquad t + v \le 3.271s, \qquad s \le (1-\epsilon)m/\lambda(m). \tag{30}$$

Given s, t, u, v satisfying these conditions, there are at most

$$\binom{r}{t+v}\binom{t+v}{v} \tag{31}$$

ways to assign the steps to the specified classes. Given such a distribution of the steps, let us consider how the non-ministeps can be selected: If step i is one of the "other" steps in (29), $a_i \ge (1+\delta)a_{i-1}$, so $a_i = a_j + a_k$, where $\delta a_{i-1} \le a_k \le a_j \le a_{i-1}$. Also $a_j \le a_i/(1+\delta)^{i-j} \le 2a_{i-1}/(1+\delta)^{i-j}$, so $\delta \le 2/(1+\delta)^{i-j}$. This gives at most β choices for j, where β is a constant that depends only on δ. There are also at most β choices for k, so the number of ways to assign j and k for each of the non-ministeps is at most

$$\beta^{2v}. \tag{32}$$

Finally, once the "j" and "k" have been selected for each of the nonministeps, there are fewer than

$$\binom{r^2}{t} \tag{33}$$

ways to choose the j and the k for the ministeps: We select t distinct pairs $(j_1, k_1), \ldots, (j_t, k_t)$ of indices in the range $0 \le k_h \le j_h < r$, in fewer than (33) ways. Then for each ministep i, in turn, we use a pair of indices (j_h, k_h) such that

a) $j_h < i$;
b) $a_{j_h} + a_{k_h}$ is as small as possible among the pairs not already used for smaller ministeps i;
c) $a_i = a_{j_h} + a_{k_h}$ satisfies the definition of ministep.

If no such pair (j_h, k_h) exists, we get no addition chain; on the other hand, any addition chain with ministeps in the designated places must be selected in one of these ways, so (33) is an upper bound on the possibilities.

Thus the total number of possible addition chains satisfying (26) is bounded by (31) times (32) times (33), summed over all relevant s, t, u, and v. The proof of Theorem E can now be completed by means of a rather standard estimation of these functions (exercise 18). ∎

Corollary. *The value of $l(n)$ is asymptotically $\lambda(n) + \lambda(n)/\lambda\lambda(n)$, for almost all n. More precisely, there is a function $f(n)$ such that $f(n) \to 0$ as $n \to \infty$, and*

$$\Pr\big(\,|l(n) - \lambda(n) - \lambda(n)/\lambda\lambda(n)| \ge f(n)\lambda(n)/\lambda\lambda(n)\,\big) = 0. \tag{34}$$

(See Section 3.5 for the definition of this probability "Pr".)

Proof. The upper bound (25) shows that (34) holds without the absolute value signs. The lower bound comes from Theorem E, if we let $f(n)$ decrease to zero slowly enough so that, when $f(n) \le \epsilon$, the value N is so large that at most ϵN values $n \le N$ have $l(n) \le \lambda(n) + (1 - \epsilon)\lambda(n)/\lambda\lambda(n)$. ∎

Star chains. Optimistic people find it reasonable to suppose that $l(n) = l^*(n)$; given an addition chain of minimal length $l(n)$, it appears hard to believe that we cannot find one of the same length that satisfies the (apparently mild) star condition. But in 1958 Walter Hansen proved the remarkable theorem that, for certain large values of n, the value of $l(n)$ is definitely less than $l^*(n)$, and he also proved several related theorems that we shall now investigate.

Hansen's theorems begin with an investigation of the detailed structure of a star chain. This structure is given in terms of other sequences and sets constructed from the given chain. Let $n = 2^{e_0} + 2^{e_1} + \cdots + 2^{e_t}$, $e_0 > e_1 > \cdots > e_t \ge 0$, and let $1 = a_0 < a_1 < \cdots < a_r = n$ be a star chain for n. If there are d doublings in this chain, we define the auxiliary sequence

$$0 = d_0 \le d_1 \le d_2 \le \cdots \le d_r = d, \tag{35}$$

where d_i is the number of doublings among steps 1, 2, ..., i. We also define a sequence of "multisets" S_0, S_1, ..., S_r, which keep track of the powers of 2 present in the chain. (A *multiset* is a mathematical entity that is like a set, but it is allowed to contain repeated elements; an object may be an element of a multiset several times, and its multiplicity of occurrences is relevant. See exercise 19 for familiar examples of multisets.) The multisets S_i are defined by the rules

a) $S_0 = \{0\}$;

b) If $a_{i+1} = 2a_i$, then $S_{i+1} = S_i + 1 = \{ x + 1 \mid x \in S_i \}$;

c) If $a_{i+1} = a_i + a_k$, $k < i$, then $S_{i+1} = S_i \uplus S_k$.

(The symbol $\uplus$ means that the multisets are combined, adding the multiplicities.) From this definition it follows that

$$a_i = \sum_{x \in S_i} 2^x, \tag{36}$$

where the terms in this sum are not necessarily distinct. In particular,

$$n = 2^{e_0} + 2^{e_1} + \cdots + 2^{e_t} = \sum_{x \in S_r} 2^x. \tag{37}$$

The number of elements in the latter sum is at most 2^f, where $f = r - d$ is the number of nondoublings.

Since n has two different binary representations in (37), we can partition the multiset S_r into multisets M_0, M_1, ..., M_t such that

$$2^{e_j} = \sum_{x \in M_j} 2^x, \qquad 0 \le j \le t. \tag{38}$$

This can be done by arranging the elements of S_r into nondecreasing order $x_1 \le x_2 \le \cdots$ and taking $M_t = \{x_1, x_2, \ldots, x_k\}$, where $2^{x_1} + \cdots + 2^{x_k} = 2^{e_t}$. This must be possible, since e_t is the smallest of the e's. Similarly, $M_{t-1} = \{x_{k+1}, x_{k+2}, \ldots, x_{k'}\}$, and so on; the process is easily visualized in binary notation.

Let M_j contain m_j elements (counting multiplicities); then $m_j \le 2^f - t$, since S_r has at most 2^f elements and it has been partitioned into $t+1$ nonempty multisets. By Eq. (38), we can see that

$$e_j \ge x > e_j - m_j, \qquad \text{for all } x \in M_j. \tag{39}$$

Our examination of the star chain's structure is completed by forming the multisets M_{ij} that record the ancestral history of M_j. The multiset S_i is partitioned into $t + 1$ multisets as follows:

a) $M_{rj} = M_j$;

b) If $a_{i+1} = 2a_i$, then $M_{ij} = M_{(i+1)j} - 1 = \{ x - 1 \mid x \in M_{(i+1)j} \}$;

c) If $a_{i+1} = a_i + a_k$, $k < i$, then (since $S_{i+1} = S_i \uplus S_k$) we let $M_{ij} = M_{(i+1)j}$ minus S_k, that is, we remove the elements of S_k from $M_{(i+1)j}$. If some element of S_k appears in two or more different multisets $M_{(i+1)j}$, we remove it from the set with the largest possible value of j; this rule uniquely defines M_{ij} for each j, when i is fixed.

From this definition it follows that

$$e_j + d_i - d \geq x > e_j + d_i - d - m_j, \qquad \text{for all } x \in M_{ij}. \tag{40}$$

As an example of this detailed construction, let us consider the star chain 1, 2, 3, 5, 10, 20, 23, for which $t = 3$, $r = 6$, $d = 3$, $f = 3$. We obtain the following array of multisets:

	S_0	S_1	S_2	S_3	S_4	S_5	S_6		
$(d_0, d_1, \ldots, d_6)$:	0	1	1	1	2	3	3		
$(a_0, a_1, \ldots, a_6)$:	1	2	3	5	10	20	23		
$(M_{03}, M_{13}, \ldots, M_{63})$:							0	M_3	$e_3 = 0$, $m_3 = 1$
$(M_{02}, M_{12}, \ldots, M_{62})$:							1	M_2	$e_2 = 1$, $m_2 = 1$
$(M_{01}, M_{11}, \ldots, M_{61})$:			0	0	1	2	2	M_1	$e_1 = 2$, $m_1 = 1$
$(M_{00}, M_{10}, \ldots, M_{60})$:	0	1	1	1	2	3	3	M_0	$e_0 = 4$, $m_0 = 2$
				1	2	3	3		

Thus $M_{40} = \{2, 2\}$, etc. From the construction we can see that d_i is the largest element of S_i; hence

$$d_i \in M_{i0}. \tag{41}$$

The most important part of this structure comes from Eq. (40); one of its immediate consequences is

Lemma K. *If M_{ij} and M_{uv} both contain a common integer x, then*

$$-m_v < (e_j - e_v) - (d_u - d_i) < m_j. \quad \blacksquare \tag{42}$$

Although Lemma K may not look extremely powerful, it says (when M_{ij} contains an element in common with M_{uv} and when m_j, m_v are reasonably small) that the number of doublings between steps u and i is approximately equal to the difference between the exponents e_v and e_j. This imposes a certain amount of regularity on the addition chain; and it suggests that we might be able to prove a result analogous to Theorem B above, that $l^*(n) = e_0 + t$, provided that the e_j are far enough apart. The next theorem shows how this can be done.

Theorem H (W. Hansen, *J. für die reine und angew. Math.* **202** (1959), 129–136). *Let $n = 2^{e_0} + 2^{e_1} + \cdots + 2^{e_t}$, $e_0 > e_1 > \cdots > e_t \geq 0$. If*

$$e_0 > 2e_1 + 2.271(t-1) \qquad \text{and} \qquad e_{i-1} \geq e_i + 2m \quad \text{for } 1 \leq i \leq t, \tag{43}$$

where $m = 2^{\lfloor 3.271(t-1) \rfloor} - t$, then $l^*(n) = e_0 + t$.

Proof. We may assume that $t > 2$, since the result of the theorem is true without restriction on the e's when $t \leq 2$. Suppose that we have a star chain $1 = a_0 < a_1 < \cdots < a_r = n$ for n with $r \leq e_0 + t - 1$. Let the integers d, f, $d_0, \ldots, d_r$,

and the multisets M_{ij} and S_i, reflect the structure of this chain, as defined above. By the corollary to Theorem A, we know that $f \le \lfloor 3.271(t-1) \rfloor$; therefore the value of m is a bona fide upper bound for the number m_j of elements in each multiset M_j.

In the summation

$$a_i = \Big(\sum_{x\in M_{i0}} 2^x\Big) + \Big(\sum_{x\in M_{i1}} 2^x\Big) + \cdots + \Big(\sum_{x\in M_{it}} 2^x\Big),$$

no carries propagate from the term corresponding to M_{ij} to the term corresponding to $M_{i(j-1)}$, if we think of this sum as being carried out in the binary number system, since the e's are so far apart. (Cf. (40).) In particular, the sum of all the terms for $j \neq 0$ will not carry up to affect the terms for $j = 0$, so we must have

$$a_i \ge \sum_{x\in M_{i0}} 2^x \ge 2^{\lambda(a_i)}, \qquad 0 \le i \le r. \tag{44}$$

In order to prove Theorem H, we would like to show that in some sense the t extra powers of n must be put in "one at a time," so we want to find a way to tell at which step each of these terms essentially enters the addition chain.

Let j be a number between 1 and t. Since M_{0j} is empty and $M_{rj} = M_j$ is nonempty, we can find the *first* step i for which M_{ij} is not empty.

From the way in which the M_{ij} are defined, we know that step i is a nondoubling: $a_i = a_{i-1} + a_u$ for some $u < i - 1$. We also know that all the elements of M_{ij} are elements of S_u. We will prove that a_u must be relatively small compared to a_i.

Let x_j be an element of M_{ij}. Then since $x_j \in S_u$, there is some v for which $x_j \in M_{uv}$. It follows that

$$d_i - d_u > m, \tag{45}$$

i.e., at least $m + 1$ doublings occur between steps u and i. For if $d_i - d_u \le m$, Lemma K tells us that $|e_j - e_v| < 2m$; hence $v = j$. But this is impossible, because M_{uj} is empty by our choice of step i.

All elements of S_u are less than or equal to $e_1 + d_i - d$. For if $x \in S_u \subseteq S_i$ and $x > e_1 + d_i - d$, then $x \in M_{u0}$ and $x \in M_{i0}$ by (40); so Lemma K implies that $|d_i - d_u| < m$, contradicting (45). In fact, this argument proves that M_{i0} has no elements in common with S_u, so $M_{(i-1)0} = M_{i0}$. From (44) we have $a_{i-1} \ge 2^{\lambda(a_i)}$, and therefore *step i is a small step.*

We can now deduce what is probably the key fact in this entire proof: *All elements of S_u are in M_{u0}.* For if not, let x be an element of S_u with $x \notin M_{u0}$. Since $x \ge 0$, (40) implies that $e_1 \ge d - d_u$, hence

$$e_0 = f + d - s \le 2.271s + d \le 2.271(t-1) + e_1 + d_u.$$

By hypothesis (43), this implies $d_u > e_1$. But $d_u \in S_u$ by (41), and it cannot be in M_{i0}, hence $d_u \le e_1 + d_i - d \le e_1$, a contradiction.

Going back to our element x_j in M_{ij}, we have $x_j \in M_{uv}$; and we have proved that $v = 0$. Therefore, by equation (40) again,

$$e_0 + d_u - d \geq x_j > e_0 + d_u - d. \tag{46}$$

For all $j = 1, 2, \ldots, t$ we have determined a number x_j satisfying (46), and a small step i at which the term 2^{e_j} may be said to have entered into the addition chain. If $j \neq j'$, the step i at which this occurs cannot be the same for both j and j'; for (46) would tell us that $|x_j - x_{j'}| < m$, while elements of M_{ij} and $M_{ij'}$ must differ by more than m, since e_j and $e_{j'}$ are so far apart. We are forced to conclude that the chain contains at least t small steps; but this is a contradiction. ∎

Theorem F (W. Hansen).

$$l(2^A + xy) \leq A + \nu(x) + \nu(y) - 1, \qquad \text{if } \lambda(x) + \lambda(y) \leq A. \tag{47}$$

Proof. An addition chain (which is *not* a star chain in general) may be constructed by combining the binary and factor methods. Let $x = 2^{x_1} + \cdots + 2^{x_u}$ and $y = 2^{y_1} + \cdots + 2^{y_v}$, where $x_1 > \cdots > x_u \geq 0$ and $y_1 > \cdots > y_v \geq 0$.

The first steps of the chain form successive powers of 2, until 2^{A-y_1} is reached; in between these steps, the additional values $2^{x_u-1} + 2^{x_u}$, $2^{x_u-2} + 2^{x_u-1} + 2^{x_u}$, ..., and x are inserted in the appropriate places. After a chain up to $2^{A-y_i} + x(2^{y_1-y_i} + \cdots + 2^{y_{i-1}-y_i})$ has been formed, we continue by adding x and doubling the resulting sum $y_i - y_{i+1}$ times; this yields

$$2^{A-y_{i+1}} + x(2^{y_1-y_{i+1}} + \cdots + 2^{y_i-y_{i+1}}).$$

If this construction is done for $i = 1, 2, \ldots, v$, assuming for convenience that $y_{v+1} = 0$, we have an addition chain for $2^A + xy$ as desired. ∎

Theorem F enables us to find values of n for which $l(n) < l^*(n)$, since Theorem H gives an explicit value of $l^*(n)$ in certain cases. For example, let $x = 2^{1016} + 1$, $y = 2^{2032} + 1$, and let

$$n = 2^{6103} + xy = 2^{6103} + 2^{3048} + 2^{2032} + 2^{1016} + 1.$$

According to Theorem F, we have $l(n) \leq 6106$. But Theorem H also applies, with $m = 508$, and this proves that $l^*(n) = 6107$.

Extensive computer calculations have shown that $n = 12509$ is the smallest value with $l(n) < l^*(n)$. No star chain for this value of n is as short as the sequence 1, 2, 4, 8, 16, 17, 32, 64, 128, 256, 512, 1024, 1041, 2082, 4164, 8328, 8345, 12509. The brute-force methods in the proof of Theorem C could be extended by computer program to determine all n such that $l(n) = \lambda(n) + 3$; this approach would also characterize all n with $\nu(n) = 5$ and $l(n) \neq l^*(n)$. (The smallest such n is $16537 = 2^{14} + 9 \cdot 17$.)

Some conjectures. Although it was reasonable to guess at first glance that $l(n) = l^*(n)$, we have now seen that this is false. Another plausible conjecture [first made by A. Goulard, and supposedly "proved" by E. de Jonquières in *l'Interm. des Math.* **2** (1895), 125–126] is that $l(2n) = l(n) + 1$; a doubling step is so efficient, it seems unlikely that there could be any shorter chain for $2n$ than to add a doubling step to the shortest chain for n. But computer calculations show that this conjecture also fails, since $l(191) = l(382) = 11$. (A star chain of length 11 for 382 is not hard to find; e.g., 1, 2, 4, 5, 9, 14, 23, 46, 92, 184, 198, 382. The number 191 is minimal such that $l(n) = 11$, and it seems to be very difficult to prove by hand that $l(191) > 10$; the computer's proof of this fact, using a backtrack method that will be sketched in Section 7.2.2, involved a detailed examination of 948 cases.) The smallest four values of n such that $l(2n) = l(n)$ are $n = 191, 701, 743, 1111$; E. G. Thurber proved in *Pacific J. Math.* **49** (1973), 229–242, that the third of these is a member of an infinite family of such n, namely $23 \cdot 2^k + 7$ for all $k \geq 5$. It seems reasonable to conjecture that $l(2n) \geq l(n)$, but even this may be false. Kevin R. Hebb has shown that $l(n) - l(mn)$ can get arbitrarily large, for all fixed integers m not a power of 2 [*Notices Amer. Math. Soc.* **21** (1974), A–294]. The smallest case in which $l(mn) < l(n)$ is $l\big((2^{13} + 1)/3\big) = 15$.

Let $c(r)$ be the smallest value of n such that $l(n) = r$. It seems to be most difficult to compute $l(n)$ for these values of n. We have the following table:

r	$c(r)$	r	$c(r)$	r	$c(r)$
1	2	7	29	13	607
2	3	8	47	14	1087
3	5	9	71	15	1903
4	7	10	127	16	3583
5	11	11	191	17	6271
6	19	12	379	18	11231

For $r \leq 11$, the value of $c(r)$ is approximately equal to $c(r-1) + c(r-2)$, and this fact led to speculation by several people that $c(r)$ grows like the function ϕ^r; but the result of Theorem D (with $n = c(r)$) implies that $r/\lg c(r) \to 1$ as $n \to \infty$. [See E. G. Thurber, *Duke Math. J.* **40** (1973), 907–913, for more detailed information about the growth of $c(r)$.] Several people had conjectured at one time that $c(r)$ would always be a prime number; but $c(15) = 11 \cdot 173$ and $c(18) = 11 \cdot 1021$. Perhaps no conjecture about addition chains is safe!

Tabulated values of $l(n)$ show that this function is surprisingly smooth; for example, $l(n) = 13$ for all n in the range $1125 \leq n \leq 1148$. The computer calculations show that a table of $l(n)$ may be prepared for all $n \leq 1000$ by using the formula

$$l(n) = \min(l(n-1) + 1, l) - \delta, \tag{48}$$

where $l = \infty$ if n is prime, otherwise $l = l(p) + l(n/p)$ if p is the smallest prime dividing n; and $\delta = 1$ for n in Table 1, $\delta = 0$ otherwise.

Table 1

VALUES OF n FOR SPECIAL ADDITION CHAINS

23	163	229	319	371	413	453	553	599	645	707	741	813	849	903
43	165	233	323	373	419	455	557	611	659	709	749	825	863	905
59	179	281	347	377	421	457	561	619	667	711	759	835	869	923
77	203	283	349	381	423	479	569	623	669	713	779	837	887	941
83	211	293	355	382	429	503	571	631	677	715	787	839	893	947
107	213	311	359	395	437	509	573	637	683	717	803	841	899	955
149	227	317	367	403	451	551	581	643	691	739	809	845	901	983

Let $d(r)$ be the number of solutions n to the equation $l(n) = r$. The following table lists the first few values of this function:

r	$d(r)$	r	$d(r)$	r	$d(r)$
1	1	6	15	11	246
2	2	7	26	12	432
3	3	8	44	13	772
4	5	9	78	14	1382
5	9	10	136	15	2481

Surely $d(r)$ must be an increasing function of r, but there is no evident way to prove this seemingly simple assertion, much less to determine the asymptotic growth of $d(r)$ for large r.

The most famous problem about addition chains that is still outstanding is the "Scholz-Brauer conjecture," which states that

$$l(2^n - 1) \leq n - 1 + l(n). \tag{49}$$

Computer calculations show, in fact, that equality holds in (49) for $1 \leq n \leq 14$; and hand calculations by E. G. Thurber [*Discrete Math.* **16** (1976), 279–289] have shown that equality holds also for $n = 15, 16, 17, 18, 20, 24, 32$. Much of the research on addition chains has been devoted to attempts to prove (49); addition chains for the number $2^n - 1$, which has so many ones in its binary representation, are of special interest, since this is the worst case for the binary method. Arnold Scholz coined the name "addition chain" (in German) and posed (49) as a problem in 1937 [*Jahresbericht der deutschen Mathematiker-Vereinigung*, class II, **47** (1937), 41–42]; Alfred Brauer proved in 1939 that

$$l^*(2^n - 1) \leq n - 1 + l^*(n). \tag{50}$$

Hansen's theorems show that $l(n)$ can be less than $l^*(n)$, so more work is definitely necessary in order to prove or disprove (49). As a step in this direction, Hansen has defined the concept of an *l^0-chain*, which lies "between" l-chains and l^*-chains. In an l^0-chain, certain of the elements are underlined; the condition is that $a_i = a_j + a_k$, where a_j is the largest underlined element less than a_i.

As an example of an l^0-chain (certainly not a minimum one), consider

$$\underline{1}, \underline{2}, \underline{4}, 5, \underline{8}, 10, 12, \underline{18}; \tag{51}$$

it is easy to verify that the difference between each element and the previous underlined element is in the chain. We let $l^0(n)$ denote the minimum length of an l^0-chain for n. Clearly $l(n) \leq l^0(n) \leq l^*(n)$.

The chain constructed in Theorem F is an l^0-chain (see exercise 22); hence we have $l^0(n) < l^*(n)$ for certain n. It is not known whether or not $l(n) = l^0(n)$ in all cases; if this equation were true, the Scholz-Brauer conjecture would be settled, because of another theorem due to Hansen:

Theorem G. $l^0(2^n - 1) \leq n - 1 + l^0(n)$.

Proof. Let $1 = a_0, a_1, \ldots, a_r = n$ be an l^0-chain of minimum length for n, and let $1 = b_0, b_1, \ldots, b_t = n$ be the subsequence of underlined elements. (We may assume that n is underlined.) Then we can get an l^0-chain for $2^n - 1$ as follows:

a) Include the $l^0(n)+1$ numbers $2^{a_i} - 1$, for $0 \leq i \leq r$, underlined if and only if a_i is underlined.

b) Include the numbers $2^i(2^{b_j} - 1)$, for $0 \leq j < t$ and for $0 < i \leq b_{j+1} - b_j$, all underlined. (This is a total of $b_1 - b_0 + \cdots + b_t - b_{t-1} = n - 1$ numbers.)

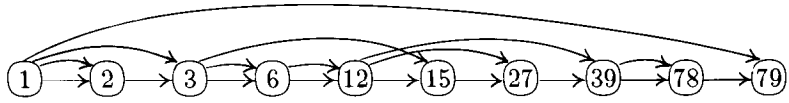
c) Sort the numbers from (a) and (b) into ascending order.

We may easily verify that this gives an l^0-chain: The numbers of (b) are all equal to twice some other element of (a) or (b); furthermore, this element is the preceding underlined element. If $a_i = b_j + a_k$, where b_j is the largest underlined element less than a_i, then $a_k = a_j - b_j \leq b_{j+1} - b_j$, so $2^{a_k}(2^{b_j} - 1) = 2^{a_i} - 2^{a_k}$ appears underlined in the chain, just preceding $2^{a_i} - 1$. Since $2^{a_i} - 1$ is equal to $(2^{a_i} - 2^{a_k}) + (2^{a_k} - 1)$, where both of these values appear in the chain, we have an addition chain with the l^0 property. ∎

The chain corresponding to (51), constructed in the proof of Theorem G, is

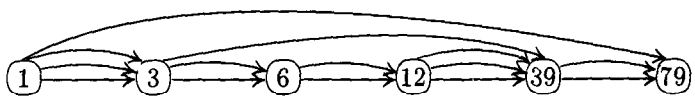
$$\underline{1}, \underline{2}, \underline{3}, \underline{6}, \underline{12}, \underline{15}, \underline{30}, 31, \underline{60}, \underline{120}, \underline{240}, \underline{255}, \underline{510}, \underline{1020}, 1023, \underline{2040},$$
$$\underline{4080}, 4095, \underline{8160}, \underline{16320}, \underline{32640}, \underline{65280}, \underline{130560}, \underline{261120}, \underline{262143}.$$

Graphical representation. An addition chain (1) corresponds in a natural way to a directed graph, where the vertices are labeled a_i for $0 \leq i \leq r$, and where we draw arcs from a_j to a_i and from a_k to a_i as a representation of each step $a_i = a_j + a_k$ in (2). For example, the addition chain 1, 2, 3, 6, 12, 15, 27, 39, 78, 79 that appears in Fig. 14 corresponds to the directed graph



If $a_i = a_j + a_k$ for more than one pair of indices (j, k), we choose a definite j and k for purposes of this construction.

In general, all but the first vertex of such a directed graph will be at the head of exactly two arcs; however, this is not really an important property of the graph, because it conceals the fact that many different addition chains can be essentially equivalent. If a vertex has out-degree 1 (i.e., only one arc leading away), it is used in only one later step, hence the later step is essentially a sum of three inputs $a_j + a_k + a_m$ that might be computed either as $(a_j + a_k) + a_m$ or as $a_j + (a_k + a_m)$ or as $a_k + (a_j + a_m)$. These three choices are immaterial, but the addition-chain conventions force us to distinguish between them. We can avoid such redundancy by deleting any vertex whose out-degree is 1 and attaching the arcs from its predecessors to its successor. For example, the above graph would become



(52)

We can also delete any vertex whose out-degree is 0, except of course the final vertex a_r, since such a vertex corresponds to a useless step in the addition chain.

In this way every addition chain leads to a reduced directed graph that contains one "source" vertex (labeled 1) and one "sink" vertex (labeled n); every vertex but the source has in-degree ≥ 2 and every vertex but the sink has out-degree ≥ 2. Conversely, any such directed graph without oriented cycles corresponds to at least one addition chain, since we can topologically sort the vertices and write down $d - 1$ addition steps for each vertex of in-degree $d > 0$. The length of the addition chain, exclusive of useless steps, can be reconstructed by looking at the reduced graph; it is

$$(\text{number of arcs}) - (\text{number of vertices}) + 1, \tag{53}$$

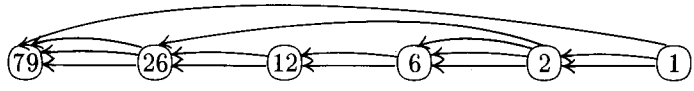
since deletion of a vertex of out-degree 1 also deletes one arc.

We say that two addition chains are *equivalent* if they have the same reduced directed graph. For example, the addition chain 1, 2, 3, 6, 12, 15, 24, 39, 40, 79 is equivalent to the chain we began with, since it also leads to (52). This example shows that a non-star chain can be equivalent to a star chain. An addition chain is equivalent to a star chain if and only if its reduced directed graph can be topologically sorted in only one way.

An important property of this graph representation has been pointed out by N. Pippenger: The label of each vertex is exactly equal to the number of oriented paths from the source to that vertex. Thus, the problem of finding an optimal addition chain for n is equivalent to minimizing the quantity (53) over all directed graphs that have one source vertex and one sink vertex and exactly n oriented paths from the source to the sink.

This characterization has a surprising corollary, because of the symmetry of the directed graph. If we reverse the direction of all the arcs, the source and the

sink exchange rôles, and we obtain another directed graph corresponding to a set of addition chains for the same n; these addition chains have the same length (53) as the chain we started with. For example, if we make the arrows in (52) run from right to left, and if we relabel the vertices according to the number of paths from the right-hand vertex, we get



. (54)

One of the star chains corresponding to this reduced directed graph is

$$1, 2, 4, 6, 12, 24, 26, 52, 78, 79;$$

we may call this a *dual* of the original addition chain.

Exercises 39 and 40 discuss important consequences of this graphical representation and the duality principle.

EXERCISES

1. [*15*] What is the value of Z when Algorithm A terminates?

2. [*24*] Write a MIX program for Algorithm A, to calculate $x^n \bmod w$ given integers n and x, where w is the word size. Assume that MIX has the binary operations SRB, JAE, etc., that are described in Section 4.5.2. Write another program that computes $x^n \bmod w$ in a serial manner (multiplying repeatedly by x), and compare the running times of these programs.

▶ **3.** [*22*] How is x^{975} calculated by (a) the binary method? (b) the ternary method? (c) the quaternary method? (d) the factor method?

4. [*M20*] Find a number n for which the octal (2^3-ary) method gives ten fewer multiplications than the binary method.

▶ **5.** [*24*] Figure 13 shows the first eight levels of the "power tree." The $(k+1)$-st level of this tree is defined as follows, assuming that the first k levels have been constructed: Take each node n of the kth level, from left to right in turn, and attach below it the nodes

$$n+1,\ n+a_1,\ n+a_2,\ \ldots,\ n+a_{k-1} = 2n$$

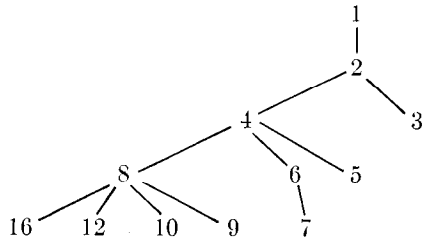
(in this order), where $1, a_1, a_2, \ldots, a_{k-1}$ is the path from the root of the tree to n; but discard any node that duplicates a number that has already appeared in the tree.

Design an efficient algorithm that constructs the first $r+1$ levels of the power tree. [*Hint:* Make use of two sets of variables LINKU[j], LINKR[j] for $0 \le j \le 2^r$; these point upwards and to the right, respectively, if j is a number in the tree.]

6. [*M26*] If a slight change is made to the definition of the power tree that is given in exercise 5, so that the nodes below n are attached in *decreasing* order

$$n + a_{k-1}, \ \ldots, \ n + a_2, \ n + a_1, \ n + 1$$

instead of increasing order, we get a tree whose first five levels are



Show that this tree gives a method of computing x^n that requires exactly as many multiplications as the binary method; therefore it is not as good as the power tree, although it has been constructed in almost the same way.

7. [*M21*] Prove that there are infinitely many values of n

a) for which the factor method is better than the binary method;
b) for which the binary method is better than the factor method;
c) for which the power tree method is better than both the binary and factor methods.

(Here the "better" method shows how to compute x^n using fewer multiplications.)

8. [*M21*] Prove that the power tree (exercise 5) never gives more multiplications for the computation of x^n than the binary method.

9. [*M21*] Design an exponentiation procedure that is analogous to Algorithm A, but based on a general radix $m \geq 2$. Your method should perform approximately $\lg n + \nu + 2m$ multiplications, where ν is the number of nonzero digits in the m-ary representation of n.

10. [*10*] Figure 14 shows a tree that indicates one way to compute x^n with the fewest possible multiplications, for all $n \leq 100$. How can this tree be conveniently represented within a computer, in just 100 memory locations?

▶ **11.** [*M26*] The tree of Fig. 14 depicts addition chains $a_0, a_1, \ldots, a_r$ having $l(a_i) = i$ for all i in the chain. Find all addition chains for n that have this property, when $n = 43$ and when $n = 77$. Show that any tree such as Fig. 14 must include either the path 1, 2, 4, 8, 9, 17, 34, 43, 77 or the path 1, 2, 4, 8, 9, 17, 34, 68, 77.

12. [*M10*] Is it possible to extend the tree shown in Fig. 14 to an infinite tree that yields a minimum-multiplication rule for computing x^n, for all positive integers n?

13. [*M21*] Find a star chain of length $A + 2$ for each of the four cases listed in Theorem C. (Consequently Theorem C holds also with l replaced by l^*.)

14. [*M35*] Complete the proof of Theorem C, by demonstrating that (a) step $r - 1$ is not a small step; and (b) $\lambda(a_{r-k})$ cannot be less than $m - 1$.

15. [*M42*] Write a computer program to extend Theorem C, characterizing all n such that $l(n) = \lambda(n) + 3$ and characterizing all n such that $l^*(n) = \lambda(n) + 3$.

16. [*HM15*] Show that Theorem D is not trivially true just because of the binary method; if $l^B(n)$ denotes the length of the addition chain for n produced by the binary S-and-X method, $l^B(n)/\lambda(n)$ does not approach a limit as $n \to \infty$.

17. [*M25*] Explain how to find the intervals $J_1, \ldots, J_h$ that are required in the proof of Lemma P.

18. [*HM24*] Let β be a positive constant. Show that there is a constant $\alpha < 2$ such that

$$\sum \binom{m+s}{t+v}\binom{t+v}{v}\beta^{2v}\binom{(m+s)^2}{t} < \alpha^m$$

for all large m, where the sum is over all s, t, v satisfying (30).

19. [*M23*] A "multiset" is like a set, but it may contain identical elements repeated a finite number of times. If A and B are multisets, we define new multisets $A \uplus B$, $A \cup B$, and $A \cap B$ in the following way: An element occurring exactly a times in A and b times in B occurs exactly $a+b$ times in $A \uplus B$, exactly $\max(a,b)$ times in $A \cup B$, and exactly $\min(a,b)$ times in $A \cap B$. (A "set" is a multiset that contains no elements more than once; if A and B are sets, so are $A \cup B$ and $A \cap B$, and the definitions given in this exercise agree with the customary definitions of set union and intersection.)

a) The prime factorization of an integer $n > 0$ is a multiset N whose elements are primes, where $\prod_{p \in N} = n$. The fact that every positive integer can be uniquely factored into primes gives us a one-to-one correspondence between the positive integers and the finite multisets of prime numbers; for example, if $n = 2^2 \cdot 3^3 \cdot 17$, the corresponding multiset is $N = \{2, 2, 3, 3, 3, 17\}$. If M and N are the multisets corresponding respectively to m and n, what multisets correspond to $\gcd(m,n)$, $\operatorname{lcm}(m,n)$, and mn?

b) Every monic polynomial $f(z)$ over the complex numbers corresponds in a natural way to the multiset F of its "roots"; we have $f(z) = \prod_{\zeta \in F}(z - \zeta)$. If $f(z)$ and $g(z)$ are the polynomials corresponding to the finite multisets F and G of complex numbers, what polynomials correspond to $F \uplus G$, $F \cup G$, and $F \cap G$?

c) Find as many interesting identities as you can that hold between multisets, with respect to the three operations $\uplus$, $\cup$, $\cap$.

20. [*M20*] What are the sequences S_i and M_{ij} ($0 \le i \le r$, $0 \le j \le t$) arising in Hansen's structural decomposition of star chains (a) of Type 3? (b) of Type 5? (The six "types" are defined in the proof of Theorem B.)

▶ **21.** [*M25*] (W. Hansen.) Let q be any positive integer. Find a value of n such that $l(n) \le l^*(n) - q$.

22. [*M20*] Prove that the addition chain constructed in the proof of Theorem F is an l^0-chain.

23. [*M20*] Prove Brauer's inequality (50).

▶ **24.** [*M22*] Generalize the proof of Theorem G to show that $l^0((B^n - 1)/(B-1)) \le (n-1)\,l^0(B) + l^0(n)$, for any integer $B > 1$; and prove that $l(2^{mn} - 1) \le l(2^m - 1) + mn - m + l^0(n)$.

25. [*20*] Let y be a fraction, $0 < y < 1$, expressed in the binary number system as $y = (.d_1 \ldots d_k)_2$. Design an algorithm to compute x^y using the operations of multiplication and square-root extraction.

▶ **26.** [*M24*] Design an efficient algorithm that computes the nth Fibonacci number F_n, modulo m, given large integers n and m.

▶ **27.** [*24*] (E. G. Straus.) Find a way to compute a general *monomial* $x_1^{n_1}x_2^{n_2}\dots x_m^{n_m}$ in at most $2\lambda(\max(n_1,n_2,\dots,n_m))+2^m-m-1$ multiplications.

28. [*M33*] (A. Schönhage.) The object of this exercise is to give a fairly short proof that $l(n)\geq\lambda(n)+\lg\nu(n)-O(\log\log(\nu(n)+1))$. (a) When $x=(x_k\dots x_0.x_{-1}\dots)_2$ and $y=(y_k\dots y_0.y_{-1}\dots)_2$ are real numbers written in binary notation, let us write $x\subseteq y$ if $x_j\leq y_j$ for all j. Give a simple rule for constructing the smallest number z with the property that $x'\subseteq x$ and $y'\subseteq y$ implies $x'+y'\subseteq z$. Denoting this number by $x\nabla y$, prove that $\nu(x\nabla y)\leq\nu(x)+\nu(y)$. (b) Given any addition chain (11) with $r=l(n)$, let the sequence d_0, d_1, ..., d_r be defined as in (35), and define the sequence A_0, A_1, ..., A_r by the following rules: $A_0=1$; if $a_i=2a_{i-1}$ then $A_i=2A_{i-1}$; otherwise if $a_i=a_j+a_k$ for some $0\leq k\leq j<i$, then $A_i=A_{i-1}\nabla(A_{i-1}/2^{d_j-d_k})$. Prove that this sequence "covers" the given chain, in the sense that $a_i\subseteq A_i$ for $0\leq i\leq r$. (c) Let δ be a positive integer (to be selected later). Call the nondoubling step $a_i=a_j+a_k$ a "baby step" if $d_j-d_k\geq\delta$, otherwise call it a "close step." Let $B_0=1$; $B_i=2B_{i-1}$ if $a_i=2a_{i-1}$; $B_i=B_{i-1}\nabla(B_{i-1}/2^{d_j-d_k})$ if $a_i=a_j+a_k$ is a baby step; and $B_i=\rho(2B_{i-1})$ otherwise, where $\rho(x)$ is the least number y such that $x/2^e\subseteq y$ for $0\leq e\leq\delta$. Show that $A_i\subseteq B_i$ and $\nu(B_i)\leq(1+\delta c_i)2^{b_i}$ for $0\leq i\leq r$, where b_i and c_i respectively denote the number of baby steps and close steps $\leq i$. [*Hint:* Show that the 1's in B_i appear in consecutive blocks of size $\geq 1+\delta c_i$.] (d) We now have $l(n)=r=b_r+c_r+d_r$ and $\nu(n)\leq\nu(B_r)\leq(1+\delta c_r)2^{b_r}$. Explain how to choose δ in order to obtain the inequality stated at the beginning of this exercise. [*Hint:* See (16), and note that $n\leq 2^r\alpha^{b_r}$ for some $\alpha<1$ depending on δ.]

29. [*M49*] Is $\nu(n)\leq 2^{l(n)-\lambda(n)}$ for all positive integers n? (If so, we have the lower bound $l(2^n-1)\geq n-1+\lceil\lg n\rceil$; cf. (17) and (49).)

30. [*20*] An *addition-subtraction chain* has the rule $a_i=a_j\pm a_k$ in place of (2); the imaginary computer described in the text has a new operation code, SUB. (This corresponds in practice to evaluating x^n using both multiplications and divisions.) Find an addition-subtraction chain, for some n, that has fewer than $l(n)$ steps.

31. [*M46*] (D. H. Lehmer.) Explore the problem of minimizing $\epsilon q+(r-q)$ in an addition chain (1), where q is the number of "simple" steps in which $a_i=a_{i-1}+1$, given a small positive "weight" ϵ. (This problem comes closer to reality for many calculations of x^n, if multiplication by x is simpler than a general multiplication; cf. Section 4.6.2.)

32. [*M30*] (A. C. Yao.) Let $l(n_1,\dots,n_m)$ be the length of the shortest addition chain that contains m given numbers $n_1<\cdots<n_m$. Prove that $l(n_1,\dots,n_m)\leq\lambda(n_m)+m\lambda(n_m)/\lambda\lambda(n_m)+O(\lambda(n_m)\lambda\lambda\lambda(n_m)/\lambda\lambda(n_m)^2)$, thereby generalizing (25).

33. [*M47*] What is the asymptotic value of $l(1,4,9,\dots,m^2)-m$, as $m\to\infty$, in the notation of exercise 32?

34. [*M50*] Is $l(2^n-1)\leq n-1+l(n)$ for all positive integers n? Does equality always hold? Does $l(n)=l^0(n)$?

35. [*M30*] (A. C. Yao, F. F. Yao, R. L. Graham.) Associate the "cost" a_ja_k with each step $a_i=a_j+a_k$ of an addition chain (1). Show that the left-to-right binary method yields a chain of minimum total cost, for all positive integers n.

36. [*15*] How many addition chains of length 9 have (52) as their reduced directed graph?

37. [*M23*] The binary addition chain for $n = 2^{e_0} + \cdots + 2^{e_t}$, when $e_0 > \cdots > e_t \geq 0$, is $1, 2, \ldots, 2^{e_0-e_1}, 2^{e_0-e_1}+1, \ldots, 2^{e_0-e_2}+2^{e_1-e_2}, 2^{e_0-e_2}+2^{e_1-e_2}+1, \ldots, n$. This corresponds to the S-and-X method described at the beginning of this section, while Algorithm A corresponds to the addition chain obtained by sorting the two sequences $(1, 2, 4, \ldots, 2^{e_0})$ and $(2^{e_t-1}+2^{e_t}, 2^{e_t-2}+2^{e_t-1}+2^{e_t}, \ldots, n)$ into increasing order. Prove or disprove: Each of these addition chains is a dual of the other.

38. [*M27*] How many addition chains without useless steps are equivalent to each of the addition chains discussed in exercise 37, when $e_0 > e_1 + 1$?

▶ **39.** [*M25*] (J. Olivos, 1979.) Let $l([n_1, n_2, \ldots, n_m])$ be the minimum number of multiplications needed to evaluate the monomial $x_1^{n_1} x_2^{n_2} \ldots x_m^{n_m}$ in the sense of exercise 27, where each n_i is a positive integer. Prove that this problem is equivalent to the problem of exercise 32, by showing that $l([n_1, n_2, \ldots, n_m]) = l(n_1, n_2, \ldots, n_m) + m - 1$. [*Hint:* Generalize the directed graph construction by considering graphs with more than one source vertex.]

▶ **40.** [*M21*] (J. Olivos.) Generalizing the factor method, prove that

$$l(m_1 n_1 + \cdots + m_t n_t) \leq l(m_1, \ldots, m_t) + l(n_1, \ldots, n_t) + t - 1,$$

where $l(n_1, \ldots, n_t)$ is defined in exercise 32.

41. [*M40*] (P. Downey, B. Leong, R. Sethi.) Let G be a connected graph with n vertices $\{1, \ldots, n\}$ and m edges, where the edges join u_j to v_j for $1 \leq j \leq m$. Prove that $l(1, 2, \ldots, 2^{An}, 2^{Au_1} + 2^{Av_1} + 1, \ldots, 2^{Au_m} + 2^{Av_m} + 1) = An + m + k$ for all sufficiently large A, where k is the minimum number of vertices in a vertex cover for G (i.e., a set containing either u_j or v_j for $1 \leq j \leq m$).

4.6.4. Evaluation of Polynomials

Now that we know efficient ways to evaluate the special polynomial x^n, let us consider the general problem of computing an nth degree polynomial

$$u(x) = u_n x^n + u_{n-1} x^{n-1} + \cdots + u_1 x + u_0, \qquad u_n \neq 0, \tag{1}$$

for given values of x. This problem arises frequently in practice.

In the following discussion we shall concentrate on minimizing the number of operations required to evaluate polynomials by computer, blithely assuming that all arithmetic operations are exact. Polynomials are most commonly evaluated using floating point arithmetic, which is not exact, and different schemes for the evaluation will, in general, give different answers. A numerical analysis of the accuracy achieved depends on the coefficients of the particular polynomial being considered, and is beyond the scope of this book; the reader should be careful to investigate the accuracy of any calculations undertaken with floating point arithmetic. In most cases the methods we shall describe turn out to be reasonably satisfactory from a numerical standpoint, but many bad examples can also be given. [See Webb Miller, *SIAM J. Computing* **4** (1975), 105–107, for a survey of the literature on stability of fast polynomial evaluation, and for

a demonstration that certain kinds of numerical stability cannot be guaranteed for some families of high-speed algorithms.]

A beginning programmer will often evaluate the polynomial (1) in a manner corresponding directly to its conventional textbook form: First $u_n x^n$ is calculated, then $u_{n-1}x^{n-1}$, ..., $u_1 x$, and finally all of the terms of (1) are added together. But even if the efficient methods of Section 4.6.3 are used to evaluate powers of x in this approach, the resulting calculation is needlessly slow unless nearly all of the coefficients u_k are zero. If the coefficients are all nonzero, an obvious alternative would be to evaluate (1) from right to left, computing the values of x^k and $u_k x^k + \cdots + u_0$ for $k = 1, \ldots, n$. Such a process involves $2n-1$ multiplications and n additions, and it might also require further instructions to store and retrieve intermediate results from memory.

Horner's rule. One of the first things a novice programmer is usually taught is an elegant way to rearrange this computation, by evaluating $u(x)$ as follows:

$$u(x) = ((\ldots(u_n x + u_{n-1})x + \cdots)x + u_0. \tag{2}$$

Start with u_n, multiply by x, add u_{n-1}, multiply by x, ..., multiply by x, add u_0. This form of the computation is usually called "Horner's rule"; we have already seen it used in connection with radix conversion in Section 4.4. The entire process requires n multiplications and n additions, minus one addition for each coefficient that is zero. Furthermore, there is no need to store partial results, since each quantity arising during the calculation is used immediately after it has been computed.

W. G. Horner gave this rule early in the nineteenth century [*Philosophical Transactions*, Royal Society of London **109** (1819), 308–335] in connection with a procedure for calculating polynomial roots. The fame of the latter method [see J. L. Coolidge, *Mathematics of Great Amateurs* (Oxford, 1949), Chapter 15] accounts for the fact that Horner's name has been attached to (2); but actually Isaac Newton had made use of the same idea 150 years earlier. In a well-known work entitled *De Analysi per Æquationes Infinitas*, originally written in 1669, Newton wrote

$$\overline{\overline{y-4} \times y : +5} \times y : -12 \times y : +17$$

for the polynomial $y^4 - 4y^3 + 5y^2 - 12y + 17$; this clearly uses the idea of (2), since he often denoted grouping by using horizontal lines and colons instead of parentheses. [See D. T. Whiteside, ed., *The Mathematical Papers of Isaac Newton* **2** (Cambridge Univ. Press, 1968), 222.]

Several generalizations of Horner's rule have been suggested. Let us first consider evaluating $u(z)$ when z is a complex number, while the coefficients u_k are real. In particular, when $z = e^{i\theta} = \cos\theta + i\sin\theta$, the polynomial $u(z)$ is essentially two Fourier series,

$$(u_0 + u_1\cos\theta + \cdots + u_n\cos n\theta) \;+\; i(u_1\sin\theta + \cdots + u_n\sin n\theta).$$

Complex addition and multiplication can obviously be reduced to a sequence of ordinary operations on real numbers:

real + complex	requires	1 addition
complex + complex	requires	2 additions
real × complex	requires	2 multiplications
complex × complex	requires	4 multiplications, 2 additions
	or	3 multiplications, 5 additions

(See exercise 41. Subtraction is here considered as if it were equivalent to addition.) Therefore Horner's rule (2) uses either $4n - 2$ multiplications and $3n - 2$ additions or $3n - 1$ multiplications and $6n - 5$ additions to evaluate $u(z)$ when $z = x + iy$ is complex. Actually $2n - 4$ of these additions can be saved, since we are multiplying by the same number z each time. An alternative procedure for evaluating $u(x + iy)$ is to let

$$\begin{aligned} &a_1 = u_n, \qquad b_1 = u_{n-1}, \qquad r = x + x, \qquad s = x^2 + y^2; \\ &a_j = b_{j-1} + ra_{j-1}, \qquad b_j = u_{n-j} - sa_{j-1}, \qquad 1 < j \le n. \end{aligned} \tag{3}$$

Then it is easy to prove by induction that $u(z) = za_n + b_n$. This scheme [*BIT* **5** (1965), 142; cf. also G. Goertzel, *AMM* **65** (1958), 34–35] requires only $2n + 2$ multiplications and $2n + 1$ additions, so it is an improvement over Horner's rule when $n \ge 3$. In the case of Fourier series, when $z = e^{i\theta}$, we have $s = 1$, so the number of multiplications drops to $n + 1$. The moral of this story is that a good programmer does not make indiscriminate use of the built-in "complex arithmetic" features of high-level programming languages.

Consider the process of dividing the polynomial $u(x)$ by $x - x_0$, using Algorithm 4.6.1D to obtain $u(x) = (x - x_0)q(x) + r(x)$; here $\deg(r) < 1$, so $r(x)$ is a constant independent of x, and $u(x_0) = 0 \cdot q(x_0) + r = r$. An examination of this division process reveals that the computation is essentially the same as Horner's rule for evaluating $u(x_0)$. Similarly, if we divide $u(z)$ by the polynomial $(z - z_0)(z - \bar{z}_0) = z^2 - 2x_0z + x_0^2 + y_0^2$, the resulting computation turns out to be equivalent to (3); we obtain $u(z) = (z - z_0)(z - \bar{z}_0)q(z) + a_nz + b_n$, hence $u(z_0) = a_nz_0 + b_n$.

In general, if we divide $u(x)$ by $f(x)$ to obtain $u(x) = f(x)q(x) + r(x)$, and if $f(x_0) = 0$, we have $u(x_0) = r(x_0)$; this observation leads to further generalizations of Horner's rule. For example, we may let $f(x) = x^2 - x_0^2$; this yields the "second-order" Horner's rule

$$\begin{aligned} u(x) = {} & \big(\ldots(u_{2\lfloor n/2\rfloor}x^2 + u_{2\lfloor n/2\rfloor-2})x^2 + \cdots\big)x^2 + u_0 \\ & + \big((\ldots(u_{2\lceil n/2\rceil-1}x^2 + u_{2\lceil n/2\rceil-3})x^2 + \cdots)x^2 + u_1\big)x. \end{aligned} \tag{4}$$

The second-order rule uses $n+1$ multiplications and n additions (see exercise 5); so it is no improvement over Horner's rule from this standpoint. But there are at least two circumstances in which (4) is useful: If we want to evaluate both $u(x)$

and $u(-x)$, this approach yields $u(-x)$ with just one more addition operation; two values can be obtained almost as cheaply as one. Moreover, if we have a computer that allows parallel computations, the two lines of (4) may be evaluated independently, so we save about half the running time.

When our computer allows parallel computation on k arithmetic units at once, a "kth-order" Horner's rule (obtained in a similar manner from $f(x) = x^k - x_0^k$) may be used. Another attractive method for parallel computation has been suggested by G. Estrin [*Proc. Western Joint Computing Conf.* **17** (1960), 33–40]; for $n = 7$, Estrin's method is:

Processor 1	Processor 2	Processor 3	Processor 4	Processor 5
$a_1 = u_7x + u_6$	$b_1 = u_5x + u_4$	$c_1 = u_3x + u_2$	$d_1 = u_1x + u_0$	x^2
$a_2 = a_1x^2 + b_1$		$c_2 = c_1x^2 + d_1$		x^4
$a_3 = a_2x^4 + c_2$				

Here $a_3 = u(x)$. However, an interesting analysis by W. S. Dorn [*IBM J. Res. and Devel.* **6** (1962), 239–245] shows that these methods might not actually be an improvement over the second-order rule, if each arithmetic unit must access a memory that communicates with only one processor at a time.

Tabulating polynomial values. If we wish to evaluate an nth degree polynomial at many points in an arithmetic progression (i.e., if we want to calculate $u(x_0)$, $u(x_0 + h)$, $u(x_0 + 2h)$, ...), the process can be reduced to addition only, after the first few steps. For if we start with any sequence of numbers $(\alpha_0, \alpha_1, \ldots, \alpha_n)$ and apply the transformation

$$\alpha_0 \leftarrow \alpha_0 + \alpha_1, \quad \alpha_1 \leftarrow \alpha_1 + \alpha_2, \quad \ldots, \quad \alpha_{n-1} \leftarrow \alpha_{n-1} + \alpha_n, \tag{5}$$

we find that k applications of (5) yields

$$\alpha_j^{(k)} = \binom{k}{0}\beta_j + \binom{k}{1}\beta_{j+1} + \binom{k}{2}\beta_{j+2} + \cdots, \qquad 0 \le j \le n,$$

where β_j denotes the initial value of α_j and $\beta_j = 0$ for $j > n$. In particular,

$$\alpha_0^{(k)} = \binom{k}{0}\beta_0 + \binom{k}{1}\beta_1 + \cdots + \binom{k}{n}\beta_n \tag{6}$$

is a polynomial of degree n in k. By properly choosing the β's, as shown in exercise 7, we can arrange things so that $\alpha_0^{(k)}$ is the desired value $u(x_0 + kh)$, for all k. In other words, each execution of the n additions in (5) will produce the next value of the given polynomial.

Caution: Rounding errors can accumulate after many repetitions of (5), and an error in α_j produces a corresponding error in the coefficients of $x^0, \ldots, x^j$ in the polynomial being computed. Therefore the values of the α's should be "refreshed" after a large number of iterations.

Derivatives and changes of variable. Sometimes we want to find the coefficients of $u(x+x_0)$, given a constant x_0 and the coefficients of $u(x)$. For example, if $u(x) = 3x^2 + 2x - 1$, then $u(x-2) = 3x^2 - 10x + 7$. This is analogous to a radix conversion problem, converting from base x to base $x+2$.

By Taylor's theorem, the desired coefficients are given by the derivatives of $u(x)$ at $x = x_0$, namely

$$u(x+x_0) = u(x_0) + u'(x_0)x + (u''(x_0)/2!)x^2 + \cdots + (u^{(n)}(x_0)/n!)x^n, \qquad (7)$$

so the problem is equivalent to evaluating $u(x)$ and all its derivatives.

If we write $u(x) = q(x)(x - x_0) + r$, then $u(x+x_0) = q(x+x_0)x + r$; so r is the constant coefficient of $u(x+x_0)$, and the problem reduces to finding the coefficients of $q(x+x_0)$, where $q(x)$ is a known polynomial of degree $n-1$. Thus the following algorithm is indicated:

H1. Set $v_j \leftarrow u_j$ for $0 \le j \le n$.

H2. For $k = 0, 1, \ldots, n-1$ (in this order), set $v_j \leftarrow v_j + x_0 v_{j+1}$ for $j = n-1, \ldots, k+1, k$ (in this order). ∎

At the conclusion of step H2 we have $u(x+x_0) = v_n x^n + \cdots + v_1 x + v_0$. This procedure was a principal part of Horner's root-finding method, and when $k = 0$ it is exactly rule (2) for evaluating $u(x_0)$.

Horner's method requires $(n^2+n)/2$ multiplications and $(n^2+n)/2$ additions; but notice that if $x_0 = 1$ we avoid all of the multiplications. Fortunately we can reduce the general problem to the case $x_0 = 1$ by introducing comparatively few multiplications and divisions:

S1. Compute and store the values $x_0^2, \ldots, x_0^n$.

S2. Set $v_j \leftarrow u_j x_0^j$ for $0 \le j \le n$. (Now $v(x) = u(x_0 x)$.)

S3. Perform step H2 but with $x_0 = 1$. (Now $v(x) = u\big(x_0(x+1)\big) = u(x_0 x + x_0)$.)

S4. Set $v_j \leftarrow v_j / x_0^j$ for $0 < j \le n$. (Now $v(x) = u(x+x_0)$ as desired.) ∎

This idea, due to M. Shaw and J. F. Traub [*JACM* **21** (1974), 161–167], has the same number of additions and the same numerical stability as Horner's method, but it needs only $2n-1$ multiplications and $n-1$ divisions. About $\frac{1}{2}n$ of these multiplications can, in turn, be avoided (see exercise 6).

If we want only the first few or the last few derivatives, Shaw and Traub have observed that there are further ways to save time. For example, if we just want to evaluate $u(x)$ and $u'(x)$, we can do the job with $2n-1$ additions and about $n + \sqrt{2n}$ multiplications/divisions as follows:

D1. Compute and store the values $x^2, x^3, \ldots, x^t, x^{2t}$, where $t = \lceil \sqrt{n/2} \rceil$.

D2. Set $v_j \leftarrow u_j x^{f(j)}$ for $0 \le j \le n$, where $f(j) = t - 1 - \big((n-1-j) \bmod 2t\big)$ for $0 \le j < n$, and $f(n) = t$.

D3. Set $v_j \leftarrow v_j + v_{j+1} x^{g(j)}$ for $j = n-1, \ldots, 1, 0$; here $g(j) = 2t$ when $n-j$ is a multiple of $2t$, otherwise $g(j) = 0$ and the multiplication by $x^{g(j)}$ need not be done.

D4. Set $v_j \leftarrow v_j + v_{j+1} x^{g(j)}$ for $j = n-1, \ldots, 2, 1$. Now $v_0 / x^{f(0)} = u(x)$ and $v_1 / x^{f(1)} = u'(x)$. ∎

Adaptation of coefficients. Let us now return to our original problem of evaluating a given polynomial $u(x)$ as rapidly as possible, for "random" values of x. The importance of this problem is due partly to the fact that standard functions such as $\sin x$, $\cos x$, e^x, etc., are usually computed by subroutines that rely on the evaluation of certain polynomials; such polynomials are evaluated so often, it is desirable to find the fastest possible way to do the computation.

Arbitrary polynomials of degree five and higher can be evaluated with fewer operations than Horner's rule requires, if we first "adapt" or "precondition" the coefficients $u_0, u_1, \ldots, u_n$. This adaptation process might involve a lot of work, as explained below; but the preliminary calculation is not wasted, since it must be done only once while the polynomial will be evaluated many times. For examples of "adapted" polynomials for standard functions, see V. Ia. Pan, *USSR Computational Math. and Math. Physics* **2** (1963), 137–146.

The simplest case for which adaptation of coefficients is helpful occurs for a fourth degree polynomial:

$$u(x) = u_4x^4 + u_3x^3 + u_2x^2 + u_1x + u_0, \qquad u_4 \neq 0. \tag{8}$$

This equation can be rewritten in a form originally suggested by T. S. Motzkin,

$$y = (x + \alpha_0)x + \alpha_1, \qquad u(x) = \big((y + x + \alpha_2)y + \alpha_3\big)\alpha_4, \tag{9}$$

for suitably "adapted" coefficients α_0, α_1, α_2, α_3, α_4. The computation in (9) involves three multiplications, five additions, and (on a one-accumulator machine like MIX) one instruction to store the partial result y into temporary storage. By comparison with Horner's rule, we have traded a multiplication for an addition and a possible storage command. Even this comparatively small savings is worthwhile if the polynomial is to be evaluated often. (Of course, if the time for multiplication is comparable to the time for addition, (9) gives no improvement; we will see that a general fourth-degree polynomial always requires at least eight arithmetic operations for its evaluation.)

By equating coefficients in (8) and (9), we obtain formulas for computing the α_j's in terms of the u_k's:

$$\begin{aligned} &\alpha_0 = \tfrac{1}{2}(u_3/u_4 - 1), \qquad \beta = u_2/u_4 - \alpha_0(\alpha_0 + 1), \qquad \alpha_1 = u_1/u_4 - \alpha_0\beta, \\ &\alpha_2 = \beta - 2\alpha_1, \qquad \alpha_3 = u_0/u_4 - \alpha_1(\alpha_1 + \alpha_2), \qquad \alpha_4 = u_4. \end{aligned} \tag{10}$$

A similar scheme, which evaluates a fourth-degree polynomial in the same number of steps as (9), appears in exercise 18; this alternative method will give greater numerical accuracy than (9) in certain cases, although it yields poorer accuracy in others.

Polynomials that arise in practice often have a rather small leading coefficient, so that the division by u_4 in (10) leads to instability. In such a case it is usually preferable to replace x by $|u_4|^{1/4}x$ as the first step, reducing (8) to a polynomial whose leading coefficient is ± 1. A similar transformation applies to

polynomials of higher degrees. This idea is due to C. T. Fike [*CACM* **10** (1967), 175–178], who has presented several interesting examples.

Any polynomial of the fifth degree may be evaluated using four multiplications, six additions, and one storing, by using the rule $u(x) = U(x)x + u_0$, where $U(x) = u_5x^4 + u_4x^3 + u_3x^2 + u_2x + u_1$ is evaluated as in (9). Alternatively, we can do the evaluation with four multiplications, five additions, and three storings, if the calculations take the form

$$y = (x + \alpha_0)^2, \qquad u(x) = \big(((y + \alpha_1)y + \alpha_2)(x + \alpha_3) + \alpha_4\big)\alpha_5. \tag{11}$$

The determination of the α's this time requires the solution of a cubic equation (see exercise 19).

On many computers the number of "storing" operations required by (11) is less than 3; for example, we may be able to compute $(x + \alpha_0)^2$ without storing $x + \alpha_0$. In fact, many computers have more than one arithmetic register for floating point calculations, so we can avoid storing altogether. Because of the wide variety of features available for arithmetic on different computers, we shall henceforth in this section count only the arithmetic operations, not the operations of storing and loading an accumulator. The computation schemes can usually be adapted to any particular computer in a straightforward manner, so that very few of these auxiliary operations are necessary; on the other hand, it must be remembered that this extra overhead might well overshadow the fact that we are saving a multiplication or two, especially if the machine code is being produced by a compiler that does not "optimize."

A polynomial $u(x) = u_6x^6 + \cdots + u_1x + u_0$ of degree six can always be evaluated using four multiplications and seven additions, with the scheme

$$\begin{aligned} z &= (x + \alpha_0)x + \alpha_1, \qquad w = (x + \alpha_2)z + \alpha_3, \\ u(x) &= \big((w + z + \alpha_4)w + \alpha_5\big)\alpha_6. \end{aligned} \tag{12}$$

[See D. E. Knuth, *CACM* **5** (1962), 595–599.] This saves two of the six multiplications required by Horner's rule. Here again we must solve a cubic equation: Since $\alpha_6 = u_6$, we may assume that $u_6 = 1$. Under this assumption, let $\beta_1 = \frac{1}{2}(u_5 - 1)$, $\beta_2 = u_4 - \beta_1(\beta_1 + 1)$, $\beta_3 = u_3 - \beta_1\beta_2$, $\beta_4 = \beta_1 - \beta_2$, $\beta_5 = u_2 - \beta_1\beta_3$. Let β_6 be a real root of the cubic equation

$$2y^3 + (2\beta_4 - \beta_2 + 1)y^2 + (2\beta_5 - \beta_2\beta_4 - \beta_3)y + (u_1 - \beta_2\beta_5) = 0. \tag{13}$$

(This equation always has a real root, since the polynomial on the left approaches $+\infty$ for large positive y, and it approaches $-\infty$ for large negative y; it must assume the value zero somewhere in between.) Now if we define

$$\beta_7 = \beta_6^2 + \beta_4\beta_6 + \beta_5, \qquad \beta_8 = \beta_3 - \beta_6 - \beta_7,$$

we have finally

$$\begin{aligned} &\alpha_0 = \beta_2 - 2\beta_6, \qquad \alpha_2 = \beta_1 - \alpha_0, \qquad \alpha_1 = \beta_6 - \alpha_0\alpha_2, \\ &\alpha_3 = \beta_7 - \alpha_1\alpha_2, \qquad \alpha_4 = \beta_8 - \beta_7 - \alpha_1, \qquad \alpha_5 = u_0 - \beta_7\beta_8. \end{aligned} \tag{14}$$

We can illustrate this procedure with a contrived example: Suppose that we want to evaluate $x^6+13x^5+49x^4+33x^3-61x^2-37x+3$. We obtain $\alpha_6=1$, $\beta_1=6$, $\beta_2=7$, $\beta_3=-9$, $\beta_4=-1$, $\beta_5=-7$, and so we meet with the cubic equation

$$2y^3-8y^2+2y+12=0. \tag{15}$$

This equation has $\beta_6=2$ as a root, and we continue to find $\beta_7=-5$, $\beta_8=-6$, $\alpha_0=3$, $\alpha_2=3$, $\alpha_1=-7$, $\alpha_3=16$, $\alpha_4=6$, $\alpha_5=-27$. The resulting scheme is therefore

$$z=(x+3)x-7, \qquad w=(x+3)z+16, \qquad u(x)=(w+z+6)w-27.$$

By sheer coincidence the quantity $x+3$ appears twice here, so we have found a method that uses three multiplications and six additions.

Another method for handling sixth-degree equations has been suggested by V. Ĭa. Pan [*Problemy Kibernetiki* **5** (1961), 17–29]. His method requires one more addition operation, but it involves only rational operations in the preliminary steps; no cubic equation needs to be solved. We may proceed as follows:

$$\begin{aligned} z&=(x+\alpha_0)x+\alpha_1, \qquad w=z+x+\alpha_2,\\ u(x)&=\big(((z-x+\alpha_3)w+\alpha_4)z+\alpha_5\big)\alpha_6. \end{aligned} \tag{16}$$

To determine the α's, we divide the polynomial once again by $u_6=\alpha_6$ so that $u(x)$ becomes monic. It can then be verified that $\alpha_0=u_5/3$ and that

$$\alpha_1=(u_1-\alpha_0u_2+\alpha_0^2u_3-\alpha_0^3u_4+2\alpha_0^5)/(u_3-2\alpha_0u_4+5\alpha_0^3). \tag{17}$$

Note that Pan's method requires that the denominator in (17) does not vanish. In other words, (16) can be used only when

$$27u_3u_6^2-18u_6u_5u_4+5u_5^3\neq 0; \tag{18}$$

in fact, this quantity should not be so small that α_1 becomes too large. Once α_1 has been determined, the remaining α's may be determined from the equations

$$\begin{gathered} \beta_1=2\alpha_0, \qquad \beta_2=u_4-\alpha_0\beta_1-\alpha_1,\\ \beta_3=u_3-\alpha_0\beta_2-\alpha_1\beta_1, \qquad \beta_4=u_2-\alpha_0\beta_3-\alpha_1\beta_2,\\ \alpha_3=\tfrac12\big(\beta_3-(\alpha_0-1)\beta_2+(\alpha_0-1)(\alpha_0^2-1)\big)-\alpha_1,\\ \alpha_2=\beta_2-(\alpha_0^2-1)-\alpha_3-2\alpha_1,\\ \alpha_4=\beta_4-(\alpha_2+\alpha_1)(\alpha_3+\alpha_1),\\ \alpha_5=u_0-\alpha_1\beta_4. \end{gathered} \tag{19}$$

We have discussed the cases of degree $n=4$, 5, 6 in detail because the smaller values of n arise most frequently in applications. Let us now consider a general evaluation scheme for nth degree polynomials, a method that involves at most $\lfloor n/2\rfloor+2$ multiplications and n additions.

Theorem E. *Every nth degree polynomial* (1) *with real coefficients,* $n \geq 3$, *can be evaluated by the scheme*

$$y = x + c, \qquad w = y^2;$$
$$z = (u_n y + \alpha_0)y + \beta_0 \quad (n \text{ even}), \qquad z = u_n y + \beta_0 \quad (n \text{ odd});$$
$$u(x) = (\ldots((z(w-\alpha_1)+\beta_1)(w-\alpha_2)+\beta_2)\ldots)(w-\alpha_m)+\beta_m; \tag{20}$$

for suitable real parameters c, α_k *and* β_k, *where* $m = \lfloor n/2 \rfloor - 1$. *In fact, it is possible to select these parameters so that* $\beta_m = 0$.

Proof. Let us first examine the circumstances under which the α's and β's can be chosen in (20), if c is fixed. Let

$$p(x) = u(x-c) = a_n x^n + a_{n-1}x^{n-1} + \cdots + a_1 x + a_0. \tag{21}$$

We want to show that $p(x)$ has the form $p_1(x)(x^2-\alpha_m)+\beta_m$ for some polynomial $p_1(x)$ and some constants α_m, β_m. If we divide $p(x)$ by $x^2-\alpha_m$, we can see that the remainder β_m is a constant only if the auxiliary polynomial

$$q(x) = a_{2m+1}x^m + a_{2m-1}x^{m-1} + \cdots + a_1, \tag{22}$$

formed from every odd-numbered coefficient of $p(x)$, is a multiple of $x - \alpha_m$. Conversely, if $q(x)$ has $x - \alpha_m$ as a factor, then $p(x) = p_1(x)(x^2 - \alpha_m) + \beta_m$, for some constant β_m that may be determined by division.

Similarly, we want $p_1(x)$ to have the form $p_2(x)(x^2 - \alpha_{m-1}) + \beta_{m-1}$, and this is the same as saying that $q(x)/(x - \alpha_m)$ is a multiple of $x - \alpha_{m-1}$; for if $q_1(x)$ is the polynomial corresponding to $p_1(x)$ as $q(x)$ corresponds to $p(x)$, we have $q_1(x) = q(x)/(x - \alpha_m)$. Continuing in the same way, we find that the parameters $\alpha_1, \beta_1, \ldots, \alpha_m, \beta_m$ will exist if and only if

$$q(x) = a_{2m+1}(x-\alpha_1)\ldots(x-\alpha_m). \tag{23}$$

In other words, either $q(x)$ is identically zero (and this can happen only when n is even), or else $q(x)$ is an mth degree polynomial having all real roots.

Now we have a surprising fact discovered by J. Eve [*Numer. Math.* **6** (1964), 17–21]: *If* $p(x)$ *has at least* $n-1$ *complex roots whose real parts are all nonnegative, or all nonpositive, then the corresponding polynomial* $q(x)$ *is identically zero or has all real roots.* (See exercise 23.) Since $u(x) = 0$ if and only if $p(x+c) = 0$, we need merely choose the parameter c large enough that at least $n-1$ of the roots of $u(x) = 0$ have a real part $\geq -c$, and (20) will apply whenever $a_{n-1} = u_{n-1} - ncu_n \neq 0$.

We can also determine c so that these conditions are fulfilled and also that $\beta_m = 0$. First the n roots of $u(x) = 0$ are determined. If $a + bi$ is a root having the largest or the smallest real part, and if $b \neq 0$, let $c = -a$ and $\alpha_m = -b^2$; then $x^2 - \alpha_m$ is a factor of $u(x-c)$. If the root with smallest or

largest real part is real, but the root with *second* smallest (or second largest) real part is nonreal, the same transformation applies. If the two roots with smallest (or largest) real parts are both real, they can be expressed in the form $a - b$ and $a + b$, respectively; let $c = -a$ and $\alpha_m = b^2$. Again $x^2 - \alpha_m$ is a factor of $u(x - c)$. (Still other values of c are often possible; see exercise 24.) The coefficient a_{n-1} will be nonzero for at least one of these alternatives, unless $q(x)$ is identically zero. ∎

Note that this method of proof usually gives at least two values of c, and we also have the chance to permute $\alpha_1, \ldots, \alpha_{m-1}$ in $(m-1)!$ ways. Some of these alternatives may give more desirable numerical accuracy than others.

***Polynomial chains.** Now let us consider questions of optimality. What are the *best possible* schemes for evaluating polynomials of various degrees, in terms of the minimum possible number of arithmetic operations? This question was first analyzed by A. M. Ostrowski in the case that no preliminary adaptation of coefficients is allowed [*Studies in Mathematics and Mechanics presented to R. von Mises* (New York: Academic Press, 1954), 40–48], and by T. S. Motzkin in the case of adapted coefficients [cf. *Bull. Amer. Math. Soc.* **61** (955), 163].

In order to investigate this question, we can extend Section 4.6.3's concept of addition chains to the notion of *polynomial chains.* A polynomial chain is a sequence of the form

$$x = \lambda_0, \quad \lambda_1, \quad \ldots, \quad \lambda_r = u(x), \tag{24}$$

where $u(x)$ is some polynomial in x, and for $1 \le i \le r$

$$\begin{aligned} &\text{either } \lambda_i = (\pm\lambda_j) \circ \lambda_k, && 0 \le j, k < i, \\ &\text{or } \lambda_i = \alpha_j \circ \lambda_k, && 0 \le k < i. \end{aligned} \tag{25}$$

Here "$\circ$" denotes any of the three operations "$+$", "$-$", or "$\times$", and α_j denotes a so-called parameter. Steps of the first kind are called *chain steps*, and steps of the second kind are called *parameter steps.* We shall assume that a different parameter α_j is used in each parameter step; if there are s parameter steps, they should involve $\alpha_1, \alpha_2, \ldots, \alpha_s$ in this order.

It follows that the polynomial $u(x)$ at the end of the chain has the form

$$u(x) = q_n x^n + \cdots + q_1 x + q_0, \tag{26}$$

where $q_n, \ldots, q_1, q_0$ are polynomials in $\alpha_1, \alpha_2, \ldots, \alpha_s$ with integer coefficients. We shall interpret the parameters $\alpha_1, \alpha_2, \ldots, \alpha_s$ as real numbers, and we shall therefore restrict ourselves to considering the evaluation of polynomials with real coefficients. The *result set* R of a polynomial chain is defined to be the set of all vectors $(q_n, \ldots, q_1, q_0)$ of real numbers that occur as $\alpha_1, \alpha_2, \ldots, \alpha_s$ independently assume all possible real values.

If for every choice of $t + 1$ distinct integers $j_0, \ldots, j_t \in \{0, 1, \ldots, n\}$ there is a nonzero multivariate polynomial $f_{j_0 \ldots j_t}$ with integer coefficients such that

$f_{j_0 \ldots j_t}(q_{j_0}, \ldots, q_{j_t}) = 0$ for all $(q_n, \ldots, q_1, q_0)$ in R, let us say that the result set R has at most t *degrees of freedom*, and that the chain (24) has at most t degrees of freedom. We also say that the chain (24) *computes* a given polynomial $u(x) = u_n x^n + \cdots + u_1 x + u_0$ if $(u_n, \ldots, u_1, u_0)$ is in R. It follows that a polynomial chain with at most n degrees of freedom cannot compute all nth degree polynomials (see exercise 27).

As an example of a polynomial chain, consider the following chain corresponding to Theorem E, when n is odd:

$$\begin{aligned} \lambda_0 &= x \\ \lambda_1 &= \alpha_1 + \lambda_0 \\ \lambda_2 &= \lambda_1 \times \lambda_1 \\ \lambda_3 &= \alpha_2 \times \lambda_1 \\ \left.\begin{aligned} \lambda_{1+3i} &= \alpha_{1+2i} + \lambda_{3i} \\ \lambda_{2+3i} &= \alpha_{2+2i} + \lambda_2 \\ \lambda_{3+3i} &= \lambda_{1+3i} \times \lambda_{2+3i} \end{aligned}\right\} & \quad 1 \le i < n/2. \end{aligned} \tag{27}$$

There are $\lfloor n/2 \rfloor + 2$ multiplications and n additions; $\lfloor n/2 \rfloor + 1$ chain steps and $n + 1$ parameter steps. By Theorem E, the result set R includes the set of all $(u_n, \ldots, u_1, u_0)$ with $u_n \neq 0$, so (27) computes all polynomials of degree n. We cannot prove that R has at most n degrees of freedom, since the result set has $n + 1$ independent components.

A polynomial chain with s parameter steps has at most s degrees of freedom. In a sense, this is obvious: we can't compute a function with t degrees of freedom using fewer than t arbitrary parameters. But this intuitive fact is not easy to prove formally; for example, there are continuous functions ("space-filling curves") that map the real line onto a plane, and such functions map a single parameter into two independent parameters. For our purposes, we need to verify that no polynomial functions with integer coefficients can have such a property; a proof appears in exercise 28.

Given this fact, we can proceed to prove the results we seek:

Theorem M (T. S. Motzkin, 1954). *A polynomial chain with $m > 0$ multiplications has at most $2m$ degrees of freedom.*

Proof. Let $\mu_1, \mu_2, \ldots, \mu_m$ be the λ_i's of the chain that are multiplication operations. Then

$$\begin{aligned} \mu_i &= S_{2i-1} \times S_{2i}, \qquad 1 \le i \le m, \\ u(x) &= S_{2m+1}, \end{aligned} \tag{28}$$

where each S_j is a certain sum of μ's, x's, and α's. Write $S_j = T_j + \beta_j$, where T_j is a sum of μ's and x's while β_j is a sum of α's.

Now $u(x)$ is expressible as a polynomial in $x, \beta_1, \ldots, \beta_{2m+1}$ with integer coefficients. Since the β's are expressible as linear functions of $\alpha_1, \ldots, \alpha_s$, the set of values represented by all real values of $\beta_1, \ldots, \beta_{2m+1}$ contains the result set of the chain. Therefore there are at most $2m + 1$ degrees of freedom; this can be improved to $2m$ when $m > 0$, as shown in exercise 30. ∎

An example of the construction in the proof of Theorem M appears in exercise 25. A similar result can be proved for additions:

Theorem A (É. G. Belaga, 1958). *A polynomial chain containing q additions and subtractions has at most $q+1$ degrees of freedom.*

Proof. [*Problemi Kibernetiki* **5** (1961), 7–15.] Let $\kappa_1, \ldots, \kappa_q$ be the λ_i's of the chain that correspond to addition or subtraction operations. Then

$$\begin{aligned} \kappa_i &= \pm T_{2i-1} \pm T_{2i}, \qquad 1 \le i \le q; \\ u(x) &= T_{2q+1}, \end{aligned} \tag{29}$$

where each T_j is a product of κ's, x's, and α's. We may write $T_j = A_j B_j$, where A_j is a product of α's and B_j is a product of κ's and x's. The following transformation may now be made to the chain, successively for $i = 1, 2, \ldots, q$: Let $\beta_i = A_{2i}/A_{2i-1}$, so that $\kappa_i = A_{2i-1}(\pm B_{2i-1} \pm \beta_i B_{2i})$. Then change κ_i to $\pm B_{2i-1} \pm \beta_i B_{2i}$, and replace each occurrence of κ_i in future formulas T_{2i+1}, $T_{2i+2}, \ldots, T_{2q+1}$ by $A_{2i-1}\kappa_i$. (This replacement may change the values of $A_{2i+1}, A_{2i+2}, \ldots, A_{2q+1}$.)

After the above transformation has been done for all i, let $\beta_{q+1} = A_{2q+1}$; then $u(x)$ can be expressed as a polynomial in $\beta_1, \ldots, \beta_{q+1}$, and x, with integer coefficients. We are almost ready to complete the proof, but we must be careful because the polynomials obtained as $\beta_1, \ldots, \beta_{q+1}$ range over all real values may not include all polynomials representable by the original chain (see exercise 26); it is possible to have $A_{2i-1} = 0$, for some values of the α's, and this makes β_i undefined.

To complete the proof, let us observe that the result set R of the original chain can be written $R = R_1 \cup R_2 \cup \cdots \cup R_q \cup R'$, where R_i is the set of result vectors possible when $A_{2i-1} = 0$, and where R' is the set of result vectors possible when all α's are nonzero. The discussion above proves that R' has at most $q+1$ degrees of freedom. If $A_{2i-1} = 0$, then $T_{2i-1} = 0$, so addition step κ_i may be dropped to obtain another chain computing the result set R_i; by induction we see that each R_i has at most q degrees of freedom. Hence by exercise 29, R has at most $q+1$ degrees of freedom. ∎

Theorem C. *If a polynomial chain* (24) *computes all nth degree polynomials $u(x) = u_n x^n + \cdots + u_0$, for some $n \ge 2$, then it includes at least $\lfloor n/2 \rfloor + 1$ multiplications and at least n addition-subtractions.*

Proof. Let there be m multiplication steps. By Theorem M, the chain has at most $2m$ degrees of freedom, so $2m \ge n+1$. Similarly, by Theorem A there are $\ge n$ addition-subtractions. ∎

This theorem states that no *single* method having fewer than $\lfloor n/2 \rfloor + 1$ multiplications or fewer than n additions can evaluate all possible nth degree polynomials. The result of exercise 29 allows us to strengthen this and say that no finite collection of such polynomial chains will suffice for all polynomials of a given degree. Some special polynomials can, of course, be evaluated more

efficiently; all we have really proved is that polynomials whose coefficients are *algebraically independent*, in the sense that they satisfy no nontrivial polynomial equation, require $\lfloor n/2 \rfloor + 1$ multiplications and n additions. Unfortunately the coefficients we deal with in computers are always rational numbers, so the above theorems don't really apply; in fact, exercise 42 shows that we can always get by with $O(\sqrt{n})$ multiplications (and a possibly huge number of additions). From a practical standpoint, the bounds of Theorem C apply to "almost all" coefficients, and they seem to apply to all reasonable schemes for evaluation. Furthermore it is possible to obtain lower bounds corresponding to those of Theorem C even in the rational case: By strengthening the above proofs, V. Strassen has shown, for example, that the polynomial

$$u(x) = \sum_{0 \le k \le n} 2^{2^{kn^3}} x^k \tag{30}$$

cannot be evaluated by any polynomial chain of length $< n^2/\lg n$ unless the chain has at least $\frac{1}{2}n - 2$ multiplications and $n - 4$ additions [*SIAM J. Computing* **3** (1974), 128–149]. The coefficients of (30) are very large; but it is also possible to find polynomials whose coefficients are just 0's and 1's, such that every polynomial chain computing them involves at least $\sqrt{n}/(4 \lg n)$ chain multiplications, for all sufficiently large n, even when the parameters α_j are allowed to be arbitrary complex numbers. [See R. J. Lipton, *SIAM J. Computing* **7** (1978), 61–69; C.-P. Schnorr, *Lecture Notes in Comp. Sci.* **53** (1977), 135–147.] Jean-Paul Van de Wiele has shown that the evaluation of certain 0–1 polynomials requires a total of at least $cn/\log n$ arithmetic operations, for some $c > 0$ [*Proc. IEEE Symp. Foundations of Comp. Sci.* **19** (1978), 159–165].

A gap still remains between the lower bounds of Theorem C and the actual operation counts known to be achievable, except in the trivial case $n = 2$. Theorem E gives $\lfloor n/2 \rfloor + 2$ multiplications, not $\lfloor n/2 \rfloor + 1$, although it does achieve the minimum number of additions. Our special methods for $n = 4$ and $n = 6$ have the minimum number of multiplications, but one extra addition. When n is odd, it is not difficult to prove that the lower bounds of Theorem C cannot be achieved simultaneously for both multiplications and additions; see exercise 33. For $n = 3$, 5, and 7, it is possible to show that at least $\lfloor n/2 \rfloor + 2$ multiplications are necessary. Exercises 35 and 36 show that the lower bounds of Theorem C cannot both be achieved when $n = 4$ or $n = 6$; thus the methods we have discussed are best possible, for $n < 8$. When n is even, Motzkin proved that $\lfloor n/2 \rfloor + 1$ multiplications are sufficient, but his construction involves an indeterminate number of additions (see exercise 39). An optimal scheme for $n = 8$ was found by V. Ia. Pan, who showed that $n + 1$ additions are necessary and sufficient for this case when there are $\lfloor n/2 \rfloor + 1$ multiplications; he also showed that $\lfloor n/2 \rfloor + 1$ multiplications and $n + 2$ additions will suffice for all even $n \ge 10$. Pan's paper [*Proc. ACM Symp. Theory of Computing* **10** (1978), 162–172] also establishes the exact minimum number of multiplications and additions needed when calculations are done entirely with complex numbers instead of

reals, for all degrees n. Exercise 40 discusses the interesting situation that arises for odd values of $n \geq 9$.

It is clear that the results we have obtained about chains for polynomials in a single variable can be extended without difficulty to multivariate polynomials. For example, if we want to find an optimum scheme for polynomial evaluation *without* adaptation of coefficients, we can regard $u(x)$ as a polynomial in the $n+2$ variables $x, u_n, \ldots, u_1, u_0$; exercise 38 shows that n multiplications and n additions are necessary in this case. Indeed, A. Borodin [*Theory of Machines and Computations*, ed. by Z. Kohavi and A. Paz (New York: Academic Press, 1971), 45–58] has proved that Horner's rule (2) is essentially the *only* way to compute $u(x)$ in $2n$ operations without preconditioning.

With minor variations, the above methods can be extended to chains involving division, i.e., to rational functions as well as polynomials. Curiously, the continued-fraction analog of Horner's rule now turns out to be optimal from an operation-count standpoint, if multiplication and division speeds are equal, even when preconditioning is allowed (see exercise 37).

Sometimes division is helpful during the evaluation of polynomials, even though polynomials are defined only in terms of multiplication and addition; we have seen examples of this in the Shaw–Traub algorithms for polynomial derivatives. Another example is the polynomial

$$x^n + \cdots + x + 1;$$

since this polynomial can be written $(x^{n+1}-1)/(x-1)$, we can evaluate it with $l(n+1)$ multiplications (see Section 4.6.3), two subtractions, and one division, while techniques that avoid division seem to require about three times as many operations (see exercise 43).

Special multivariate polynomials. The *determinant* of an $n \times n$ matrix may be considered to be a polynomial in n^2 variables x_{ij}, $1 \leq i, j \leq n$. If $x_{11} \neq 0$, we have

$$\det \begin{pmatrix} x_{11} & x_{12} & \ldots & x_{1n} \\ x_{21} & x_{22} & \ldots & x_{2n} \\ x_{31} & x_{32} & \ldots & x_{3n} \\ \vdots & \vdots & & \vdots \\ x_{n1} & x_{n2} & \ldots & x_{nn} \end{pmatrix} = x_{11} \det \begin{pmatrix} x_{22}-(x_{21}/x_{11})x_{12} & \ldots & x_{2n}-(x_{21}/x_{11})x_{1n} \\ x_{32}-(x_{31}/x_{11})x_{12} & \ldots & x_{3n}-(x_{31}/x_{11})x_{1n} \\ \vdots & & \vdots \\ x_{n2}-(x_{n1}/x_{11})x_{12} & \ldots & x_{nn}-(x_{n1}/x_{11})x_{1n} \end{pmatrix}. \tag{31}$$

The determinant of an $n \times n$ matrix may therefore be evaluated by evaluating the determinant of an $(n-1) \times (n-1)$ matrix and performing an additional $(n-1)^2+1$ multiplications, $(n-1)^2$ additions, and $n-1$ divisions. Since a 2×2 determinant can be evaluated with two multiplications and one addition, we see that the determinant of almost all matrices (namely those for which no division by zero is needed) can be computed with at most $(2n^3-3n^2+7n-6)/6$ multiplications, $(2n^3-3n^2+n)/6$ additions, and $(n^2-n-2)/2$ divisions.

When zero occurs, the determinant is even easier to compute. For example, if $x_{11} = 0$ but $x_{21} \neq 0$, we have

$$\det\begin{pmatrix} 0 & x_{12} & \dots & x_{1n} \\ x_{21} & x_{22} & \dots & x_{2n} \\ x_{31} & x_{32} & \dots & x_{3n} \\ \vdots & \vdots & & \vdots \\ x_{n1} & x_{n2} & \dots & x_{nn} \end{pmatrix} = -x_{21} \det\begin{pmatrix} x_{12} & \dots & x_{1n} \\ x_{32}-(x_{31}/x_{21})x_{22} & \dots & x_{3n}-(x_{31}/x_{21})x_{2n} \\ \vdots & & \vdots \\ x_{n2}-(x_{n1}/x_{21})x_{22} & \dots & x_{nn}-(x_{n1}/x_{21})x_{2n} \end{pmatrix}. \tag{32}$$

Here the reduction to an $(n-1)\times(n-1)$ determinant saves $n-1$ of the multiplications and $n-1$ of the additions used in (31), and this certainly compensates for the additional bookkeeping required to recognize this case. Therefore any determinant can be evaluated with roughly $\frac{2}{3}n^3$ arithmetic operations (including division); this is remarkable, since it is a polynomial with $n!$ terms and n variables in each term.

If we want to evaluate the determinant of a matrix with *integer* elements, the above process appears to be unattractive since it requires rational arithmetic. However, we can use the method to evaluate the determinant mod p, for any prime p, since division mod p is possible (exercise 4.5.2–15). If this is done for sufficiently many primes p, the exact value of the determinant can be found as explained in Section 4.3.2, since Hadamard's inequality (4.6.1–25) gives an upper bound on the magnitude.

The coefficients of the *characteristic polynomial* $\det(xI - X)$ of an $n \times n$ matrix X can also be computed in $O(n^3)$ steps; cf. J. H. Wilkinson, *The Algebraic Eigenvalue Problem* (Oxford: Clarendon Press, 1965), 353–355, 410–411.

The *permanent* of a matrix is a polynomial that is very similar to the determinant; the only difference is that all of its nonzero coefficients are $+1$. Thus we have

$$\operatorname{per}\begin{pmatrix} x_{11} & \dots & x_{1n} \\ \vdots & & \vdots \\ x_{n1} & \dots & x_{nn} \end{pmatrix} = \sum x_{1j_1}x_{2j_2}\dots x_{nj_n}, \tag{33}$$

summed over all permutations $j_1\, j_2 \dots j_n$ of $\{1, 2, \dots, n\}$. It would seem that this function should be even easier to compute than its more complicated-looking cousin, but no way to evaluate the permanent as efficiently as the determinant is known. Exercises 9 and 10 show that substantially fewer than $n!$ operations will suffice, for large n, but the execution time of all known methods still grows exponentially with the size of the matrix. In fact, Leslie G. Valiant has shown that it is as difficult to compute the permanent of a given 0–1 matrix as it is to count the number of accepting computations of a nondeterministic polynomial-time Turing machine, if we ignore polynomial factors in the running time of the calculation. Therefore a polynomial-time evaluation algorithm for permanents would imply that scores of other well known problems that have resisted efficient solution would be solvable in polynomial time. On the other hand, Valiant proved that the permanent of an $n \times n$ integer matrix can be evaluated modulo 2^k in $O(n^{4k-3})$ steps for all $k \geq 2$. [See *Theoretical Comp. Sci.* 8 (1979), 189–201.]

Another fundamental operation involving matrices is, of course, *matrix multiplication:* If $X = (x_{ij})$ is an $m \times n$ matrix, $Y = (y_{jk})$ is an $n \times s$ matrix, and $Z = (z_{ik})$ is an $m \times s$ matrix, then the formula $Z = XY$ means that

$$z_{ik} = \sum_{1 \le j \le n} x_{ij}\, y_{jk}, \qquad 1 \le i \le m, \qquad 1 \le k \le s. \tag{34}$$

This equation may be regarded as the computation of ms simultaneous polynomials in $mn+ns$ variables; each polynomial is the "inner product" of two n-place vectors. A straightforward calculation would involve mns multiplications and $ms(n-1)$ additions; but S. Winograd discovered in 1967 that there is a way to trade about half of the multiplications for additions:

$$z_{ik} = \sum_{1 \le j \le n/2} (x_{i,2j} + y_{2j-1,k})(x_{i,2j-1} + y_{2j,k}) - a_i - b_k + c_{ik};$$

$$a_i = \sum_{1 \le j \le n/2} x_{i,2j}\, x_{i,2j-1}; \qquad b_k = \sum_{1 \le j \le n/2} y_{2j-1,k}\, y_{2j,k};$$

$$c_{ik} = \begin{cases} 0, & n \text{ even;} \\ x_{in} y_{nk}, & n \text{ odd.} \end{cases} \tag{35}$$

This scheme uses $\lceil n/2 \rceil ms + \lfloor n/2 \rfloor (m+s)$ multiplications and $(n+2)ms + (\lfloor n/2 \rfloor - 1)(ms + m + s)$ additions or subtractions; the total number of operations has increased slightly, but the number of multiplications has roughly been halved. [See *IEEE Trans.* **C–17** (1968), 693–694.] Winograd's surprising construction led many people to look more closely at the problem of matrix multiplication, and it touched off widespread speculation that $n^3/2$ multiplications would be necessary to multiply $n \times n$ matrices, because of the somewhat similar lower bound that was known to hold for polynomials in one variable.

An even better scheme for large n was discovered by Volker Strassen in 1968; he found a way to compute the product of 2×2 matrices with only seven multiplications, without relying on the commutativity of multiplication as in (35). Since $2n \times 2n$ matrices can be partitioned into four $n \times n$ matrices, his idea can be used recursively to obtain the product of $2^k \times 2^k$ matrices with only 7^k multiplications instead of $(2^k)^3 = 8^k$. The number of additions also grows as order 7^k. Strassen's original 2×2 identity [*Numer. Math.* **13** (1969), 354–356] used 7 multiplications and 18 additions; S. Winograd later discovered the following more economical formula:

$$\begin{pmatrix} a & b \\ c & d \end{pmatrix} \begin{pmatrix} A & C \\ B & D \end{pmatrix} =$$

$$\begin{pmatrix} aA + bB & w + (c+d)(C-A) + (a+b-c-d)D \\ w + (a-c)(D-C) - d(A-B-C+D) & w + (a-c)(D-C) + (c+d)(C-A) \end{pmatrix},$$

$$\text{where } w = aA - (a-c-d)(A-C+D). \tag{36}$$

If intermediate results are appropriately saved, (36) involves 7 multiplications and only 15 additions; by induction on k, we can multiply $2^k \times 2^k$ matrices with 7^k multiplications and $5(7^k - 4^k)$ additions. The total number of operations needed to multiply $n \times n$ matrices has therefore been reduced from order n^3 to $O(n^{\lg 7}) = O(n^{2.8074})$. A similar reduction applies also to the evaluation of determinants and matrix inverses; cf. J. R. Bunch and J. E. Hopcroft, *Math. Comp.* **28** (1974), 231–236.

Strassen's exponent $\lg 7$ resisted numerous attempts at improvement until 1978, when Viktor Pan discovered that it could be lowered to $\log_{70} 143640 \approx 2.795$ (see exercise 60). This new breakthrough led to further intensive analysis of the problem, and the combined efforts of D. Bini, M. Capovani, G. Lotti, F. Romani, A. Schönhage, V. Pan, S. Winograd, and D. Coppersmith culminated in constructions that have an asymptotic running time of $O(n^{2.5161})$. Exercises 60–64 discuss some of the interesting techniques that were used to derive this bound; a full account of the developments has been prepared by V. Îa. Pan, *Computers and Math.*, to appear.

These theoretical results are quite striking, but from a practical standpoint they are of limited use because n must be very large before we overcome the effect of additional bookkeeping costs. Richard Brent [Stanford Computer Science report CS157 (March, 1970), see also *Numer. Math.* **16** (1970), 145–156] found that a careful implementation of Winograd's scheme (35), with appropriate scaling for numerical stability, became better than the conventional method only when $n \geq 40$, and it saved only about 7 percent of the running time when $n = 100$. For complex arithmetic the situation was somewhat different; (35) became advantageous for $n > 20$, and saved 18 percent when $n = 100$. He estimated that Strassen's scheme would not begin to excel over (35) until $n \approx 250$; and such enormous matrices, containing more than 60,000 entries, rarely occur in practice (unless they are very sparse, when other techniques apply). Furthermore, the known methods of order n^β where $\beta < 2.7$ have such large constants of proportionality that they require more than 10^{23} multiplications before they start to beat Strassen's scheme.

By contrast, the methods we shall discuss next are eminently practical and have found wide use. The *discrete Fourier transform* f of a complex-valued function F of n variables, over respective domains of $m_1, \ldots, m_n$ elements, is defined by the equation

$$f(s_1, \ldots, s_n) = \sum_{\substack{0 \le t_1 < m_1 \\ \cdots \\ 0 \le t_n < m_n}} \exp\left(2\pi i \left(\frac{s_1 t_1}{m_1} + \cdots + \frac{s_n t_n}{m_n}\right)\right) F(t_1, \ldots, t_n) \qquad (37)$$

for $0 \le s_1 < m_1, \ldots, 0 \le s_n < m_n$; the name "transform" is justified because we can recover the values $F(t_1, \ldots, t_n)$ from the values $f(s_1, \ldots, s_n)$, as shown in exercise 13. In the important special case that all $m_j = 2$, we have

$$f(s_1, \ldots, s_n) = \sum_{0 \le t_1, \ldots, t_n \le 1} (-1)^{s_1 t_1 + \cdots + s_n t_n} F(t_1, \ldots, t_n) \qquad (38)$$

for $0 \le s_1, \ldots, s_n \le 1$, and this may be regarded as a simultaneous evaluation of 2^n linear polynomials in 2^n variables $F(t_1, \ldots, t_n)$. A well-known technique due to F. Yates [*The Design and Analysis of Factorial Experiments* (Harpenden: Imperial Bureau of Soil Sciences, 1937)] can be used to reduce the number of additions implied in (38) from $2^n(2^n - 1)$ to $n2^n$. Yates's method can be understood by considering the case $n = 3$: Let $x_{t_1t_2t_3} = F(t_1, t_2, t_3)$.

Given	First step	Second step	Third step
x_{000}	$x_{000}+x_{001}$	$x_{000}+x_{001}+x_{010}+x_{011}$	$x_{000}+x_{001}+x_{010}+x_{011}+x_{100}+x_{101}+x_{110}+x_{111}$
x_{001}	$x_{010}+x_{011}$	$x_{100}+x_{101}+x_{110}+x_{111}$	$x_{000}-x_{001}+x_{010}-x_{011}+x_{100}-x_{101}+x_{110}-x_{111}$
x_{010}	$x_{100}+x_{101}$	$x_{000}-x_{001}+x_{010}-x_{011}$	$x_{000}+x_{001}-x_{010}-x_{011}+x_{100}+x_{101}-x_{110}-x_{111}$
x_{011}	$x_{110}+x_{111}$	$x_{100}-x_{101}+x_{110}-x_{111}$	$x_{000}-x_{001}-x_{010}+x_{011}+x_{100}-x_{101}-x_{110}+x_{111}$
x_{100}	$x_{000}-x_{001}$	$x_{000}+x_{001}-x_{010}-x_{011}$	$x_{000}+x_{001}+x_{010}+x_{011}-x_{100}-x_{101}-x_{110}-x_{111}$
x_{101}	$x_{010}-x_{011}$	$x_{100}+x_{101}-x_{110}-x_{111}$	$x_{000}-x_{001}+x_{010}-x_{011}-x_{100}+x_{101}-x_{110}+x_{111}$
x_{110}	$x_{100}-x_{101}$	$x_{000}-x_{001}-x_{010}+x_{011}$	$x_{000}+x_{001}-x_{010}-x_{011}-x_{100}-x_{101}+x_{110}+x_{111}$
x_{111}	$x_{110}-x_{111}$	$x_{100}-x_{101}-x_{110}+x_{111}$	$x_{000}-x_{001}-x_{010}+x_{011}-x_{100}+x_{101}+x_{110}-x_{111}$

To get from the "Given" to the "First step" requires four additions and four subtractions; and the interesting feature of Yates's method is that exactly the same transformation that takes us from "Given" to "First step" will take us from "First step" to "Second step" and from "Second step" to "Third step." In each case we do four additions, then four subtractions; and after three steps we magically have the desired Fourier transform $f(s_1, s_2, s_3)$ in the place originally occupied by $F(s_1, s_2, s_3)$.

This special case is often called the *Walsh transform* of 2^n data elements, since the corresponding pattern of signs was studied by J. L. Walsh [*Amer. J. Math.* **45** (1923), 5–24]. Note that the number of sign changes from left to right in the "Third step" above assumes the respective values

$$0,\ 7,\ 3,\ 4,\ 1,\ 6,\ 2,\ 5;$$

this is a permutation of the numbers $\{0, 1, 2, 3, 4, 5, 6, 7\}$. Walsh observed that there will be exactly 0, 1, ..., $2^n - 1$ sign changes in the general case, if we permute the transformed elements appropriately, so the coefficients provide discrete approximations to sine waves with various frequencies. (See H. F. Harmuth, *IEEE Spectrum* **6**, 11 (Nov. 1969), 82–91, for applications of this property; and see Section 7.2.1 for further discussion of the Walsh coefficients.)

Yates's method can be generalized to the evaluation of any discrete Fourier transform, and, in fact, to the evaluation of any set of sums that can be written in the general form

$$f(s_1, s_2, \ldots, s_n) = \sum_{\substack{0 \le t_1 < m_1 \\ \cdots \\ 0 \le t_n < m_n}} g_1(s_1, s_2, \ldots, s_n, t_1) g_2(s_2, \ldots, s_n, t_2) \ldots g_n(s_n, t_n) F(t_1, t_2, \ldots, t_n) \quad (39)$$

for $0 \le s_j < m_j$, given the functions $g_j(s_j, \ldots, s_n, t_j)$. We proceed as follows.

$$f^{[0]}(t_1, t_2, t_3, \ldots, t_n) = F(t_1, t_2, t_3, \ldots, t_n);$$

$$f^{[1]}(s_n, t_1, t_2, \ldots, t_{n-1}) = \sum_{0 \le t_n < m_n} g_n(s_n, t_n) f^{[0]}(t_1, t_2, \ldots, t_n);$$

$$f^{[2]}(s_{n-1}, s_n, t_1, \ldots, t_{n-2}) = \sum_{0 \le t_{n-1} < m_{n-1}} g_{n-1}(s_{n-1}, s_n, t_{n-1}) f^{[1]}(s_n, t_1, \ldots, t_{n-1});$$

$$\vdots$$

$$f^{[n]}(s_1, s_2, s_3, \ldots, s_n) = \sum_{0 \le t_1 < m_1} g_1(s_1, \ldots, s_n, t_1) f^{[n-1]}(s_2, s_3, \ldots, s_n, t_1);$$

$$f(s_1, s_2, s_3, \ldots, s_n) = f^{[n]}(s_1, s_2, s_3, \ldots, s_n). \tag{40}$$

For Yates's method as shown above, $g_j(s_j, \ldots, s_n, t_j) = (-1)^{s_j t_j}$; $f^{[0]}(t_1, t_2, t_3)$ represents the "Given"; $f^{[1]}(s_3, t_1, t_2)$ represents the "First step"; etc. Whenever a desired set of sums can be put into the form of (39), for reasonably simple functions $g_j(s_j, \ldots, s_n, t_j)$, the scheme (40) will reduce the amount of computation from order N^2 to order $N \log N$ or thereabouts, where $N = m_1 \ldots m_n$ is the number of data points; furthermore this scheme is ideally suited to parallel computation. The important special case of one-dimensional Fourier transforms is discussed in exercises **14** and **53**; we have considered the one-dimensional case also in Section 4.3.3.

Let us consider one more special case of polynomial evaluation. *Lagrange's interpolation polynomial* of order n, which we shall write as

$$\begin{aligned} u^{[n]}(x) = {} & y_0 \frac{(x - x_1)(x - x_2) \ldots (x - x_n)}{(x_0 - x_1)(x_0 - x_2) \ldots (x_0 - x_n)} \\ & + y_1 \frac{(x - x_0)(x - x_2) \ldots (x - x_n)}{(x_1 - x_0)(x_1 - x_2) \ldots (x_1 - x_n)} \\ & + \cdots + y_n \frac{(x - x_0)(x - x_1) \ldots (x - x_{n-1})}{(x_n - x_0)(x_n - x_1) \ldots (x_n - x_{n-1})}, \end{aligned} \tag{41}$$

is the only polynomial of degree $\le n$ in x that takes on the respective values $y_0, y_1, \ldots, y_n$ at the $n + 1$ distinct points $x = x_0, x_1, \ldots, x_n$. (For it is evident from (41) that $u^{[n]}(x_k) = y_k$ for $0 \le k \le n$. If $f(x)$ is any such polynomial of degree $\le n$, then $g(x) = f(x) - u^{[n]}(x)$ is of degree $\le n$, and $g(x)$ is zero for $x = x_0, x_1, \ldots, x_n$; therefore $g(x)$ is a multiple of the polynomial $(x - x_0)(x - x_1) \ldots (x - x_n)$. The degree of the latter polynomial is greater than n, so $g(x) = 0$.) If we assume that the values of a function in some table are well approximated by a polynomial, Lagrange's formula (41) may therefore be used to "interpolate" for values of the function at points x not appearing in the table. Unfortunately, there seem to be quite a few additions, subtractions, multiplications, and divisions in Lagrange's formula; in fact, there are exactly n additions, $2n^2+2$ subtractions, $2n^2+n-1$ multiplications, and $n+1$ divisions.

But fortunately (as we might be conditioned to suspect by now), improvement is possible.

The basic idea for simplifying (41) is to note that $u^{[n]}(x) - u^{[n-1]}(x)$ is zero for $x = x_0, \ldots, x_{n-1}$; thus $u^{[n]}(x) - u^{[n-1]}(x)$ is a polynomial of degree n or less, and a multiple of $(x - x_0)\ldots(x - x_{n-1})$. We conclude that $u^{[n]}(x) = \alpha_n(x - x_0)\ldots(x - x_{n-1}) + u^{[n-1]}(x)$, where α_n is a constant. This leads us to *Newton's interpolation formula*

$$u^{[n]}(x) = \alpha_n(x - x_0)(x - x_1)\ldots(x - x_{n-1}) + \cdots + \alpha_2(x - x_0)(x - x_1) + \alpha_1(x - x_0) + \alpha_0, \tag{42}$$

where the α's are some constants we should like to determine from x_0, x_1, $\ldots$, x_n, y_0, y_1, $\ldots$, y_n. Note that this formula holds for all n; the coefficient α_k does not depend on x_{k+1}, $\ldots$, x_n, or y_{k+1}, $\ldots$, y_n. Once the α's are known, Newton's interpolation formula is convenient for calculation, since we may generalize Horner's rule once again and write

$$u^{[n]}(x) = ((\ldots(\alpha_n(x - x_{n-1}) + \alpha_{n-1})(x - x_{n-2}) + \cdots)(x - x_0) + \alpha_0). \tag{43}$$

This requires n multiplications and $2n$ additions. Alternatively, we may evaluate each of the individual terms of (42) from right to left; with $2n - 1$ multiplications and $2n$ additions we thereby calculate all of the values $u^{[0]}(x)$, $u^{[1]}(x)$, $\ldots$, $u^{[n]}(x)$, and this indicates whether or not an interpolation process is "converging."

The coefficients α_k in Newton's formula may be found by computing the *divided differences* in the following tableau (shown for $n = 3$):

$$\begin{array}{lllll} y_0 & & & & \\ & (y_1 - y_0)/(x_1 - x_0) = y_1' & & & \\ y_1 & & (y_2' - y_1')/(x_2 - x_0) = y_2'' & & \\ & (y_2 - y_1)/(x_2 - x_1) = y_2' & & (y_3'' - y_2'')/(x_3 - x_0) = y_3''' & \\ y_2 & & (y_3' - y_2')/(x_3 - x_1) = y_3'' & & \\ & (y_3 - y_2)/(x_3 - x_2) = y_3' & & & \\ y_3 & & & & \end{array} \tag{44}$$

It is possible to prove that $\alpha_0 = y_0$, $\alpha_1 = y_1'$, $\alpha_2 = y_2''$, etc., and to show that the divided differences have important relations to the derivatives of the function being interpolated; see exercise 15. Therefore the following calculation (corresponding to (44)) may be used to obtain the α's:

> Start with $(\alpha_0, \alpha_1, \ldots, \alpha_n) \leftarrow (y_0, y_1, \ldots, y_n)$; then, for $k = 1, 2, \ldots, n$ (in this order), set $\alpha_j \leftarrow (\alpha_j - \alpha_{j-1})/(x_j - x_{j-k})$ for $j = n, n - 1, \ldots, k$ (in this order).

This process requires $\frac{1}{2}(n^2 + n)$ divisions and $n^2 + n$ subtractions, so about three-fourths of the work implied in (41) has been saved.

For example, suppose that we want to estimate $\frac{3}{2}!$ from the values of 0!, 1!, 2!, and 3!, using a cubic polynomial. The divided differences are

x	y	y'	y''	y'''
0	1			
		0		
1	1		$\frac{1}{2}$	
		1		$\frac{1}{3}$
2	2		$\frac{3}{2}$	
		4		
3	6			

so $u^{[0]}(x) = u^{[1]}(x) = 1$, $u^{[2]}(x) = \frac{1}{2}x(x-1)+1$, $u^{[3]}(x) = \frac{1}{3}x(x-1)(x-2)+\frac{1}{2}x(x-1)+1$. Setting $x = \frac{3}{2}$ in the latter polynomial gives $-\frac{1}{8}+\frac{3}{8}+1 = 1.25$; presumably the "correct" value is $\Gamma(\frac{3}{2}+1) = \frac{3}{4}\sqrt{\pi} \approx 1.33$.

An important and somewhat surprising application of polynomial interpolation was discovered by Adi Shamir [*CACM* **22** (1979), 612–613], who observed that polynomials mod p can be used to "share a secret." This means that we can design a system of secret keys or passwords such that the knowledge of any $n+1$ of the keys enables efficient calculation of a magic number N that unlocks a door (say), but the knowledge of any n of the keys gives no information whatsoever about N. Shamir's amazingly simple solution to this problem is to choose a random polynomial $u(x) = u_n x^n + \cdots + u_1 x + u_0$, where $0 \le u_i < p$ and p is a large prime number. Each part of the secret is an integer x in the range $0 < x < p$, together with the value of $u(x) \bmod p$; and the supersecret number N is the constant term u_0. Given $n+1$ values $u(x_i)$, we can deduce N by interpolation. But if only n values of $u(x_i)$ are given, there is a unique polynomial $u(x)$ having a given constant term but the same values at $x_1, \ldots, x_n$; thus the n values do not make one particular N more likely than any other.

It is instructive to note that evaluation of the interpolation polynomial is just a special case of the Chinese remainder algorithm of Section 4.3.2 and exercise 4.6.2–3, since we know the values of $u^{[n]}(x)$ modulo the relatively prime polynomials $x - x_0, \ldots, x - x_n$. (As we have seen in Section 4.6.2, $f(x) \bmod (x - x_0) = f(x_0)$.) Under this interpretation, Newton's formula (42) is precisely the "mixed-radix representation" of Eq. 4.3.2–24; and 4.3.2–23 yields another way to compute $\alpha_0, \ldots, \alpha_n$ using the same number of operations as (44).

By applying fast Fourier transforms, it is possible to reduce the running time for interpolation to $O(n(\log n)^2)$, and a similar reduction can also be made for related algorithms such as the solution to the Chinese remainder problem and the evaluation of an nth degree polynomial at n different points. [See E. Horowitz, *Inf. Proc. Letters* **1** (1972), 157–163; R. Moenck and A. Borodin, *J. Comp. Syst. Sci.* **8** (1974), 336–385; and A. Borodin, *Complexity of Sequential and Parallel Numerical Algorithms*, ed. by J. F. Traub (New York: Academic Press, 1973), 149–180.] However, this must be regarded as a purely theoretical possibility at present, since the known algorithms have a rather large overhead factor that makes them unattractive unless n is quite large.

A remarkable modification of the method of divided differences, an extension that applies to rational functions instead of to polynomials, was introduced by T. N. Thiele in 1909. Thiele's method of "reciprocal differences" is discussed in L. M. Milne-Thompson's *Calculus of Finite Differences* (London: MacMillan, 1933), Chapter 5; see also R. W. Floyd, *CACM* **3** (1960), 508.

***Bilinear forms.** Several of the problems we have considered in this section are special cases of the general problem of evaluating a set of *bilinear forms*

$$z_k = \sum_{\substack{1\le i\le m\\ 1\le j\le n}} t_{ijk}x_iy_j, \qquad \text{for } 1 \le k \le s, \tag{45}$$

where the t_{ijk} are specific coefficients belonging to some given field. The three-dimensional array (t_{ijk}) is called an $m \times n \times s$ *tensor*, and we can display it by writing down s matrices of size $m \times n$, one for each value of k. For example, the problem of multiplying complex numbers, namely the problem of evaluating

$$z_1 + iz_2 = (x_1 + ix_2)(y_1 + iy_2) = (x_1y_1 - x_2y_2) + i(x_1y_2 + x_2y_1), \tag{46}$$

is the problem of computing the bilinear form specified by the $2 \times 2 \times 2$ tensor

$$\begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} \quad \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}.$$

Matrix multiplication as defined in (34) is the problem of evaluating a set of bilinear forms corresponding to a particular $mn \times ns \times ms$ tensor. Fourier transforms (37) can also be cast in this mold, although they are linear instead of bilinear, if we let the x's be constant rather than variable.

The evaluation of bilinear forms is most easily studied if we restrict ourselves to what might be called *normal* evaluation schemes, in which all chain multiplications take place between a linear combination of the x's and a linear combination of the y's. Thus, we form r products

$$w_l = (a_{1l}x_1 + \cdots + a_{ml}x_m)(b_{1l}y_1 + \cdots + b_{nl}y_n), \qquad \text{for } 1 \le l \le r, \tag{47}$$

and obtain the z's as linear combinations of these products,

$$z_k = c_{k1}w_1 + \cdots + c_{kr}w_r, \qquad \text{for } 1 \le k \le s. \tag{48}$$

Here all the a's, b's, and c's belong to a given field of coefficients. By comparing (48) to (45), we see that a normal evaluation scheme is correct for the tensor (t_{ijk}) if and only if

$$t_{ijk} = a_{i1}b_{j1}c_{k1} + \cdots + a_{ir}b_{jr}c_{kr} \tag{49}$$

for $1 \le i \le m$, $1 \le j \le n$, and $1 \le k \le s$.

A nonzero tensor (t_{ijk}) is said to be of rank one if there are three vectors $(a_1, \ldots, a_m)$, $(b_1, \ldots, b_n)$, $(c_1, \ldots, c_s)$ such that $t_{ijk} = a_i b_j c_k$ for all i, j, k. We can extend this definition to all tensors by saying that *the rank of* (t_{ijk}) *is the minimum number* r *such that* (t_{ijk}) *is expressible as the sum of* r *rank-one tensors* in the given field. Comparing this definition with Eq. (49) shows that the rank of a tensor is the minimum number of chain multiplications in a normal evaluation of the corresponding bilinear forms. Incidentally, when $s = 1$ the tensor (t_{ijk}) is just an ordinary matrix, and the rank of (t_{ij1}) as a tensor is the same as its rank as a matrix (see exercise 49). The concept of tensor rank was introduced by F. L. Hitchcock in *J. Math. and Physics* **6** (1927), 164–189; its application to the complexity of polynomial evaluation was pointed out in an important paper by V. Strassen, *J. für die reine und angew. Math.* **264** (1973), 184–202.

Winograd's scheme (35) for matrix multiplication is "abnormal" because it mixes x's and y's before multiplying them. The Strassen-Winograd scheme (36), on the other hand, does not rely on the commutativity of multiplication, so it is normal. In fact, (36) corresponds to the following way to represent the $4 \times 4 \times 4$ tensor for 2×2 matrix multiplication as a sum of seven rank-one tensors:

$$\begin{pmatrix}1&0&0&0\\0&1&0&0\\0&0&0&0\\0&0&0&0\end{pmatrix}\begin{pmatrix}0&0&0&0\\0&0&0&0\\1&0&0&0\\0&1&0&0\end{pmatrix}\begin{pmatrix}0&0&1&0\\0&0&0&1\\0&0&0&0\\0&0&0&0\end{pmatrix}\begin{pmatrix}0&0&0&0\\0&0&0&0\\0&0&1&0\\0&0&0&1\end{pmatrix} = \begin{pmatrix}1&0&0&0\\0&0&0&0\\0&0&0&0\\0&0&0&0\end{pmatrix}\begin{pmatrix}1&0&0&0\\0&0&0&0\\0&0&0&0\\0&0&0&0\end{pmatrix}\begin{pmatrix}1&0&0&0\\0&0&0&0\\0&0&0&0\\0&0&0&0\end{pmatrix}\begin{pmatrix}1&0&0&0\\0&0&0&0\\0&0&0&0\\0&0&0&0\end{pmatrix}$$
$$+\begin{pmatrix}0&0&0&0\\0&1&0&0\\0&0&0&0\\0&0&0&0\end{pmatrix}\begin{pmatrix}0&0&0&0\\0&0&0&0\\0&0&0&0\\0&0&0&0\end{pmatrix}\begin{pmatrix}0&0&0&0\\0&0&0&0\\0&0&0&0\\0&0&0&0\end{pmatrix}\begin{pmatrix}0&0&0&0\\0&0&0&0\\0&0&0&0\\0&0&0&0\end{pmatrix}+\begin{pmatrix}0&0&0&0\\0&0&0&0\\0&0&0&0\\0&0&0&0\end{pmatrix}\begin{pmatrix}0&0&\bar1&\bar1\\0&0&0&0\\0&0&1&1\\0&0&0&0\end{pmatrix}\begin{pmatrix}0&0&0&0\\0&0&0&0\\0&0&0&0\\0&0&0&0\end{pmatrix}\begin{pmatrix}0&0&\bar1&\bar1\\0&0&0&0\\0&0&1&1\\0&0&0&0\end{pmatrix}$$
$$+\begin{pmatrix}0&0&0&0\\0&0&0&0\\0&0&0&0\\0&0&0&0\end{pmatrix}\begin{pmatrix}0&0&0&0\\0&0&0&0\\0&0&0&0\\1&1&\bar1&\bar1\end{pmatrix}\begin{pmatrix}0&0&0&0\\0&0&0&0\\0&0&0&0\\0&0&0&0\end{pmatrix}\begin{pmatrix}0&0&0&0\\0&0&0&0\\0&0&0&0\\0&0&0&0\end{pmatrix}+\begin{pmatrix}0&0&0&0\\0&0&0&0\\0&0&0&0\\0&0&0&0\end{pmatrix}\begin{pmatrix}0&0&0&0\\0&0&0&0\\0&0&0&0\\0&0&0&0\end{pmatrix}\begin{pmatrix}0&0&0&0\\0&0&0&0\\\bar1&0&1&0\\1&0&\bar1&0\end{pmatrix}\begin{pmatrix}0&0&0&0\\0&0&0&0\\\bar1&0&1&0\\1&0&\bar1&0\end{pmatrix}$$
$$+\begin{pmatrix}0&0&0&0\\0&0&0&0\\0&0&0&0\\0&0&0&0\end{pmatrix}\begin{pmatrix}0&0&0&0\\0&0&0&0\\0&0&0&0\\0&0&0&0\end{pmatrix}\begin{pmatrix}0&0&0&\bar1\\0&0&0&1\\0&0&0&1\\0&0&0&\bar1\end{pmatrix}\begin{pmatrix}0&0&0&0\\0&0&0&0\\0&0&0&0\\0&0&0&0\end{pmatrix}+\begin{pmatrix}0&0&0&0\\0&0&0&0\\0&0&0&0\\0&0&0&0\end{pmatrix}\begin{pmatrix}\bar1&0&1&1\\0&0&0&0\\1&0&\bar1&\bar1\\\bar1&0&1&1\end{pmatrix}\begin{pmatrix}\bar1&0&1&1\\0&0&0&0\\1&0&\bar1&\bar1\\\bar1&0&1&1\end{pmatrix}\begin{pmatrix}\bar1&0&1&1\\0&0&0&0\\1&0&\bar1&\bar1\\\bar1&0&1&1\end{pmatrix}. \tag{50}$$

(Here $\bar1$ stands for -1.)

The fact that (49) is symmetric in i, j, k and invariant under a variety of transformations makes the study of tensor rank mathematically tractable, and it also leads to some surprising consequences about bilinear forms. We can permute the indices i, j, k to obtain "transposed" bilinear forms, and the transposed tensor clearly has the same rank; but the corresponding bilinear forms are conceptually quite different. For example, a normal scheme for evaluating an $(m \times n)$ times $(n \times s)$ matrix product implies the existence of a normal scheme to evaluate an $(n \times s)$ times $(s \times m)$ matrix product, using the same number of chain multiplications. In matrix terms these two problems hardly seem to be related at all—they involve different numbers of dot products on vectors of different sizes—but in tensor terms they are equivalent. [Cf. V. Ía. Pan, *Uspekhi Mat.*

Nauk **27**,5 (1972), 249–250; J. E. Hopcroft and J. Musinski, *SIAM J. Computing* **2** (1973), 159–173.]

When the tensor (t_{ijk}) can be represented as a sum (49) of r rank-one tensors, let A, B, C be the matrices (a_{il}), (b_{jl}), (c_{kl}) of respective sizes $m \times r$, $n \times r$, $s \times r$; we shall say that A, B, C is a *realization* of the tensor (t_{ijk}). For example, the realization of 2×2 matrix multiplication in (50) can be specified by the matrices

$$A = \begin{pmatrix} 1 & 0 & \bar{1} & 0 & 0 & \bar{1} & 1 \\ 0 & 1 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 1 & 0 & \bar{1} & 1 & \bar{1} \\ 0 & 0 & 0 & 1 & 1 & \bar{1} & 1 \end{pmatrix}, \quad B = \begin{pmatrix} 1 & 0 & 0 & 1 & 1 & 0 & \bar{1} \\ 0 & 1 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & \bar{1} & \bar{1} & 0 & 1 \\ 0 & 0 & 1 & \bar{1} & 0 & 1 & 1 \end{pmatrix}, \quad C = \begin{pmatrix} 1 & 1 & 0 & 0 & 0 & 0 & 0 \\ 1 & 0 & 1 & 1 & 0 & 0 & 1 \\ 1 & 0 & 0 & 0 & 1 & 1 & 1 \\ 1 & 0 & 1 & 0 & 1 & 0 & 1 \end{pmatrix}. \tag{51}$$

An $m \times n \times s$ tensor (t_{ijk}) can also be represented as a matrix by grouping its subscripts together. We shall write $(t_{(ij)k})$ for the $mn \times s$ matrix whose rows are indexed by the pair of subscripts $\langle i, j \rangle$ and whose columns are indexed by k. Similarly, $(t_{k(ij)})$ stands for the $s \times mn$ matrix that contains t_{ijk} in row k and column $\langle i, j \rangle$; $(t_{(ik)j})$ is an $ms \times n$ matrix, and so on. The indices of an array need not be integers, and we are using ordered pairs as indices here. We can use this notation to derive the following simple but useful lower bound on the rank of a tensor.

Lemma T. *Let A, B, C be a realization of an $m \times n \times s$ tensor (t_{ijk}). Then* $\operatorname{rank}(A) \geq \operatorname{rank}(t_{i(jk)})$, $\operatorname{rank}(B) \geq \operatorname{rank}(t_{j(ik)})$, *and* $\operatorname{rank}(C) \geq \operatorname{rank}(t_{k(ij)})$; *consequently*

$$\operatorname{rank}(t_{ijk}) \geq \max\bigl(\operatorname{rank}(t_{i(jk)}), \operatorname{rank}(t_{j(ik)}), \operatorname{rank}(t_{k(ij)})\bigr).$$

Proof. It suffices by symmetry to show that $r \geq \operatorname{rank}(A) \geq \operatorname{rank}(t_{i(jk)})$. Since A is an $m \times r$ matrix, it is obvious that A cannot have rank greater than r. Furthermore, according to (49), the matrix $(t_{i(jk)})$ is equal to AQ, where Q is the $r \times ns$ matrix defined by $Q_{l\langle j,k\rangle} = b_{jl}\, c_{kl}$. If x is any row vector such that $xA = 0$ then $xAQ = 0$, hence all linear dependencies in A occur also in AQ. It follows that $\operatorname{rank}(AQ) \leq \operatorname{rank}(A)$. ∎

As an example of the use of Lemma T, let us consider the problem of polynomial multiplication. Suppose we want to multiply a general polynomial of degree 2 by a general polynomial of degree 3, obtaining the coefficients of the product:

$$\begin{aligned}(x_0 + x_1 u + x_2 u^2)(y_0 + y_1 u + y_2 u^2 + y_3 u^3) \\ = z_0 + z_1 u + z_2 u^2 + z_3 u^3 + z_4 u^4 + z_5 u^5.\end{aligned} \tag{52}$$

This is the problem of evaluating six bilinear forms corresponding to the $3 \times 4 \times 6$ tensor

$$\begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix}\begin{pmatrix} 0 & 1 & 0 & 0 \\ 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix}\begin{pmatrix} 0 & 0 & 1 & 0 \\ 0 & 1 & 0 & 0 \\ 1 & 0 & 0 & 0 \end{pmatrix}\begin{pmatrix} 0 & 0 & 0 & 1 \\ 0 & 0 & 1 & 0 \\ 0 & 1 & 0 & 0 \end{pmatrix}\begin{pmatrix} 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 1 & 0 \end{pmatrix}\begin{pmatrix} 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}. \tag{53}$$

For brevity, we may write (52) as $x(u)y(u) = z(u)$, letting $x(u)$ denote the polynomial $x_0 + x_1u + x_2u^2$, etc. Note that we have come full circle from the way we began this section, since Eq. (1) refers to $u(x)$, not $x(u)$; the notation has changed because the *coefficients* of the polynomials are now the variables of interest to us.

If each of the six matrices in (53) is regarded as a vector of length 12 indexed by $\langle i, j\rangle$, it is clear that the vectors are linearly independent, since they are nonzero in different positions; hence the rank of (53) is at least 6 by Lemma T. Conversely, it is possible to obtain the coefficients $z_0, z_1, \ldots, z_5$ by making only six chain multiplications, for example by computing

$$x(0)y(0),\ x(1)y(1),\ \ldots,\ x(5)y(5); \tag{54}$$

this gives the values of $z(0), z(1), \ldots, z(5)$, and the formulas developed above for interpolation will yield the coefficients of $z(u)$. The evaluation of $x(j)$ and $y(j)$ can be carried out entirely in terms of additions and/or parameter multiplications, and the interpolation formula merely takes linear combinations of these values. Thus, all of the chain multiplications are shown in (54), and the rank of (53) is 6. (We used essentially this same technique when multiplying high-precision numbers in Algorithm 4.3.3C.)

The realization A, B, C of (53) sketched in the above paragraph turns out to be

$$\begin{pmatrix} 1 & 1 & 1 & 1 & 1 & 1 \\ 0 & 1 & 2 & 3 & 4 & 5 \\ 0 & 1 & 4 & 9 & 16 & 25 \end{pmatrix},\quad \begin{pmatrix} 1 & 1 & 1 & 1 & 1 & 1 \\ 0 & 1 & 2 & 3 & 4 & 5 \\ 0 & 1 & 4 & 9 & 16 & 25 \\ 0 & 1 & 8 & 27 & 64 & 125 \end{pmatrix},\quad \begin{pmatrix} 120 & 0 & 0 & 0 & 0 & 0 \\ -274 & 600 & -600 & 400 & -150 & 24 \\ 225 & -770 & 1070 & -780 & 305 & -50 \\ -85 & 355 & -590 & 490 & -205 & 35 \\ 15 & -70 & 130 & -120 & 55 & -10 \\ -1 & 5 & -10 & 10 & -5 & 1 \end{pmatrix} \times \tfrac{1}{120}. \tag{55}$$

Thus, the scheme does indeed require the minimum number of chain multiplications, but it is completely impractical because it involves so many additions and parameter multiplications. We shall now study a practical approach to the generation of more efficient schemes, suggested by S. Winograd.

In the first place, to evaluate the coefficients of $x(u)y(u)$ when $\deg(x) = m$ and $\deg(y) = n$, one can use the identity

$$x(u)y(u) = \big(x(u)y(u) \bmod p(u)\big) + x_m y_n p(u), \tag{56}$$

when $p(u)$ is any monic polynomial of degree $m+n$. The polynomial $p(u)$ should be chosen so that the coefficients of $x(u)y(u) \bmod p(u)$ are easy to evaluate.

In the second place, to evaluate the coefficients of $x(u)y(u) \bmod p(u)$, when the polynomial $p(u)$ can be factored into $q(u)r(u)$ where $\gcd\big(q(u), r(u)\big) = 1$, one can use the identity

$$\begin{aligned} x(u)y(u) \bmod q(u)r(u) = \Big(&a(u)r(u)\big(x(u)y(u) \bmod q(u)\big) \\ &+ b(u)q(u)\big(x(u)y(u) \bmod r(u)\big)\Big) \bmod q(u)r(u) \end{aligned} \tag{57}$$

where $a(u)r(u)+b(u)q(u)=1$; this is essentially the Chinese remainder theorem applied to polynomials.

In the third place, to evaluate the coefficients of $x(u)y(u) \bmod p(u)$ when $p(u)$ has only one irreducible factor over the field of coefficients, one can use the identity

$$x(u)y(u) \bmod p(u) = \big(x(u) \bmod p(u)\big)\big(y(u) \bmod p(u)\big) \bmod p(u). \tag{58}$$

Repeated application of (56), (57), and (58) tends to produce efficient schemes, as we shall see.

For our example problem (52), let us choose $p(u)=u^5-u$ and apply (56); the reason for this choice of $p(u)$ will appear as we proceed. Writing $p(u)=u(u^4-1)$, rule (57) reduces to

$$\begin{aligned} x(u)y(u) \bmod u(u^4-1) = \big(&-(u^4-1)x_0y_0 \\ &+ u^4\big(x(u)y(u) \bmod (u^4-1)\big)\big) \bmod (u^5-u). \end{aligned} \tag{59}$$

Here we have used the fact that $x(u)y(u) \bmod u = x_0y_0$; in general it is a good idea to choose $p(u)$ in such a way that $p(0)=0$, so that this simplification can be used. If we could now determine the coefficients w_0, w_1, w_2, w_3 of the polynomial $x(u)y(u) \bmod (u^4-1) = w_0+w_1u+w_2u^2+w_3u^3$, our problem would be solved, since

$$u^4\big(x(u)y(u) \bmod (u^4-1)\big) \bmod (u^5-u) = w_0u^4+w_1u+w_2u^2+w_3u^3,$$

and the combination of (56) and (59) would reduce to

$$x(u)y(u) = x_0y_0+(w_1-x_2y_3)u+w_2u^2+w_3u^3+(w_0-x_0y_0)u^4+x_2y_3u^5. \tag{60}$$

(This formula can, of course, be verified directly.)

The problem remaining to be solved is to compute $x(u)y(u) \bmod (u^4-1)$; and this subproblem is interesting in itself. Let us momentarily allow $x(u)$ to be of degree 3 instead of degree 2. Then the coefficients of $x(u)y(u) \bmod (u^4-1)$ are respectively

$$\begin{aligned} &x_0y_0+x_1y_3+x_2y_2+x_3y_1, \quad x_0y_1+x_1y_0+x_2y_3+x_3y_2, \\ &\qquad x_0y_2+x_1y_1+x_2y_0+x_3y_3, \quad x_0y_3+x_1y_2+x_2y_1+x_3y_0, \end{aligned}$$

and the corresponding tensor is

$$\begin{pmatrix}1&0&0&0\\0&0&0&1\\0&0&1&0\\0&1&0&0\end{pmatrix}\begin{pmatrix}0&1&0&0\\1&0&0&0\\0&0&0&1\\0&0&1&0\end{pmatrix}\begin{pmatrix}0&0&1&0\\0&1&0&0\\1&0&0&0\\0&0&0&1\end{pmatrix}\begin{pmatrix}0&0&0&1\\0&0&1&0\\0&1&0&0\\1&0&0&0\end{pmatrix}. \tag{61}$$

In general when $\deg(x)=\deg(y)=n-1$, the coefficients of $x(u)y(u) \bmod (u^n-1)$ are called the *cyclic convolution* of $(x_0,x_1,\ldots,x_{n-1})$ and $(y_0,y_1,\ldots,y_{n-1})$. The

kth coefficient w_k is the bilinear form $\sum x_i y_j$ summed over all i and j with $i+j \equiv k$ (modulo n).

The cyclic convolution of degree 4 can be obtained by applying rule (57). The first step is to find the factors of u^4-1, namely $(u-1)(u+1)(u^2+1)$. We could write this as $(u^2-1)(u^2+1)$, then apply rule (57), then use (57) again on the part modulo $(u^2-1)=(u-1)(u+1)$; but it is easier to generalize the Chinese remainder rule (57) directly to the case of several relatively prime factors. For example, we have

$$\begin{aligned} &x(u)y(u) \bmod q_1(u)q_2(u)q_3(u) \\ &\quad = \Big(a_1(u)q_2(u)q_3(u)\big(x(u)y(u) \bmod q_1(u)\big) + a_2(u)q_1(u)q_3(u)\big(x(u)y(u) \bmod q_2(u)\big) \\ &\qquad + a_3(u)q_1(u)q_2(u)\big(x(u)y(u) \bmod q_3(u)\big)\Big) \bmod q_1(u)q_2(u)q_3(u), \end{aligned} \tag{62}$$

where $a_1(u)q_2(u)q_3(u) + a_2(u)q_1(u)q_3(u) + a_3(u)q_1(u)q_2(u) = 1$. (The latter equation can be understood in another way, by noting that the partial fraction expansion of $1/q_1(u)q_2(u)q_3(u)$ is $a_1(u)/q_1(u)+a_2(u)/q_2(u)+a_3(u)/q_3(u)$. When each of the q's is a linear polynomial $u-\alpha_i$, the generalized Chinese remainder rule reduces to ordinary interpolation as in Eq. (41), since $f(u) \bmod (u-\alpha_i) = f(\alpha_i)$.) From (62) we obtain

$$\begin{aligned} x(u)y(u) \bmod (u^4-1) = \Big(&\tfrac{u^3+u^2+u+1}{4}x(1)y(1) - \tfrac{u^3-u^2+u-1}{4}x(-1)y(-1) \\ &- \tfrac{u^2-1}{2}\big(x(u)y(u) \bmod (u^2+1)\big)\Big) \bmod (u^4-1). \end{aligned} \tag{63}$$

The remaining problem is to evaluate $x(u)y(u) \bmod (u^2+1)$, and it is time to invoke rule (58). First we reduce $x(u)$ and $y(u)$ mod (u^2+1), obtaining $X(u) = (x_0 - x_2) + (x_1 - x_3)u$, $Y(u) = (y_0 - y_2) + (y_1 - y_3)u$. Then (58) tells us to evaluate $X(u)Y(u) = Z_0 + Z_1u + Z_2u^2$, and to reduce this in turn modulo (u^2+1), obtaining $(Z_0 - Z_2) + Z_1u$. The job of computing $X(u)Y(u)$ is simple; we can use rule (56) with $p(u) = u(u+1)$ and we get

$$Z_0 = X_0Y_0, \quad Z_1 = X_0Y_0 - (X_0-X_1)(Y_0-Y_1) + X_1Y_1, \quad Z_2 = X_1Y_1.$$

(We have thereby rediscovered the trick of Eq. 4.3.3–2 in a more systematic way.) Putting everything together yields the following realization A, B, C of degree-4 cyclic convolution:

$$\begin{pmatrix} 1&1&1&0&1\\ 1&\bar1&0&1&\bar1\\ 1&1&\bar1&0&\bar1\\ 1&\bar1&0&\bar1&1 \end{pmatrix}, \quad \begin{pmatrix} 1&1&1&0&1\\ 1&\bar1&0&1&\bar1\\ 1&1&\bar1&0&\bar1\\ 1&\bar1&0&\bar1&1 \end{pmatrix}, \quad \begin{pmatrix} 1&1&2&\bar2&0\\ 1&\bar1&2&2&\bar2\\ 1&1&\bar2&2&0\\ 1&\bar1&\bar2&\bar2&2 \end{pmatrix} \times \frac{1}{4}. \tag{64}$$

Here $\bar1$ stands for -1 and $\bar2$ for -2.

The tensor for cyclic convolution of degree n satisfies

$$t_{i,j,k} = t_{k,-j,i}, \tag{65}$$

treating the subscripts modulo n, since $t_{ijk} = 1$ if and only if $i + j \equiv k$ (modulo n). Thus if (a_{il}), (b_{jl}), (c_{kl}) is a realization of the cyclic convolution, so is (c_{kl}), $(b_{-j,l})$, (a_{il}); in particular, we can realize (61) by transforming (64) into

$$\begin{pmatrix} 1 & 1 & 2 & \bar{2} & 0 \\ 1 & \bar{1} & 2 & 2 & \bar{2} \\ 1 & 1 & \bar{2} & 2 & 0 \\ 1 & \bar{1} & \bar{2} & \bar{2} & 2 \end{pmatrix} \times \frac{1}{4}, \quad \begin{pmatrix} 1 & 1 & 1 & 0 & 1 \\ 1 & \bar{1} & 0 & \bar{1} & 1 \\ 1 & 1 & \bar{1} & 0 & \bar{1} \\ 1 & \bar{1} & 0 & 1 & \bar{1} \end{pmatrix}, \quad \begin{pmatrix} 1 & 1 & 1 & 0 & 1 \\ 1 & \bar{1} & 0 & 1 & \bar{1} \\ 1 & 1 & \bar{1} & 0 & \bar{1} \\ 1 & \bar{1} & 0 & \bar{1} & 1 \end{pmatrix}. \tag{66}$$

Now all of the complicated scalars appear in the A matrix. This is important in practice, since we often want to compute the convolution for many values of y_0, y_1, y_2, y_3 but for a fixed choice of x_0, x_1, x_2, x_3. In such a situation, the arithmetic on x's can be done once and for all, and we need not count it. Thus (66) leads to the following scheme for evaluating the cyclic convolution w_0, w_1, w_2, w_3 when x_0, x_1, x_2, x_3 are known in advance:

$$\begin{gathered} s_1 = y_0 + y_2, \quad s_2 = y_1 + y_3, \quad s_3 = s_1 + s_2, \quad s_4 = s_1 - s_2, \\ s_5 = y_0 - y_2, \quad s_6 = y_3 - y_1, \quad s_7 = s_5 - s_6; \\ m_1 = \tfrac{x_0+x_1+x_2+x_3}{4} \cdot s_3, \quad m_2 = \tfrac{x_0-x_1+x_2-x_3}{4} \cdot s_4, \quad m_3 = \tfrac{x_0+x_1-x_2-x_3}{2} \cdot s_5, \\ m_4 = \tfrac{-x_0+x_1+x_2-x_3}{2} \cdot s_6, \quad m_5 = \tfrac{x_3-x_1}{2} \cdot s_7; \\ t_1 = m_1 + m_2, \quad t_2 = m_3 + m_5, \quad t_3 = m_1 - m_2, \quad t_4 = m_4 - m_5; \\ w_0 = t_1 + t_2, \quad w_1 = t_3 + t_4, \quad w_2 = t_1 - t_2, \quad w_3 = t_3 - t_4. \end{gathered} \tag{67}$$

There are 5 multiplications and 15 additions, while the definition of cyclic convolution involves 16 multiplications and 12 additions. We will prove later that 5 multiplications are necessary.

Going back to our original multiplication problem (52), using (60), we have derived the realization

$$\begin{pmatrix} 4 & 0 & 1 & 1 & 2 & \bar{2} & 0 \\ 0 & 0 & 1 & \bar{1} & 2 & 2 & \bar{2} \\ 0 & 4 & 1 & 1 & \bar{2} & 2 & 0 \end{pmatrix} \times \frac{1}{4}, \quad \begin{pmatrix} 1 & 0 & 1 & 1 & 1 & 0 & 1 \\ 0 & 0 & 1 & \bar{1} & 0 & \bar{1} & 1 \\ 0 & 0 & 1 & 1 & \bar{1} & 0 & \bar{1} \\ 0 & 1 & 1 & \bar{1} & 0 & 1 & \bar{1} \end{pmatrix}, \quad \begin{pmatrix} 1 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & \bar{1} & 1 & \bar{1} & 0 & 1 & \bar{1} \\ 0 & 0 & 1 & 1 & \bar{1} & 0 & \bar{1} \\ 0 & 0 & 1 & \bar{1} & 0 & \bar{1} & 1 \\ \bar{1} & 0 & 1 & 1 & 1 & 0 & 1 \\ 0 & 1 & 0 & 0 & 0 & 0 & 0 \end{pmatrix}. \tag{68}$$

This scheme uses one more than the minimum number of chain multiplications, but it requires far fewer parameter multiplications than (55). Of course, it must be admitted that the scheme is still rather complicated: If our goal is simply to compute the coefficients z_0, z_1, $\ldots$, z_5 of the product of two given polynomials $(x_0 + x_1u + x_2u^2)(y_0 + y_1u + y_2u^2 + y_3u^3)$, as a one-shot problem, our best bet is still to use the obvious method that does 12 multiplications and 6 additions—unless (say) the x's and y's are matrices. Note that if the x's are fixed as the y's vary, the new scheme does the evaluation with 7 multiplications and 17 additions. Even though (68) isn't especially useful as it stands, our derivation has

illustrated important techniques that are useful in a variety of other situations. For example, Winograd has used this approach to compute Fourier transforms using significantly fewer multiplications than the "fast Fourier transform" algorithm needs (see exercise 53).

Let us conclude this section by determining the exact rank of the $n \times n \times n$ tensor that corresponds to the multiplication of two polynomials modulo a third,

$$z_0 + z_1 u + \cdots + z_{n-1}u^{n-1}$$
$$= (x_0 + x_1 u + \cdots + x_{n-1}u^{n-1})(y_0 + y_1 u + \cdots + y_{n-1}u^{n-1}) \bmod p(u). \quad (69)$$

Here $p(u)$ stands for any given monic polynomial of degree n; in particular, $p(u)$ might be $u^n - 1$, so one of the results of our investigation will be to deduce the rank of the tensor corresponding to cyclic convolution of degree n. It will be convenient to write $p(u)$ in the form

$$p(u) = u^n - p_{n-1}u^{n-1} - \cdots - p_1 u - p_0, \quad (70)$$

so that $u^n \equiv p_0 + p_1 u + \cdots + p_{n-1}u^{n-1}$ (modulo $p(u)$).

The tensor element t_{ijk} is the coefficient of u^k in $u^{i+j} \bmod p(u)$; and this is the element in row i, column k of the matrix P^j, where

$$P = \begin{pmatrix} 0 & 1 & 0 & \ldots & 0 \\ 0 & 0 & 1 & \ldots & 0 \\ \vdots & \vdots & \vdots & & \vdots \\ 0 & 0 & 0 & \ldots & 1 \\ p_0 & p_1 & p_2 & \cdots & p_{n-1} \end{pmatrix} \quad (71)$$

is called the "companion matrix" of $p(u)$. (The indices i, j, k in our discussion will run from 0 to $n-1$ instead of from 1 to n.) It is convenient to transpose the tensor, for if $T_{ijk} = t_{ikj}$ the individual layers of (T_{ijk}) for $k = 0, 1, 2, \ldots, n-1$ are simply given by the matrices

$$I \quad P \quad P^2 \quad \ldots \quad P^{n-1}. \quad (72)$$

The first rows of the matrices in (72) are respectively the unit vectors $(1,0,0,\ldots,0)$, $(0,1,0,\ldots,0)$, $(0,0,1,\ldots,0)$, $\ldots$, $(0,0,0,\ldots,1)$, hence a linear combination such as $\sum_{0\le k<n} v_k P^k$ will be the zero matrix if and only if the v_k are all zero. Furthermore, most of these linear combinations are actually nonsingular matrices, for we have

$$(w_0, w_1, \ldots, w_{n-1}) \sum_{0\le k<n} v_k P^k = (0,0,\ldots,0)$$
$$\text{if and only if} \quad v(u)w(u) \equiv 0 \pmod{p(u)},$$

where $v(u) = v_0 + v_1 u + \cdots + v_{n-1}u^{n-1}$ and $w(u) = w_0 + w_1 u + \cdots + w_{n-1}u^{n-1}$. Thus, $\sum_{0\le k<n} v_k P^k$ is a singular matrix if and only if the polynomial $v(u)$ is a multiple of some factor of $p(u)$. We are now ready to prove the desired result.

Theorem W (S. Winograd, 1975). *Let $p(u)$ be a monic polynomial of degree n whose complete factorization over a given infinite field is*

$$p(u) = p_1(u)^{e_1} \dots p_q(u)^{e_q}. \tag{73}$$

Then the rank of the tensor (72) *corresponding to the bilinear forms* (69) *is* $2n-q$ *over this field.*

Proof. The bilinear forms can be evaluated with only $2n-q$ chain multiplications by using rules (56), (57), (58) in an appropriate fashion, so we must prove only that the rank r is $\geq 2n-q$. The above discussion establishes the fact that $\operatorname{rank}(T_{(ij)k}) = n$; hence by Lemma T, any $n \times r$ realization A, B, C of (T_{ijk}) has $\operatorname{rank}(C) = n$. Our strategy will be to use Lemma T again, by finding a vector $(v_0, v_1, \dots, v_{n-1})$ that has the following two properties:

a) The vector $(v_0, v_1, \dots, v_{n-1})C$ has at most $q + r - n$ nonzero coefficients.
b) The matrix $v(P) = \sum_{0 \leq k < n} v_k P^k$ is nonsingular.

This and Lemma T will prove that $q + r - n \geq n$, since the identity

$$\sum_{1 \leq l \leq r} a_{il}\, b_{jl} \Bigg(\sum_{0 \leq k < n} v_k\, c_{kl} \Bigg) = v(P)_{ij}$$

shows how to realize the $n \times n \times 1$ tensor $v(P)$ of rank n with $q + r - n$ chain multiplications.

We may assume for convenience that the first n columns of C are linearly independent. Let D be the $n \times n$ matrix such that the first n columns of DC are equal to the identity matrix. Our goal will be achieved if there is a linear combination $(v_0, v_1, \dots, v_{n-1})$ of at most q rows of D, such that $v(P)$ is nonsingular; such a vector will satisfy conditions (a) and (b).

Since the rows of D are linearly independent, no irreducible factor $p_\lambda(u)$ divides the polynomials corresponding to every row. Given a vector $w = (w_0, w_1, \dots, w_{n-1})$, let "covered($w$)" be the set of all λ such that $w(u)$ is not a multiple of $p_\lambda(u)$. From two vectors v and w we can find a linear combination $v + \alpha w$ such that

$$\text{covered}(v + \alpha w) = \text{covered}(v) \cup \text{covered}(w), \tag{74}$$

for some α in the field. The reason is that if λ is covered by v or w but not both, then λ is covered by $v + \alpha w$ for all nonzero α; if λ is covered by both v and w but λ is not covered by $v + \alpha w$, then λ is covered by $v + \beta w$ for all $\beta \neq \alpha$. By trying $q + 1$ different values of α, at least one must yield (74). In this way we can systematically construct a linear combination of at most q rows of D, covering all λ for $1 \leq \lambda \leq q$. ∎

One of the most important corollaries of Theorem W is that the rank of a tensor can depend on the field from which we draw the elements of the realization A, B, C. For example, consider the tensor corresponding to cyclic convolution of degree 5; this is equivalent to multiplication of polynomials mod $p(u) = u^5 - 1$. Over the field of rational numbers, the complete factorization of $p(u)$ is $(u-1)\times(u^4+u^3+u^2+u+1)$ by exercise 4.6.2–32, so the tensor rank is $10-2=8$. On the other hand, the complete factorization over the real numbers, in terms of the number $\phi = \frac{1}{2}(1+\sqrt{5})$, is $(u-1)(u^2+\phi u+1)(u^2-\phi^{-1}u+1)$; thus, the rank is only 7, if we allow arbitrary real numbers to appear in A, B, C. Over the complex numbers the rank is 5. This phenomenon does not occur in two-dimensional tensors (i.e., matrices), where the rank can be determined by evaluating determinants of submatrices and testing for 0. The rank of a matrix does not change when the field containing its elements is embedded in a larger field, but the rank of a tensor *can* decrease when the field gets larger.

In the paper that introduced Theorem W [*Math. Systems Theory* **10** (1977), 169–180], Winograd went on to show that *all* realizations of (69) in $2n-q$ chain multiplications correspond to the use of (57), when q is greater than 1. Furthermore he has shown that the only way to evaluate the coefficients of $x(u)y(u)$ in $\deg(x)+\deg(y)+1$ chain multiplications is to use interpolation or to use (56) with a polynomial that splits into distinct linear factors in the field. Finally he has proved that the only way to evaluate $x(u)y(u) \bmod p(u)$ in $2n-1$ chain multiplications when $q=1$ is essentially to use (58). These results hold for *all* polynomial chains, not only "normal" ones. He has extended the results to multivariate polynomials in *SIAM J. Computing* **9** (1980), 225–229.

The tensor rank of an arbitrary $m \times n \times 2$ tensor in a suitably large field has been determined by Joseph Ja'Ja', *SIAM J. Computing* **8** (1979), 443–462.

For further reading. In this section we have barely scratched the surface of a very large subject in which many beautiful theories are emerging; a considerably more comprehensive treatment appears in the book *Computational Complexity of Algebraic and Numeric Problems* by A. Borodin and I. Munro (New York: American Elsevier, 1975).

EXERCISES

1. [*15*] What is a good way to evaluate an "odd" polynomial

$$u(x) = u_{2n+1}x^{2n+1} + u_{2n-1}x^{2n-1} + \cdots + u_1x?$$

▶ **2.** [*M20*] Instead of computing $u(x+x_0)$ by steps H1 and H2 as in the text, discuss the application of Horner's rule (2) when *polynomial* multiplication and addition are used instead of arithmetic in the domain of coefficients.

3. [*20*] Give a method analogous to Horner's rule, for evaluating a polynomial in two variables $\sum_{i+j\le n} u_{ij}x^iy^j$. (This polynomial has $(n+1)(n+2)/2$ coefficients, and "total degree" n.) Count the number of additions and multiplications you use.

4. [*M20*] The text shows that scheme (3) is superior to Horner's rule when we are evaluating a polynomial with real coefficients at a complex point z. Compare (3) to Horner's rule when *both* the coefficients and the variable z are complex numbers; how many (real) multiplications and addition-subtractions are required by each method?

5. [*M15*] Count the number of multiplications and additions required by the second-order rule (4).

6. [*22*] (L. de Jong and J. van Leeuwen.) Show how to improve on steps S1, ..., S4 of the Shaw–Traub algorithm by computing only about $\frac{1}{2}n$ powers of x_0.

7. [*M24*] How can $\beta_0, \ldots, \beta_n$ be calculated so that (6) has the value $u(x_0 + kh)$ for all integers k?

8. [*M20*] The factorial power $x^{\underline{k}}$ is defined to be $k!\binom{x}{k} = x(x-1)\ldots(x-k+1)$. Explain how to evaluate $u_n x^{\underline{n}} + \cdots + u_1 x^{\underline{1}} + u_0$ with at most n multiplications and $2n-1$ additions, starting with x and the $n+3$ constants $u_n, \ldots, u_0, 1, n-1$.

9. [*M24*] (H. J. Ryser.) Show that if $X = (x_{ij})$ is an $n \times n$ matrix, then

$$\operatorname{per}(X) = \sum (-1)^{n-\epsilon_1-\cdots-\epsilon_n} \prod_{1\le i\le n} \sum_{1\le j\le n} \epsilon_j x_{ij}$$

summed over all 2^n choices of $\epsilon_1, \ldots, \epsilon_n$ equal to 0 or 1 independently. Count the number of addition and multiplication operations required to evaluate $\operatorname{per}(X)$ by this formula.

10. [*M21*] The permanent of an $n \times n$ matrix $X = (x_{ij})$ may be calculated as follows: Start with the n quantities $x_{11}, x_{12}, \ldots, x_{1n}$. For $1 \le k < n$, assume that the $\binom{n}{k}$ quantities A_{kS} have been computed, for all k-element subsets S of $\{1, 2, \ldots, n\}$, where $A_{kS} = \sum x_{1j_1} \ldots x_{kj_k}$ summed over all $k!$ permutations $j_1 \ldots j_k$ of the elements of S; then form all of the sums

$$A_{(k+1)S} = \sum_{j\in S} A_{k(S\setminus\{j\})}\, x_{(k+1)j}.$$

We have $\operatorname{per}(X) = A_{n\{1,\ldots,n\}}$.

How many additions and multiplications does this method require? How much temporary storage is needed?

11. [*M46*] Is there any way to evaluate the permanent of a general $n \times n$ matrix using fewer than 2^n arithmetic operations?

12. [*M50*] What is the minimum number of multiplications required to form the product of two $n \times n$ matrices? What is the smallest exponent β such that $O(n^{\beta+\epsilon})$ multiplications are sufficient for all $\epsilon > 0$?

13. [*M23*] Find the inverse of the general discrete Fourier transform (37), by expressing $F(t_1, \ldots, t_n)$ in terms of the values of $f(s_1, \ldots, s_n)$. [*Hint:* See Eq. 1.2.9–13.]

▶ **14.** [*HM28*] (*"Fast Fourier transforms."*) Show that the scheme (40) can be used to evaluate the one-dimensional discrete Fourier transform

$$f(s) = \sum_{0\le t<2^n} F(t)\,\omega^{st}, \qquad \omega = e^{2\pi i/2^n}, \qquad 0 \le s < 2^n,$$

using arithmetic on complex numbers. Estimate the number of arithmetic operations performed.

▸ **15.** [*HM28*] The nth *divided difference* $f(x_0, x_1, \ldots, x_n)$ of a function $f(x)$ at $n+1$ distinct points x_0, x_1, $\ldots$, x_n is defined by the formula

$$f(x_0, x_1, \ldots, x_n) = (f(x_0, x_1, \ldots, x_{n-1}) - f(x_1, \ldots, x_{n-1}, x_n))/(x_0 - x_n),$$

for $n > 0$. Thus $f(x_0, x_1, \ldots, x_n) = \sum_{0\le k\le n} f(x_k)/\prod_{0\le j\le n,\, j\ne k}(x_k - x_j)$ is a symmetric function of its $n+1$ arguments. (a) Prove that $f(x_0, \ldots, x_n) = f^{(n)}(\theta)/n!$, for some θ between $\min(x_0, \ldots, x_n)$ and $\max(x_0, \ldots, x_n)$, if the nth derivative $f^{(n)}(x)$ exists and is continuous. [*Hint:* Prove the identity

$$f(x_0, x_1, \ldots, x_n) = \int_0^1 dt_1 \int_0^{t_1} dt_2 \ldots \int_0^{t_{n-1}} dt_n f^{(n)}(x_0(1-t_1) + x_1(t_1-t_2) + \cdots + x_{n-1}(t_{n-1}-t_n) + x_n(t_n-0)).$$

This formula also defines $f(x_0, x_1, \ldots, x_n)$ in a useful manner when the x_j are not distinct.] (b) If $y_j = f(x_j)$, show that $\alpha_j = f(x_0, \ldots, x_j)$ in Newton's interpolation polynomial (42).

16. [*M22*] How can we readily compute the coefficients of $u^{[n]}(x) = u_n x^n + \cdots + u_0$, if we are given the values of x_0, x_1, $\ldots$, x_{n-1}, α_0, α_1, $\ldots$, α_n in Newton's interpolation polynomial (42)?

17. [*M45*] Is there a way to evaluate the polynomial

$$\sum_{1\le i<j\le n} x_i x_j = x_1 x_2 + \cdots + x_{n-1} x_n$$

with fewer than $n-1$ multiplications and $2n-4$ additions? (There are $\binom{n}{2}$ terms.)

18. [*M20*] If the fourth-degree scheme (9) were changed to

$$y = (x + \alpha_0)x + \alpha_1, \qquad u(x) = ((y - x + \alpha_2)y + \alpha_3)\alpha_4,$$

what formulas for computing the α_j's in terms of the u_k's would take the place of (10)?

▸ **19.** [*M24*] Explain how to determine the adapted coefficients α_0, α_1, $\ldots$, α_5 in (11) from the coefficients u_5, $\ldots$, u_1, u_0 of $u(x)$, and find the α's for the particular polynomial $u(x) = x^5 + 5x^4 - 10x^3 - 50x^2 + 13x + 60$.

▸ **20.** [*21*] Write a MIX program that evaluates a fifth-degree polynomial according to scheme (11); try to make the program as efficient as possible, by making slight modifications to (11). Use MIX's floating point arithmetic operators FADD and FMUL, which are described in Section 4.2.1.

21. [*20*] Find two additional ways to evaluate the polynomial $x^6 + 13x^5 + 49x^4 + 33x^3 - 61x^2 - 37x + 3$ by scheme (12), using the two roots of (15) that were not considered in the text.

22. [*18*] What is the scheme for evaluating $x^6 - 3x^5 + x^4 - 2x^3 + x^2 - 3x - 1$, using Pan's method (16)?

23. [*HM30*] (J. Eve.) Let $f(z) = a_n z^n + a_{n-1}z^{n-1} + \cdots + a_0$ be a polynomial of degree n with real coefficients, having at least $n-1$ roots with a nonnegative real part. Let

$$g(z) = a_n z^n + a_{n-2}z^{n-2} + \cdots + a_{n \bmod 2}\, z^{n \bmod 2},$$
$$h(z) = a_{n-1}z^{n-1} + a_{n-3}z^{n-3} + \cdots + a_{(n-1) \bmod 2}\, z^{(n-1) \bmod 2}.$$

Assume that $h(z)$ is not identically zero.

a) Show that $g(z)$ has at least $n-2$ imaginary roots (i.e., roots whose real part is zero), and $h(z)$ has at least $n-3$ imaginary roots. [*Hint:* Consider the number of times the path $f(z)$ circles the origin as z goes around the path shown in Fig. 15, for a sufficiently large radius R.]

b) Prove that the squares of the roots of $g(z) = 0$ and $h(z) = 0$ are all real.

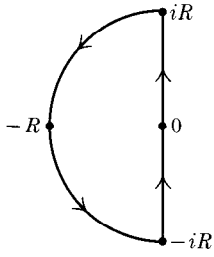


Fig. 15. Proof of Eve's theorem.

▸ **24.** [*M24*] Find values of c and α_k, β_k satisfying the conditions of Theorem E, for the polynomial $u(x) = (x+7)(x^2+6x+10)(x^2+4x+5)(x+1)$. Choose these values so that $\beta_2 = 0$. Give two different solutions to this problem!

25. [*M20*] When the construction in the proof of Theorem M is applied to the (inefficient) polynomial chain

$$\lambda_1 = \alpha_1 + \lambda_0, \quad \lambda_2 = -\lambda_0 - \lambda_0, \quad \lambda_3 = \lambda_1 + \lambda_1, \quad \lambda_4 = \alpha_2 \times \lambda_3,$$
$$\lambda_5 = \lambda_0 - \lambda_0, \quad \lambda_6 = \alpha_6 - \lambda_5, \quad \lambda_7 = \alpha_7 + \lambda_6, \quad \lambda_8 = \lambda_7 \times \lambda_7,$$
$$\lambda_9 = \lambda_1 \times \lambda_4, \quad \lambda_{10} = \alpha_8 - \lambda_9, \quad \lambda_{11} = \lambda_3 - \lambda_{10},$$

how can $\beta_1, \beta_2, \ldots, \beta_9$ be expressed in terms of $\alpha_1, \ldots, \alpha_8$?

▸ **26.** [*M21*] (a) Give the polynomial chain corresponding to Horner's rule for evaluating polynomials of degree $n = 3$. (b) Using the construction that appears in the text's proof of Theorem A, express κ_1, κ_2, κ_3, and the result polynomial $u(x)$ in terms of β_1, β_2, β_3, β_4, and x. (c) Show that the result set obtained in (b), as β_1, β_2, β_3, and β_4 independently assume all real values, omits certain vectors in the result set of (a).

27. [*M22*] Let R be a set that includes all $(n+1)$-tuples $(q_n, \ldots, q_1, q_0)$ of real numbers such that $q_n \neq 0$; prove that R does not have at most n degrees of freedom.

28. [*HM20*] Show that if $f_0(\alpha_1, \ldots, \alpha_s)$, $\ldots$, $f_s(\alpha_1, \ldots, \alpha_s)$ are multivariate polynomials with integer coefficients, then there is a nonzero polynomial $g(x_0, \ldots, x_s)$ with integer coefficients such that $g(f_0(\alpha_1, \ldots, \alpha_s), \ldots, f_s(\alpha_1, \ldots, \alpha_s)) = 0$ for all real α_1, $\ldots$, α_s. (Hence any polynomial chain with s parameters has at most s degrees of freedom.) [*Hint:* Use the theorems about "algebraic dependence" that are found, for example, in B. L. van der Waerden's *Modern Algebra*, tr. by Fred Blum (New York: Ungar, 1949), Section 64.]

▶ **29.** [*M20*] Let R_1, R_2, ..., R_m all be sets of $(n+1)$-tuples of real numbers having at most t degrees of freedom. Show that the union $R_1 \cup R_2 \cup \cdots \cup R_m$ also has at most t degrees of freedom.

▶ **30.** [*M28*] Prove that a polynomial chain with m_c chain multiplications and m_p parameter multiplications has at most $2m_c + m_p + \delta_{0m_c}$ degrees of freedom. [*Hint:* Generalize Theorem M, showing that the first chain multiplication and each parameter multiplication can essentially introduce only one new parameter into the result set.]

31. [*M23*] Prove that a polynomial chain capable of computing all *monic* polynomials of degree n has at least $\lfloor n/2 \rfloor$ multiplications and at least n addition-subtractions.

32. [*M24*] Find a polynomial chain of minimum possible length that can compute all polynomials of the form $u_4x^4 + u_2x^2 + u_0$; and prove that its length is minimal.

▶ **33.** [*M25*] Let $n \geq 3$ be odd. Prove that a polynomial chain with $\lfloor n/2 \rfloor + 1$ multiplication steps cannot compute all polynomials of degree n unless it has at least $n+2$ addition-subtraction steps. [*Hint:* See exercise 30.]

34. [*M26*] Let λ_0, λ_1, ..., λ_r be a polynomial chain in which all of the addition and subtraction steps are parameter steps, and in which there is at least one parameter multiplication. Assume that this scheme has m multiplications and $k = r - m$ addition-subtractions, and that the polynomial computed by the chain has maximum degree n. Prove that all polynomials computable by this chain, for which the coefficient of x^n is not zero, can be computed by another chain that has at most m multiplications and at most k additions, and no subtractions; and whose last step is the only parameter multiplication.

▶ **35.** [*M25*] Show that any polynomial chain that computes a general fourth-degree polynomial using three multiplications must have at least five addition-subtractions. [*Hint:* Assume that there are only four addition-subtractions, and show that exercise 34 applies; this means the scheme must have a particular form that is incapable of representing all fourth-degree polynomials.]

36. [*M27*] Show that any polynomial chain that computes a general sixth-degree polynomial using only four multiplications must have at least seven addition-subtractions. (Cf. exercise 35.)

37. [*M21*] (T. S. Motzkin.) Show that "almost all" rational functions of the form

$$(u_nx^n + u_{n-1}x^{n-1} + \cdots + u_1x + u_0)/(x^n + v_{n-1}x^{n-1} + \cdots + v_1x + v_0),$$

with coefficients in a field S, can be evaluated using the scheme

$$\alpha_1 + \beta_1/(x + \alpha_2 + \beta_2/(x + \cdots + \beta_n/(x + \alpha_{n+1})\ldots)),$$

for suitable α_j, β_j in S. (This continued fraction scheme has n divisions and $2n$ additions; by "almost all" rational functions we mean all except those whose coefficients satisfy some nontrivial polynomial equation.) Determine the α's and β's for the rational function $(x^2 + 10x + 29)/(x^2 + 8x + 19)$.

▸ **38.** [*HM32*] (V. Îa. Pan, 1962.) The purpose of this exercise is to prove that Horner's rule is really optimal if no preliminary adaptation of coefficients is made; we need n multiplications and n additions to compute $u_n x^n + \cdots + u_1 x + u_0$, if the variables u_n, $\ldots$, u_1, u_0, x, and arbitrary constants are given. Consider chains that are as before except that u_n, $\ldots$, u_1, u_0, x are each considered to be variables; we may say, for example, that $\lambda_{-j-1} = u_j$, $\lambda_0 = x$. In order to show that Horner's rule is best, it is convenient to prove a somewhat more general theorem: Let $A = (a_{ij})$, $0 \le i \le m$, $0 \le j \le n$, be an $(m+1) \times (n+1)$ matrix of real numbers, of rank $n+1$; and let $B = (b_0, \ldots, b_m)$ be a vector of real numbers. Prove that *any polynomial chain that computes*

$$P(x; u_0, \ldots, u_n) = \sum_{0 \le i \le m} (a_{i0}u_0 + \cdots + a_{in}u_n + b_i)x^i$$

involves at least n chain multiplications. (Note that this does not mean only that we are considering some fixed chain in which the parameters α_j are assigned values depending on A and B; it means that both the chain *and* the values of the α's may depend on the given matrix A and vector B. No matter how A, B, and the values of α_j are chosen, it is impossible to compute $P(x; u_0, \ldots, u_n)$ without doing n "chain-step" multiplications.) The assumption that A has rank $n+1$ implies that $m \ge n$. [*Hint:* Show that from any such scheme we can derive another that has fewer chain multiplications and that has n decreased by one.]

39. [*M29*] (T. S. Motzkin, 1954.) Show that schemes of the form $w_1 = x(x+\alpha_1)+\beta_1$, $w_k = w_{k-1}(w_1 + \gamma_k x + \alpha_k) + \delta_k x + \beta_k$ for $1 < k \le m$, where the α_k, β_k are real and the γ_k, δ_k are integers, can be used to evaluate all monic polynomials of degree $2m$ over the real numbers. (We may have to choose α_k, β_k, γ_k, and δ_k differently for different polynomials.) Try to let $\delta_k = 0$ whenever possible.

40. [*M41*] Can the lower bound in the number of multiplications in Theorem C be raised from $\lfloor n/2 \rfloor + 1$ to $\lceil n/2 \rceil + 1$? (Cf. exercise 33.)

41. [*22*] Show that the real and imaginary parts of $(a + bi)(c + di)$ can be obtained by doing 3 multiplications and 5 additions of real numbers, where two of the additions involve a and b only.

42. [*36*] (M. Paterson and L. Stockmeyer.) (a) Prove that a polynomial chain with $m \ge 2$ chain multiplications has at most $m^2 + 1$ degrees of freedom. (b) Show that for all $n \ge 2$ there exist polynomials of degree n, all of whose coefficients are 0 or 1, that cannot be evaluated by any polynomial chain with fewer than $\lfloor \sqrt{n} \rfloor$ multiplications, if we require all parameters α_j to be integers. (c) Show that any polynomial of degree n with integer coefficients can be evaluated by an all-integer algorithm that performs at most $2\lfloor \sqrt{n} \rfloor$ multiplications, if we don't care how many additions we do.

43. [*22*] Explain how to evaluate $x^n + \cdots + x + 1$ with $2l(n+1) - 2$ multiplications and $l(n+1)$ additions (no divisions or subtractions), where $l(n)$ is the function studied in Section 4.6.3.

▸ **44.** [*HM22*] Let (t_{ijk}) be an $m \times n \times s$ tensor, and let F, G, H be nonsingular matrices of respective sizes $m \times m$, $n \times n$, $s \times s$. If

$$T_{ijk} = \sum_{1 \le p \le m} \sum_{1 \le q \le n} \sum_{1 \le r \le s} F_{ip} G_{jq} H_{kr} t_{pqr}$$

for all i, j, k, prove that the tensor (T_{ijk}) has the same rank as (t_{ijk}). [*Hint:* Consider what happens when F^{-1}, G^{-1}, H^{-1} are applied in the same way to (T_{ijk}).]

45. [*M28*] Prove that all pairs (z_1, z_2) of bilinear forms in (x_1, x_2) and (y_1, y_2) can be evaluated with at most three chain multiplications. In other words, show that every $2 \times 2 \times 2$ tensor has rank ≤ 3.

46. [*M25*] Prove that for all m, n, and s there exists an $m \times n \times s$ tensor whose rank is at least $\lceil mns/(m+n+s) \rceil$. Conversely, show that every $m \times n \times s$ tensor has rank at most $mns/\max(m, n, s)$.

47. [*M48*] Is it possible to determine the rank of any given tensor (t_{ijk}) over, say, the field of rational numbers, in a finite number of steps? (There is a finite way to compute the tensor rank over algebraically closed fields like the complex numbers, since this is a special case of the results of Alfred Tarski, *A Decision Method for Elementary Algebra and Geometry*, 2nd ed. (Berkeley, California: Univ. of California Press, 1951); but the known algorithms do not make this computation really feasible except for very small tensors. Over the field of rational numbers, the problem isn't even known to be solvable in finite time.)

48. [*M49*] If (t_{ijk}) and (t'_{ijk}) are tensors of sizes $m \times n \times s$ and $m' \times n' \times s'$, respectively, their *direct sum* $(t_{ijk}) \oplus (t'_{ijk}) = (t''_{ijk})$ is the $(m+m') \times (n+n') \times (s+s')$ tensor defined by $t''_{ijk} = t_{ijk}$ if $i \leq m$, $j \leq n$, $k \leq s$; $t''_{ijk} = t'_{i-m,j-n,k-s}$ if $i > m$, $j > n$, $k > s$; and $t''_{ijk} = 0$ otherwise. Their direct product $(t_{ijk}) \otimes (t'_{ijk}) = (t'''_{ijk})$ is the $mm' \times nn' \times ss'$ tensor defined by $t_{\langle ii' \rangle \langle jj' \rangle \langle kk' \rangle} = t_{ijk} t'_{i'j'k'}$. Derive the upper bounds $\operatorname{rank}(t''_{ijk}) \leq \operatorname{rank}(t_{ijk}) + \operatorname{rank}(t'_{ijk})$ and $\operatorname{rank}(t'''_{ijk}) \leq \operatorname{rank}(t_{ijk}) \cdot \operatorname{rank}(t'_{ijk})$.

▸ **49.** [*HM25*] Show that the rank of an $m \times n \times 1$ tensor (t_{ijk}) is the same as its rank as an $m \times n$ matrix (t_{ij1}), according to the traditional definition of matrix rank as the maximum number of linearly independent rows.

50. [*HM20*] (S. Winograd.) Let (t_{ijk}) be the $mn \times n \times m$ tensor corresponding to multiplication of an $m \times n$ matrix by an $n \times 1$ column vector. Prove that the rank of (t_{ijk}) is mn.

▸ **51.** [*M24*] (S. Winograd.) Devise an algorithm for cyclic convolution of degree 2 that uses 2 multiplications and 4 additions, not counting operations on the x_i. Similarly, devise an algorithm for degree 3, using 4 multiplications and 11 additions. (Cf. (67), which solves the analogous problem for degree 4.)

52. [*M25*] (S. Winograd.) Let $n = n'n''$ where $\gcd(n', n'') = 1$. Given normal schemes for cyclic convolutions of degrees n' and n'', using respectively (m', m'') chain multiplications, (p', p'') parameter multiplications, and (a', a'') additions, show how to construct a normal scheme for cyclic convolution of degree n using $m'm''$ chain multiplications, $p'n'' + m'p''$ parameter multiplications, and $a'n'' + m'a''$ additions.

53. [*HM40*] (S. Winograd.) Let ω be a complex mth root of unity, and consider the one-dimensional discrete Fourier transform

$$f(s) = \sum_{1 \leq t \leq m} F(t)\omega^{st}, \qquad \text{for } 1 \leq s \leq m.$$

(a) When $m = p^e$ is a power of an odd prime, show that efficient normal schemes for computing cyclic convolutions of degrees $(p-1)p^k$, for $0 \leq k < e$, will lead to efficient algorithms for computing the Fourier transform on m complex numbers. Give a similar construction for the case $p = 2$. (b) When $m = m'm''$ and $\gcd(m', m'') = 1$, show that Fourier transformation algorithms for m' and m'' can be combined to yield a Fourier transformation algorithm for m elements.

54. [*M23*] Theorem W refers to an infinite field. How many elements must a finite field have in order for the proof of Theorem W to be valid?

55. [*HM22*] Determine the rank of tensor (72) when P is an *arbitrary* $n \times n$ matrix.

56. [*M32*] (V. Strassen.) Show that any polynomial chain that evaluates a set of *quadratic forms* $\sum_{1\le i,j\le n} \tau_{ijk}x_ix_k$ for $1 \le k \le s$ must use at least $\frac{1}{2}\text{rank}(\tau_{ijk}+\tau_{jik})$ chain multiplications. [*Hint:* Show that the minimum number of chain multiplications is the minimum rank of (t_{ijk}) taken over all tensors (t_{ijk}) such that $t_{ijk}+t_{jik} = \tau_{ijk}+\tau_{jik}$ for all i, j, k.] Use this to prove that any polynomial chain that evaluates a set of bilinear forms (45) corresponding to a tensor (t_{ijk}), whether normal or abnormal, must use at least $\frac{1}{2}\text{rank}(t_{ijk})$ chain multiplications.

57. [*M20*] Show that fast Fourier transforms can be used to compute the coefficients of the product $x(u)y(u)$ of two given polynomials of degree n, using $O(n \log n)$ operations of (exact) addition and multiplication of complex numbers. [*Hint:* Consider the product of Fourier transforms of the coefficients.]

58. [*HM28*] (a) Show that any realization A, B, C of the polynomial multiplication tensor (53) must have the following property: Any nonzero linear combination of the three rows of A must be a vector with at least four nonzero elements; and any nonzero linear combination of the four rows of B must have at least three nonzero elements. (b) Find a realization A, B, C of (53) using only 0, $+1$, and -1 as elements, where $t = 8$. Try to use as many 0's as possible.

▶ **59.** [*M40*] (**H. J. Nussbaumer, 1980.**) The text defines the cyclic convolution of two sequences $(x_0, x_1, \ldots, x_{n-1})$ and $(y_0, y_1, \ldots, y_{n-1})$ to be the sequence $(z_0, z_1, \ldots, z_{n-1})$ where $z_k = x_0y_k + \cdots + x_ky_0 + x_{k+1}y_{n-1} + \cdots + x_{n-1}y_{k+1}$. Let us define the *negacyclic convolution* similarly, but with

$$z_k = x_0y_k + \cdots + x_ky_0 - (x_{k+1}y_{n-1} + \cdots + x_{n-1}y_{k+1}).$$

Construct efficient algorithms for cyclic and negacyclic convolution over the integers when n is a power of 2. Your algorithms should deal entirely with integers, and they should perform at most $O(n \log n)$ multiplications and at most $O(n \log n \log\log n)$ additions or subtractions or divisions of even numbers by 2.

60. [*M27*] (V. Îa. Pan.) The problem of $(m \times n)$ times $(n \times s)$ matrix multiplication corresponds to an $mn \times ns \times sm$ tensor $(t_{\langle i,j'\rangle\langle j,k'\rangle\langle k,i'\rangle})$ where $t_{\langle i,j'\rangle\langle j,k'\rangle\langle k,i'\rangle} = 1$ if and only $i' = i$ and $j' = j$ and $k' = k$. The rank of this tensor $T(m,n,s)$ is the smallest r such that numbers $a_{ij'l}$, $b_{jk'l}$, $c_{ki'l}$ exist satisfying

$$\sum_{\substack{1\le i\le m\\1\le j\le n\\1\le k\le s}} x_{ij}\,y_{jk}\,z_{ki} = \sum_{1\le l\le r}\Bigg(\sum_{\substack{1\le i\le m\\1\le j'\le n}} a_{ij'l}\,x_{ij'}\Bigg)\Bigg(\sum_{\substack{1\le j\le n\\1\le k'\le s}} b_{jk'l}\,y_{jk'}\Bigg)\Bigg(\sum_{\substack{1\le k\le s\\1\le i'\le m}} c_{ki'l}\,z_{ki'}\Bigg).$$

Let $M(n)$ be the rank of $T(n,n,n)$. The purpose of this exercise is to exploit the symmetry of such a trilinear representation, obtaining efficient realizations of matrix multiplication over the integers when $m = n = s = 2\nu$. For convenience we divide the indices $\{1,\ldots,n\}$ into two subsets $O = \{1,3,\ldots,n-1\}$ and $E = \{2,4,\ldots,n\}$ of ν elements each, and we set up a one-to-one correspondence between O and E by the rule $\tilde{\imath} = i+1$ if $i \in O$; $\tilde{\imath} = i-1$ if $i \in E$. Thus we have $\tilde{\tilde{\imath}} = i$ for all indices i.

a) The first construction is based on the identity

$$abc + ABC = (a+A)(b+B)(c+C) - (a+A)bC - A(b+B)c - aB(c+C).$$

It follows that

$$\sum_{1\le i,j,k\le n} x_{ij}\,y_{jk}\,z_{ki} = \sum_{(i,j,k)\in S} (x_{ij}+x_{\bar{k}\tilde{\imath}})(y_{jk}+y_{\tilde{\imath}\bar{\jmath}})(z_{ki}+z_{\bar{\jmath}\bar{k}}) - \Sigma_1 - \Sigma_2 - \Sigma_3,$$

where $S = E\times E\times E \cup E\times E\times O \cup E\times O\times E \cup O\times E\times E$ is the set of all triples of indices containing at most one odd index; Σ_1 is the sum of all terms of the form $(x_{ij}+x_{\bar{k}\tilde{\imath}})y_{jk}\,z_{\bar{\jmath}\bar{k}}$ for $(i,j,k)\in S$; and Σ_2, Σ_3 similarly are sums of the terms $x_{\bar{k}\tilde{\imath}}(y_{jk}+y_{\tilde{\imath}\bar{\jmath}})z_{ki}$, $x_{ij}\,y_{\tilde{\imath}\bar{\jmath}}(z_{ki}+z_{\bar{\jmath}\bar{k}})$. Clearly S has $4\nu^3 = \frac{1}{2}n^3$ terms. Show that each of Σ_1, Σ_2, Σ_3 can be realized as the sum of $3\nu^2$ trilinear terms; furthermore, if the 3ν triples of the forms $(i,i,\tilde{\imath})$ and $(i,\tilde{\imath},i)$ and $(\tilde{\imath},i,i)$ are removed from S, we can modify Σ_1, Σ_2, and Σ_3 in such a way that the identity is still valid, without adding any new trilinear terms. Thus $M(n) \le \frac{1}{2}n^3 - \frac{3}{2}n + \frac{9}{4}n^2$ when n is even.

b) Apply the method of (a) to show that two *independent* matrix multiplication problems of size $m\times n\times s$ can be performed with $mns + mn + ns + sm$ noncommutative multiplications.

c) The second construction is based on the identity

$$\begin{aligned} abc + ABC + \mathcal{A}\mathcal{B}\mathcal{C} = {} & (a+A+\mathcal{A})(b+B+\mathcal{B})(c+C+\mathcal{C}) \\ & - (a\mathcal{B}(c+C+\mathcal{C}) + Ab(c+C+\mathcal{C}) + \mathcal{A}B(c+C+\mathcal{C})) \\ & - (a(b+B)C + A(B+\mathcal{B})\mathcal{C} + \mathcal{A}(\mathcal{B}+b)c) \\ & - ((a+\mathcal{A})b\mathcal{C} + (A+a)Bc + (\mathcal{A}+A)\mathcal{B}C) \\ & - (aB\mathcal{C} + A\mathcal{B}c + \mathcal{A}bC). \end{aligned}$$

Show that

$$\sum_{1\le i,j,k\le n} x_{ij}\,y_{jk}\,z_{ki} = \sum_{\substack{(i,j,k)\in S \\ 0\le\epsilon,\varsigma,\eta\le 1}} t(i,j,k;\epsilon,\varsigma,\eta) - \Sigma_1 - \Sigma_2 - \Sigma_3;$$

here $t(i,j,k;\epsilon,\varsigma,\eta) = ((-1)^{\varsigma+\eta}x_{i+\epsilon,j+\varsigma} + (-1)^{\epsilon+\varsigma}x_{j+\eta,k+\epsilon} + (-1)^{\eta+\epsilon}x_{k+\varsigma,i+\eta})\cdot((-1)^{\eta+\epsilon}y_{j+\varsigma,k+\eta} + (-1)^{\varsigma+\eta}y_{k+\epsilon,i+\varsigma} + (-1)^{\epsilon+\varsigma}y_{i+\eta,j+\epsilon})\cdot((-1)^{\epsilon+\varsigma}z_{k+\eta,i+\epsilon} + (-1)^{\eta+\epsilon}z_{i+\varsigma,j+\eta} + (-1)^{\varsigma+\eta}z_{j+\epsilon,k+\varsigma})$ corresponds to the first term on the right-hand side of the above identity and Σ_1, Σ_2, Σ_3 correspond respectively to the next three groups of terms; the remaining terms (namely those corresponding to $aB\mathcal{C} + A\mathcal{B}c + \mathcal{A}bC$) cancel out of the sum. The set S in this case is different from the S in part (a); it consists of all $(i,j,k)\in O\times O\times O$ such that $i\le j$ and $i<k$. It follows from this construction that $M(n) \le \frac{8}{3}((\frac{n}{2})^3 - (\frac{n}{2})) + 6n^2$ when n is even.

61. [*M23*] Let (t_{ijk}) be a tensor over an arbitrary field. We define $\operatorname{rank}_d(t_{ijk})$ as the minimum value of r such that there is a realization of the form

$$\sum_{1\le l\le r} a_{il}(u)b_{jl}(u)c_{kl}(u) = t_{ijk}u^d + O(u^{d+1}),$$

where $a_{il}(u)$, $b_{jl}(u)$, $c_{kl}(u)$ are polynomials in u over the field. Thus rank_0 is the ordinary rank of a tensor. Prove that (a) $\operatorname{rank}_{d+1}(t_{ijk}) \le \operatorname{rank}_d(t_{ijk})$; (b) $\operatorname{rank}(t_{ijk}) \le \binom{d+2}{2}\operatorname{rank}_d(t_{ijk})$; (c) $\operatorname{rank}_d((t_{ijk})\oplus(t'_{ijk})) \le \operatorname{rank}_d(t_{ijk}) + \operatorname{rank}_d(t'_{ijk})$, in the sense of exercise 48; (d) $\operatorname{rank}_{d+d'}((t_{ijk})\otimes(t'_{ijk})) \le \operatorname{rank}_d(t_{ijk})\cdot\operatorname{rank}_{d'}(t'_{ijk})$.

62. [*M24*] The *border rank* of (t_{ijk}), denoted by $\underline{\text{rank}}(t_{ijk})$, is $\min_{d\ge 0} \text{rank}_d(t_{ijk})$, where rank_d is defined in exercise 61. Prove that the tensor $\left(\begin{smallmatrix}1&0\\0&1\end{smallmatrix}\right)\left(\begin{smallmatrix}0&1\\0&0\end{smallmatrix}\right)$ has rank 3 but border rank 2, over every field.

63. [*M30*] Let $T(m,n,s)$ be the tensor for matrix multiplication as in exercise 59. (a) Show that $T(m,n,s)\otimes T(M,N,S) = T(mM,nN,sS)$. (b) If $T(m,n,s)$ has rank $\le r$, show that the number of noncommutative multiplications $M(N)$ for the product of $N\times N$ matrices is $O(N^{\beta(m,n,s,r)})$ as $N\to\infty$, where $\beta(m,n,s,r) = 3\log r/\log mns$. (c) If $T(m,n,s)$ has border rank $\le r$, show that we have $M(N) = O(N^{\beta(m,n,s,r)}(\log N)^2)$. (d) If the tensor $pT(m,n,s)$ obtained by taking the direct sum of p copies of $T(m,n,s)$ has border rank $\le pr$, where $p < r$, show that a similar formula holds. (This tensor corresponds to p independent matrix multiplications.)

64. [*M40*] (Pan and Winograd.) The purpose of this exercise is to combine the ideas of exercises 60–63, in order to obtain asymptotic bounds on $M(N)$ as $N\to\infty$.

a) Modify the construction of exercise 60(b) to show that $T(m,n,s)\oplus T(s,m,n)$ has border rank $\le mns + mn + ns$.

b) Show that the construction of exercise 60(c) can be altered to prove that the border rank of $T(m,n,2s)\oplus T(2n,s,m)\oplus T(s,2m,n)$ is at most $2(m+1)n(s+2)$, by finding constants α_1, α_2, …, α_6 such that

$$\begin{aligned}
u^{2d}\sum_{i,j,k,\sigma}&(x_{ij}y_{j\tilde{k}}z_{\tilde{k}i} + X_{\tilde{\jmath}k}Y_{ki}Z_{i\tilde{\jmath}} + \mathcal{X}_{k\tilde{\imath}}\mathcal{Y}_{\tilde{\imath}j}Z_{jk})\\
&\equiv \sum_{i,j,k,\sigma}(\sigma x_{ij} + u^d X_{\tilde{\jmath}k} + \sigma u^{d+2}\mathcal{X}_{k\tilde{\imath}})(\sigma u^{d-1}y_{j\tilde{k}} + \sigma u^d Y_{ki} + \mathcal{Y}_{\tilde{\imath}j})\\
&\qquad\qquad\times(u^{d+1}z_{\tilde{k}i} + \sigma Z_{i\tilde{\jmath}} + \sigma u^{d-2}Z_{jk})\\
&+\alpha_2\sum_{i,j,\sigma}(\alpha_1\sigma x_{ij} + \sigma u^{d+2}\textstyle\sum_k \mathcal{X}_{k\tilde{\imath}})(\alpha_1\mathcal{Y}_{\tilde{\imath}j} + \sigma u^d\sum_k Y_{ki})\\
&\qquad\qquad\times(\alpha_1\sigma Z_{i\tilde{\jmath}} + u^{d+1}\textstyle\sum_k z_{\tilde{k}i})\\
&+\alpha_3\sum_{i,j,\sigma}(\sigma x_{ij} + u^d\textstyle\sum_k X_{\tilde{\jmath}k})(\mathcal{Y}_{\tilde{\imath}j} + \sigma u^{d-1}\sum_k y_{j\tilde{k}})\\
&\qquad\qquad\times(\sigma Z_{i\tilde{\jmath}} + \sigma u^{d-2}\textstyle\sum_k Z_{jk})\\
&+\alpha_4\sum_{j,k,\sigma}(\sigma\textstyle\sum_i x_{ij} + u^d X_{\tilde{\jmath}k})(\sum_i \mathcal{Y}_{\tilde{\imath}j} + \sigma u^{d-1}y_{j\tilde{k}})\\
&\qquad\qquad\times(\sigma\textstyle\sum_i Z_{i\tilde{\jmath}} + \sigma u^{d-2}Z_{jk})\\
&+\alpha_5\sum_{j,\sigma}(\sigma\textstyle\sum_i x_{ij} + u^d\sum_k X_{\tilde{\jmath}k})(\sum_i \mathcal{Y}_{\tilde{\imath}j} + \sigma u^{d-1}\sum_k y_{j\tilde{k}})\\
&\qquad\qquad\times(\sigma\textstyle\sum_i Z_{i\tilde{\jmath}} + \sigma u^{d-2}\sum_k Z_{jk})\\
&+\alpha_6\sum_{j,\sigma}(\sigma\textstyle\sum_i x_{ij})(\sum_i \mathcal{Y}_{\tilde{\imath}j})(\sigma\sum_i Z_{i\tilde{\jmath}})
\end{aligned}$$

(modulo u^{2d+1}), for sufficiently large d. Here the summations are to be carried out for $1\le i\le m$, $1\le j\le n$, $1\le k\le s$, and $\sigma = \pm 1$; the subscript $\tilde{\imath}$ means σi, so that $\tilde{\imath}$ takes the $2m$ values ± 1, …, $\pm m$.

c) Use the result of (b) in connection with exercise 63 to show that $M(N) = O(N^{\beta+\epsilon})$ for all $\epsilon > 0$, where $\beta = \beta(m,n,2s,\frac{2}{3}(m+1)n(s+2))$.

*4.7. MANIPULATION OF POWER SERIES

IF WE ARE GIVEN two power series

$$U(z) = U_0 + U_1 z + U_2 z^2 + \cdots, \qquad V(z) = V_0 + V_1 z + V_2 z^2 + \cdots, \tag{1}$$

whose coefficients belong to a field, we can form their sum, their product, their quotient, etc., to obtain new power series. A polynomial is obviously a special case of a power series, in which there are only finitely many terms.

Of course, only a finite number of terms can be represented and stored within a computer, so it makes sense to ask whether power series arithmetic is even possible on computers; and if it is possible, what makes it different from polynomial arithmetic? The answer is that we work with only the first N coefficients of the power series, where N is a parameter that may in principle be arbitrarily large; instead of ordinary polynomial arithmetic, we are essentially doing polynomial arithmetic modulo z^N, and this often leads to a somewhat different point of view. Furthermore, special operations like "reversion" can be performed on power series but not on polynomials, since polynomials are not closed under these operations.

Manipulation of power series has several applications to numerical analysis, but perhaps its greatest use is the determination of asymptotic expansions (as we have seen in Section 1.2.11.3), or the calculation of quantities defined by certain generating functions. The latter applications make it desirable to calculate the coefficients exactly, instead of with floating point arithmetic. All of the algorithms in this section, with obvious exceptions, can be done using rational operations only, so the techniques of Section 4.5.1 can be used to obtain exact results when desired.

The calculation of $W(z) = U(z) \pm V(z)$ is, of course, trivial, since we have $W_n = U_n \pm V_n$ for $n = 0, 1, 2, \ldots$. It is also easy to calculate $W(z) = U(z)V(z)$, using the familiar "Cauchy product rule":

$$W_n = \sum_{0 \le k \le n} U_k V_{n-k} = U_0 V_n + U_1 V_{n-1} + \cdots + U_n V_0. \tag{2}$$

The quotient $W(z) = U(z)/V(z)$, when $V_0 \neq 0$, can be obtained by interchanging U and W in (2); we obtain the rule

$$\begin{aligned} W_n &= \Bigg(U_n - \sum_{0 \le k < n} W_k V_{n-k} \Bigg) \Big/ V_0 \\ &= (U_n - W_0 V_n - W_1 V_{n-1} - \cdots - W_{n-1} V_1)/V_0. \end{aligned} \tag{3}$$

This recurrence relation for the W's makes it easy to determine $W_0, W_1, W_2, \ldots$ successively, without inputting U_n and V_n until after W_{n-1} has been computed. Let us say that a power series manipulation algorithm with the latter property is "on-line"; an on-line algorithm can be used to determine N coefficients $W_0, W_1, \ldots, W_{N-1}$ of the result without knowing N in advance, so it is possible in

theory to run the algorithm indefinitely and compute the entire power series; or to run it until a certain condition is met. (The opposite of "on-line" is "off-line.")

If the coefficients U_k and V_k are integers but the W_k are not, the recurrence relation (3) involves computation with fractions. This can be avoided by the all-integer approach described in exercise 2.

Let us now consider the operation of computing $W(z) = V(z)^\alpha$, where α is an "arbitrary" power. For example, we could calculate the square root of $V(z)$ by taking $\alpha = \frac{1}{2}$, or we could find $V(z)^{-10}$ or even $V(z)^\pi$. If V_m is the first nonzero coefficient of $V(z)$, we have

$$\begin{aligned} V(z) &= V_m z^m(1 + (V_{m+1}/V_m)z + (V_{m+2}/V_m)z^2 + \cdots), \\ V(z)^\alpha &= V_m^\alpha z^{\alpha m}(1 + (V_{m+1}/V_m)z + (V_{m+2}/V_m)z^2 + \cdots)^\alpha. \end{aligned} \tag{4}$$

This will be a power series if and only if αm is a nonnegative integer. From (4) we can see that the problem of computing general powers can be reduced to the case that $V_0 = 1$; then the problem is to find coefficients of

$$W(z) = (1 + V_1 z + V_2 z^2 + V_3 z^3 + \cdots)^\alpha. \tag{5}$$

Clearly $W_0 = 1^\alpha = 1$.

The obvious way to find the coefficients of (5) is to use the binomial theorem (Eq. 1.2.9–19), or (if α is a positive integer) to try repeated squaring as in Section 4.6.3; but a much simpler and more efficient device for calculating powers has been suggested by J. C. P. Miller. [See P. Henrici, *JACM* **3** (1956), 10–15.] If $W(z) = V(z)^\alpha$, we have by differentiation

$$W_1 + 2W_2 z + 3W_3 z^2 + \cdots = W'(z) = \alpha V(z)^{\alpha-1} V'(z); \tag{6}$$

therefore

$$W'(z)V(z) = \alpha W(z)V'(z). \tag{7}$$

If we now equate the coefficients of z^{n-1} in (7), we find that

$$\sum_{0 \le k \le n} k W_k V_{n-k} = \alpha \sum_{0 \le k \le n} (n-k) W_k V_{n-k}, \tag{8}$$

and this gives us a useful computational rule valid for all $n \ge 1$:

$$\begin{aligned} W_n &= \sum_{1 \le k \le n} \left(\left(\frac{\alpha+1}{n} \right) k - 1 \right) V_k W_{n-k} \\ &= \big((\alpha{+}1{-}n)V_1 W_{n-1} + (2\alpha{+}2{-}n)V_2 W_{n-2} + \cdots + n\alpha V_n\big)/n. \end{aligned} \tag{9}$$

This equation leads to a simple on-line algorithm by which we can successively determine W_1, W_2, ..., using approximately $2n$ multiplications to compute the nth coefficient. Note the special case $\alpha = -1$, in which (9) becomes the special case $U(z) = V_0 = 1$ of (3).

A similar technique can be used to form $f\big(V(z)\big)$ when f is any function that satisfies a simple differential equation. (For example, see exercise 4.) A comparatively straightforward "power series method" is often used to obtain the solution of differential equations; this technique is explained in nearly all textbooks about differential equations.

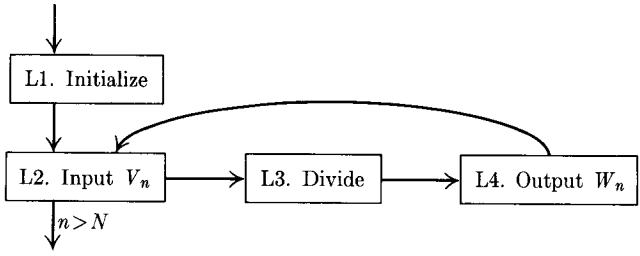

Fig. 16. Power series reversion by Algorithm L.

Reversion of series. The transformation of power series that is perhaps of greatest interest is called "reversion of series." This problem is to solve the equation

$$z = t + V_2t^2 + V_3t^3 + V_4t^4 + \cdots \tag{10}$$

for t, obtaining the coefficients of the power series

$$t = z + W_2z^2 + W_3z^3 + W_4z^4 + \cdots. \tag{11}$$

Several interesting ways to achieve such a reversion are known. We might say that the "classical" method is one based on Lagrange's remarkable inversion formula [*Mémoires Acad. Royale des Sciences et Belles-Lettres de Berlin* **24** (1768), 251–326], which states that

$$W_n = U_{n-1}/n,$$

if

$$U_0 + U_1t + U_2t^2 + \cdots = (1 + V_2t + V_3t^2 + \cdots)^{-n}. \tag{12}$$

For example, we have $(1-t)^{-5} = \binom{4}{4} + \binom{5}{4}t + \binom{6}{4}t^2 + \cdots$; hence W_5 in the reversion of $z = t - t^2$ is equal to $\binom{8}{4}/5 = 14$. This checks with the formulas for enumerating binary trees in Section 2.3.4.4.

Relation (12) shows that we can revert the series (10) if we compute the negative powers $(1+V_2t+V_3t^2+\cdots)^{-n}$ for $n = 1, 2, 3, \ldots$. A straightforward application of this idea would lead to an on-line reversion algorithm that uses approximately $N^3/2$ multiplications to find N coefficients, but Eq. (9) makes it possible to work with only the first n coefficients of $(1 + V_2t + V_3t^2 + \cdots)^{-n}$, obtaining an on-line algorithm that requires only about $N^3/6$ multiplications.

Algorithm L (*Lagrangian power series reversion*). This on-line algorithm inputs the value of V_n in (10) and outputs the value of W_n in (11), for $n = 2, 3, 4, \ldots, N$. (The number N need not be specified in advance; some other termination criterion may be substituted.)

L1. [Initialize.] Set $n \leftarrow 1$, $U_0 \leftarrow 1$. (The relation

$$(1 + V_2t + V_3t^2 + \cdots)^{-n} = U_0 + U_1t + \cdots + U_{n-1}t^{n-1} + O(t^n) \tag{13}$$

will be maintained throughout this algorithm.)

L2. [Input V_n.] Increase n by 1. If $n > N$, the algorithm terminates; otherwise input the next coefficient, V_n.

L3. [Divide.] Set $U_k \leftarrow U_k - U_{k-1}V_2 - \cdots - U_1V_k - V_{k+1}$, for $k = 1, 2, \ldots, n-2$ (in this order); then set

$$U_{n-1} \leftarrow -2U_{n-2}V_2 - 3U_{n-3}V_3 - \cdots - (n-1)U_1V_{n-1} - nV_n.$$

(We have thereby divided $U(z)$ by $V(z)/z$; cf. (3) and (9).)

L4. [Output W_n.] Output U_{n-1}/n (which is W_n) and return to L2. ∎

When applied to the example $z = t - t^2$, Algorithm L computes

n	V_n	U_0	U_1	U_2	U_3	U_4	W_n
1	1	1					1
2	−1	1	2				1
3	0	1	3	6			2
4	0	1	4	10	20		5
5	0	1	5	15	35	70	14

Exercise 8 shows that a slight modification of Algorithm L will solve a considerably more general problem with only a little more effort.

Let us now consider solving the equation

$$U_1z + U_2z^2 + U_3z^3 + \cdots = t + V_2t^2 + V_3t^3 + \cdots \tag{14}$$

for t, obtaining the coefficients of the power series

$$t = W_1z + W_2z^2 + W_3z^3 + W_4z^4 + \cdots. \tag{15}$$

Eq. (10) is the special case $U_1 = 1$, $U_2 = U_3 = \cdots = 0$. If $U_1 \neq 0$, we may assume that $U_1 = 1$, if we replace z by (U_1z); but we shall consider the general equation (14), since U_1 might equal zero.

Algorithm T (*General power series reversion*). This on-line algorithm inputs the values of U_n and V_n in (14) and outputs the value of W_n in (15), for $n = 1, 2, 3, \ldots, N$. An auxiliary matrix T_{mn}, $1 \leq m \leq n \leq N$, is used in the calculations.

T1. [Initialize.] Set $n \leftarrow 1$. Let the first two inputs (namely, U_1 and V_1) be stored in T_{11} and V_1, respectively. (We must have $V_1 = 1$.)

T2. [Output W_n.] Output the value of T_{1n} (which is W_n).

T3. [Input U_n, V_n.] Increase n by 1. If $n > N$, the algorithm terminates; otherwise store the next two inputs (namely, U_n and V_n) in T_{1n} and V_n.

T4. [Multiply.] Set

$$T_{mn} \leftarrow T_{11}T_{m-1,n-1} + T_{12}T_{m-1,n-2} + \cdots + T_{1,n-m+1}T_{m-1,m-1}$$

and $T_{1n} \leftarrow T_{1n} - V_mT_{mn}$, for $2 \leq m \leq n$. (After this step we have

$$t^m = T_{mm}z^m + T_{m,m+1}z^{m+1} + \cdots + T_{mn}z^n + O(z^{n+1}), \tag{16}$$

for $1 \leq m \leq n$. It is easy to verify (16) by induction for $m \geq 2$, and when $m = 1$, we have $U_n = T_{1n} + V_2T_{2n} + \cdots + V_nT_{nn}$ by (14) and (16).) Return to step T2. ∎

Equation (16) explains the mechanism of this algorithm, which is due to Henry C. Thacher, Jr. [*CACM* **9** (1966), 10–11]. The running time is essentially the same as Algorithm L, but considerably more storage space is required. An example of this algorithm is worked out in exercise 9.

Still another approach to power series reversion has been proposed by R. P. Brent and H. T. Kung [*JACM* **25** (1978), 581–595], based on the fact that standard iterative procedures used to find roots of equations over the real numbers can also be applied to equations over power series. In particular, we can consider Newton's method for computing approximations to a real number t such that $f(t) = 0$, given a function f that is well-behaved near t: If x is a good approximation to t, then $\phi(x) = x - f(x)/f'(x)$ will be even better, for if we write $x = t + \epsilon$ we have $f(x) = f(t) + \epsilon f'(t) + O(\epsilon^2)$, $f'(x) = f'(t) + O(\epsilon)$; consequently $\phi(x) = t + \epsilon - \big(0 + \epsilon f'(t) + O(\epsilon^2)\big)/\big(f'(t) + O(\epsilon)\big) = t + O(\epsilon^2)$. Applying this idea to power series, let $f(x) = V(x) - U(z)$, where U and V are the power series in Eq. (14). We wish to find the power series t in z such that $f(t) = 0$. Let $x = W_1 z + \cdots + W_{n-1} z^{n-1} = t + O(z^n)$ be an "approximation" to t of order n; then $\phi(x) = x - f(x)/f'(x)$ will be an approximation of order $2n$, since the assumptions of Newton's method hold for this f and t.

In other words, we can use the following procedure:

Algorithm N (*General power series reversion by Newton's method*). This "semi-on-line" algorithm inputs the values of U_n and V_n in (14) for $2^k \le n < 2^{k+1}$ and then outputs the values of W_n in (15) for $2^k \le n < 2^{k+1}$, thereby producing its answers in batches of 2^k at a time, for $k = 0, 1, 2, \ldots, K$.

N1. [Initialize.] Set $N \leftarrow 1$. (We will have $N = 2^k$.) Input the first coefficients U_1 and V_1 (where $V_1 = 1$), and set $W_1 \leftarrow U_1$.

N2. [Output.] Output W_n for $N \le n < 2N$.

N3. [Input.] Set $N \leftarrow 2N$. If $N > 2^K$, the algorithm terminates; otherwise input the values U_n and V_n for $N \le n < 2N$.

N4. [Newtonian step.] Use an algorithm for power series composition (see exercise 11) to evaluate the coefficients Q_j and R_j $(0 \le j < N)$ in the power series

$$\begin{aligned} U_1 z + \cdots + U_{2N-1} z^{2N-1} - V(W_1 z + \cdots + W_{N-1} z^{N-1}) \\ = R_0 z^N + R_1 z^{N+1} + \cdots + R_{N-1} z^{2N-1} + O(z^{2N}), \\ V'(W_1 z + \cdots + W_{N-1} z^{N-1}) = Q_0 + Q_1 z + \cdots + Q_{N-1} z^{N-1} + O(z^N), \end{aligned}$$

where $V(x) = x + V_2 x^2 + \cdots$ and $V'(x) = 1 + 2V_2 x + \cdots$. Then set $W_N, \ldots, W_{2N-1}$ to the coefficients in the power series

$$\frac{R_0 + R_1 z + \cdots + R_{N-1} z^{N-1}}{Q_0 + Q_1 z + \cdots + Q_{N-1} z^{N-1}} = W_N + \cdots + W_{2N-1} z^{N-1} + O(z^N)$$

and return to step N2. ∎

The running time for this algorithm to obtain the coefficients up to $N = 2^K$ is $T(N)$, where

$$T(2N) = T(N) + (\text{time to do step N4}) + O(N). \tag{17}$$

Straightforward algorithms for composition and division in step N4 will take order N^3 steps, so Algorithm N will run slower than Algorithm T. However, Brent and Kung have found a way to do the required composition of power series with $O(N \log N)^{3/2}$ arithmetic operations, and exercise 6 gives an even faster algorithm for division; hence (17) shows that power series reversion can be achieved by doing only $O(N \log N)^{3/2}$ operations as $N \to \infty$. (On the other hand the constant of proportionality is such that N must be really large before Algorithms L and T lose out to this "high-speed" method.)

Historical note: J. N. Bramhall and M. A. Chapple published the first $O(n^3)$ method for power series reversion in *CACM* **4** (1961), 317–318, 503. It was an off-line algorithm whose running time was approximately the same as that of Algorithms L and T.

Iteration of series. If we want to study the behavior of an iterative process $x_n \leftarrow f(x_{n-1})$, we are interested in studying the n-fold composition of a given function f with itself, namely $x_n = f(f(\ldots f(x_0)\ldots))$. Let us define $f^0(x) = x$ and $f^n(x) = f\big(f^{n-1}(x)\big)$, so that

$$f^{m+n}(x) = f^m\big(f^n(x)\big) \tag{18}$$

for all integers m, $n \geq 0$. It also makes sense to define $f^n(x)$ when n is a negative integer, namely to let f^n and f^{-n} be inverse functions such that $x = f^n\big(f^{-n}(x)\big)$; then (18) holds for *all* integers m and n. Reversion of series is essentially the operation of finding the inverse function $f^{-1}(x)$; for example, Eqs. (10) and (11) essentially state that $z = V\big(W(z)\big)$ and that $t = W\big(V(t)\big)$, so $W = V^{-1}$.

Suppose we are given two power series $V(z) = z + V_2 z^2 + \cdots$ and $W(z) = z + W_2 z^2 + \cdots$ such that $W = V^{-1}$. Let u be any nonzero constant, and consider the function

$$U(z) = W\big(uV(z)\big). \tag{19}$$

It is easy to see that $U\big(U(z)\big) = W\big(u^2 V(z)\big)$, and in general that

$$U^n(z) = W\big(u^n V(z)\big) \tag{20}$$

for all integers n. Therefore we have a simple expression for the nth iterate U^n, which can be calculated with roughly the same amount of work for all n. Furthermore, we can even use (20) to define U^n for non-integer values of n; the "half iterate" $U^{1/2}$, for example, is a function such that $U^{1/2}\big(U^{1/2}(z)\big) = U(z)$. (There are two such functions $U^{1/2}$, obtained by using $\sqrt{u}$ and $-\sqrt{u}$ as the value of $u^{1/2}$.)

We obtained the simple state of affairs in (20) by starting with V and u, then defining U. But in practice we generally want to go the other way: Starting with some given function U, we want to find V and u such that (19) holds, i.e., such that

$$V\big(U(z)\big) = u\,V(z). \tag{21}$$

Such a function V is called the *Schröder function* of U, because it was introduced by Ernst Schröder in *Math. Annalen* **3** (1871), 296–322. Let us now look at the problem of finding the Schröder function $V(z) = z + V_2 z^2 + \cdots$ of a given power series $U = U_1 z + U_2 z^2 + \cdots$. Clearly $u = U_1$ if (21) is to hold.

Expanding (21) with $u = U_1$ and equating coefficients of z leads to a sequence of equations that begins

$$\begin{aligned} U_1^2 V_2 + U_2 &= U_1 V_2 \\ U_1^3 V_3 + 2U_1 U_2 V_2 + U_3 &= U_1 V_3 \\ U_1^4 V_4 + 3U_1^2 U_2 V_3 + 2U_1 U_3 V_2 + U_2^2 V_2 + U_3 &= U_1 V_4 \end{aligned}$$

and so on. Clearly there is no solution when $U_1 = 0$ (unless trivially $U_2 = U_3 = \cdots = 0$); otherwise there is a unique solution unless U_1 is a root of unity. We might have expected that something funny would happen when $U_1^n = 1$, since Eq. (20) tells us that $U^n(z) = z$ if the Schröder function exists. For the moment let us assume that U_1 is nonzero and not a root of unity; then the Schröder function does exist, and the next question is how to compute it without doing too much work.

The following procedure has been suggested by R. P. Brent and J. F. Traub. Equation (21) leads to subproblems of a similar but more complicated form, so we set ourselves a more general task whose subtasks have the same form: Let us try to find $V(z) = V_0 + V_1 z + \cdots + V_{n-1} z^{n-1}$ such that

$$V\big(U(z)\big) = W(z)V(z) + S(z) + O(z^n), \tag{22}$$

given $U(z)$, $W(z)$, $S(z)$, and n, where n is a power of 2 and $U(0) = 0$. If $n = 1$ we simply let $V_0 = S(0)/\big(1 - W(0)\big)$, with $V_0 = 1$ if $S(0) = 0$ and $W(0) = 1$. Furthermore it is possible to go from n to $2n$: First we find $R(z)$ such that

$$V\big(U(z)\big) = W(z)V(z) + S(z) - z^n R(z) + O(z^{2n}). \tag{23}$$

Then we compute

$$\hat{W}(z) = W(z)\big(z/U(z)\big)^n, \qquad \hat{S}(z) = R(z)\big(z/U(z)\big)^n \tag{24}$$

and find $\hat{V}(z) = V_n + V_{n+1} z + \cdots + V_{2n-1} z^{n-1}$ such that

$$\hat{V}\big(U(z)\big) = \hat{W}(z)\hat{V}(z) + \hat{S}(z) + O(z^n). \tag{25}$$

It follows that $V^*\big(U(z)\big) = W(z)V^*(z) + S(z) + O(z^{2n})$ as desired, where $V^*(z)$ is equal to $V(z) + z^n \hat{V}(z)$.

The running time $T(n)$ of this procedure satisfies

$$T(2n) = 2T(n) + C(n), \tag{26}$$

where $C(n)$ is the time to compute $R(z)$, $\hat{W}(z)$, and $\hat{S}(z)$. The function $C(n)$ is dominated by the time to compute $V\big(U(z)\big)$ modulo z^{2n}, and $C(n)$ presumably grows faster than order $n^{1+\epsilon}$; therefore the solution $T(n)$ to (26) will be of order $C(n)$. For example, if $C(n) = cn^3$ we have $T(n) \approx \frac{4}{3}cn^3$; or if $C(n)$ is $O(n \log n)^{3/2}$ using "fast" composition, we have $T(n) = O(n \log n)^{3/2}$.

The procedure breaks down when $W(0) = 1$ and $S(0) \neq 0$, so we need to investigate when this can happen. It is easy to prove by induction on n that the solution of (22) by the Brent–Traub method entails consideration of exactly n subproblems, in which the coefficient of $V(z)$ on the right-hand side takes the respective values $W(z)\big(z/U(z)\big)^j$ for $0 \leq j < n$ in some order. If $W(0) = U_1$ and if U_1 is not a root of unity, we therefore have $W(0) = 1$ only when $j = 1$; the procedure will fail in this case only if (22) has no solution for $n = 2$.

The Schröder function for U can therefore be found by solving (22) for $n = 2, 4, 8, 16, \ldots$, with $W(z) = U_1$ and $S(z) = 0$, whenever U_1 is nonzero and not a root of unity.

If $U_1 = 1$, there is no Schröder function unless $U(z) = z$. But Brent and Traub have found a fast way to compute $U^n(z)$ even when $U_1 = 1$, by making use of a function $V(z)$ such that

$$V\big(U(z)\big) = U'(z)V(z). \tag{27}$$

If two functions $U(z)$ and $\hat{U}(z)$ both satisfy (27), for the same V, it is easy to check that their composition $U\big(\hat{U}(z)\big)$ does too; therefore all iterates of $U(z)$ are solutions of (27). Suppose that $U(z) = z + U_k z^k + U_{k+1}z^{k+1} + \cdots$ where $k \geq 2$ and $U_k \neq 0$. Then it can be shown that there is a unique power series of the form $V(z) = z^k + V_{k+1}z^{k+1} + V_{k+2}z^{k+2} + \cdots$ satisfying (27). Conversely if such a function $V(z)$ is given, and if $k \geq 2$ and U_k are given, then there is a unique power series of the form $U(z) = z + U_k z^k + U_{k+1}z^{k+1} + \cdots$ satisfying (27); the desired iterate $U^n(z)$ is the unique power series $P(z)$ satisfying

$$V\big(P(z)\big) = P'(z)V(z) \tag{28}$$

such that $P(z) = z + nU_k z^k + \cdots$. Both $V(z)$ and $P(z)$ can be found by appropriate algorithms (see exercise 14).

If U_1 is a kth root of unity, but not equal to 1, the same method can be applied to the function $U^k(z) = z + \cdots$, and $U^k(z)$ can be found from $U(z)$ by doing $l(k)$ composition operations (cf. Section 4.6.3). We can also handle the case $U_1 = 0$: If $U(z) = U_k z^k + U_{k+1}z^{k+1} + \cdots$ where $k \geq 2$ and $U_k \neq 0$, the idea is to find a solution to the equation $V\big(U(z)\big) = U_k V(z)^k$; then $U^n(z) = V^{-1}\big(U_k^{(k^n-1)/(k-1)}V(z)^{k^n}\big)$. Finally, if $U(z) = U_0 + U_1 z + \cdots$ where $U_0 \neq 0$, let α be a "fixed point" such that $U(\alpha) = \alpha$, and let $\hat{U}(z) = U(\alpha + z) - \alpha = zU'(\alpha) + z^2U''(\alpha)/2! + \cdots$; then $U^n(z) = \hat{U}^n(z - \alpha) + \alpha$. Further details can be found in Brent and Traub's paper [*SIAM J. Computing* **9** (1980), 54–66].

Algebraic functions. The coefficients of each power series $W(z)$ that satisfies a general equation of the form

$$A_n(z)W(z)^n + \cdots + A_1(z)W(z) + A_0(z) = 0, \tag{29}$$

where each $A_i(z)$ is a polynomial, can be computed efficiently by using methods due to H. T. Kung and J. F. Traub; see *JACM* **25** (1978), 245–260.

EXERCISES

1. [*M10*] The text explains how to divide $U(z)$ by $V(z)$ when $V_0 \neq 0$; how should the division be done when $V_0 = 0$?

2. [*20*] If the coefficients of $U(z)$ and $V(z)$ are integers and $V_0 \neq 0$, find a recurrence relation for the integers $V_0^{n+1}W_n$, where W_n is defined by (3). How would you use this for power series division?

3. [*M15*] Does formula (9) give the right results when $\alpha = 0$? When $\alpha = 1$?

▶ **4.** [*HM23*] Show that simple modifications of (9) can be used to calculate $e^{V(z)}$ and $\ln(1 + V(z))$, when $V(z) = V_1 z + V_2 z^2 + \cdots$.

5. [*M00*] What happens when a power series is reverted twice; i.e., if the output of Algorithm L or T is reverted again?

▶ **6.** [*M21*] (H. T. Kung.) Apply Newton's method to the computation of $W(z) = 1/V(z)$, when $V(0) \neq 0$, by finding the power series root of the equation $f(x) = 0$, where $f(x) = x^{-1} - V(z)$.

7. [*M23*] Use Lagrange's inversion formula (12) to find a simple expression for the coefficient W_n in the reversion of $z = t - t^m$.

▶ **8.** [*M25*] Lagrange's inversion formula can be generalized as follows: If $W(z) = W_1 z + W_2 z^2 + \cdots = G_1 t + G_2 t^2 + G_3 t^3 + \cdots = G(t)$, where z and t are related by Eq. (10), then $W_n = U_{n-1}/n$ where

$$U_0 + U_1 z + U_2 z^2 + \cdots = (G_1 + 2G_2 z + 3G_3 z^2 + \cdots)(1 + V_2 z + V_3 z^2 + \cdots)^{-n}.$$

(Equation (12) is the special case $G_1 = 1$, $G_2 = G_3 = \cdots = 0$. This equation can be proved, for example, by using tree-enumeration formulas as in exercise 2.3.4.4–33.) Extend Algorithm L so that it obtains the coefficients W_1, W_2, ... in this more general situation, without substantially increasing its running time.

9. [*11*] Find the values of T_{mn} computed by Algorithm T as it determines the first five coefficients in the reversion of $z = t - t^2$.

10. [*M20*] Given that $y = x^\alpha + a_1 x^{\alpha+1} + a_2 x^{\alpha+2} + \cdots$, $\alpha \neq 0$, show how to compute the coefficients in the expansion $x = y^{1/\alpha} + b_2 y^{2/\alpha} + b_3 y^{3/\alpha} + \cdots$.

▶ **11.** [*M25*] (*Composition of power series.*) Let

$$U(z) = U_0 + U_1 z + U_2 z^2 + \cdots \quad \text{and} \quad V(z) = V_1 z + V_2 z^2 + V_3 z^3 + \cdots;$$

design an algorithm that computes the first N coefficients of $U(V(z))$.

12. [*M20*] Find a connection between polynomial division and power series division: Given polynomials $u(x)$ and $v(x)$ of respective degrees m and n over a field, show how to find the polynomials $q(x)$, $r(x)$ such that $u(x) = q(x)v(x) + r(x)$ and $\deg(r) < n$, using only operations on power series.

13. [*M27*] (*Rational function approximation.*) It is occasionally desirable to find polynomials whose quotient has the same initial terms as a given power series. For example, if $W(z) = 1 + z + 3z^2 + 7z^3 + \cdots$, there are essentially four different ways to express $W(z)$ as $w_1(z)/w_2(z) + O(z^4)$ where $w_1(z)$ and $w_2(z)$ are polynomials with $\deg(w_1) + \deg(w_2) < 4$:

$$\begin{aligned}
(1 + z + 3z^2 + 7z^3)/1 &= 1 + z + 3z^2 + 7z^3 + 0z^4 + \cdots,\\
(3 - 4z + 2z^2)/(3 - 7z) &= 1 + z + 3z^2 + 7z^3 + \tfrac{49}{3}z^4 + \cdots,\\
(1 - z)/(1 - 2z - z^2) &= 1 + z + 3z^2 + 7z^3 + 17z^4 + \cdots,\\
1/(1 - z - 2z^2 - 2z^3) &= 1 + z + 3z^2 + 7z^3 + 15z^4 + \cdots.
\end{aligned}$$

Rational functions of this kind are commonly called *Padé approximations*, since they were studied extensively by H. E. Padé [*Annales Scient. de l'École Normale Supérieure* (3) **9** (1892), S1–S93].

Show that all Padé approximations $W(z) = w_1(z)/w_2(z) + O(z^N)$ with $\deg(w_1) + \deg(w_2) < N$ can be obtained by applying an extended Euclidean algorithm to the polynomials z^N and $W_0 + W_1 z + \cdots + W_{N-1} z^{N-1}$; and design an all-integer algorithm for the case that each W_i is an integer. [*Hint:* See exercise 4.6.1–26.]

▸ **14.** [*HM30*] Fill in the details of Brent and Traub's method for calculating $U^n(z)$ when $U(z) = z + U_k z^k + \cdots$, using (27) and (28).

And it shall be,
when thou hast made an end of reading this book,
that thou shalt bind a stone to it,
and cast it into the midst of Euphrates.

—Jeremiah 51:63

ANSWERS TO EXERCISES

This branch of mathematics is the only one, I believe,
in which good writers frequently get results entirely erroneous.
. . . It may be doubted if there is a single
extensive treatise on probabilities in existence
which does not contain solutions absolutely indefensible.

—C. S. PEIRCE, in *Popular Science Monthly* (1878)

NOTES ON THE EXERCISES

1. An average problem for a mathematically inclined reader.

3. See W. J. LeVeque, *Topics in Number Theory* **2** (Reading, Mass.: Addison–Wesley, 1956), Chapter 3. [*Note:* One of the men who read a preliminary draft of the manuscript of this book reported that he had discovered a truly remarkable proof, which the margin of his copy was too small to contain.]

SECTION 3.1

1. (a) This will usually fail, since "round" telephone numbers are often selected by the telephone user when possible. In some communities, telephone numbers are perhaps assigned randomly. But it would be a mistake in any case to try to get several successive random numbers from the same page, since the same telephone number is often listed several times in a row.

(b) But do you use the left-hand page or the right-hand page? Say, use the left-hand page number, divide by 2, and take the units digit. The total number of pages should be a multiple of 20; but even so, this method will have some bias.

(c) The markings on the faces will slightly bias the die, but for practical purposes this method is quite satisfactory (and it has been used by the author in the preparation of several examples in this set of books). See *Math. Comp.* **15** (1961), 94–95, for further discussion of these dice.

(d) (This is a hard question thrown in purposely as a surprise.) The number is not quite uniformly random. If the average number of emissions per minute is m, the probability that the counter registers k is $e^{-m}m^k/k!$ (the Poisson distribution); so the digit 0 is selected with probability $e^{-m}\sum_{k\geq 0} m^{10k}/(10k)!$, etc. The units digit will be even with probability $e^{-m}\cosh m = \frac{1}{2}+\frac{1}{2}e^{-2m}$, and this is never equal to $\frac{1}{2}$ (although the error is negligibly small when m is large).

(e) Okay, provided that the time since the previous digit selected in this way is random. However, there is possible bias in borderline cases.

(f,g) No, people usually think of certain digits (like 7) with higher probability.

(h) Okay; your assignment of numbers to the horses had probability $\frac{1}{10}$ of assigning a given digit to the winning horse.

2. The number of such sequences is the multinomial coefficient $1000000!/(100000!)^{10}$; the probability is this number divided by $10^{1000000}$, the total number of sequences of a million digits. By Stirling's approximation we find that the probability is close to $1/(16\pi^4 10^{22}\sqrt{2\pi}) \approx 2.55 \times 10^{-26}$, about one chance in 4×10^{25}.

3. 3040504030.

4. Step K11 can be entered only from step K10 or step K2, and in either case we find it impossible for X to be zero by a simple argument. If X could be zero at that point, the algorithm would not terminate.

5. Since only 10^{10} ten-digit numbers are possible, some value of X must be repeated during the first $10^{10}+1$ steps; and as soon as a value is repeated, the sequence continues to repeat its past behavior.

6. (a) Arguing as in the previous exercise, the sequence must eventually repeat a value; let this repetition occur for the first time at step $\mu+\lambda$, where $X_{\mu+\lambda} = X_\mu$. (This condition defines μ and λ.) We have $0 \leq \mu < m$, $0 < \lambda \leq m$, $\mu+\lambda \leq m$. The values $\mu = 0$, $\lambda = m$ are attained iff f is a cyclic permutation; and $\mu = m-1$, $\lambda = 1$ occurs, e.g., if $X_0 = 0$, $f(x) = x+1$ for $x < m-1$, and $f(m-1) = m-1$.

(b) We have, for $r \geq n$, $X_r = X_n$ iff $r-n$ is a multiple of λ and $n \geq \mu$. Hence $X_{2n} = X_n$ iff n is a multiple of λ and $n \geq \mu$. The desired results now follow immediately. [*Note:* This is essentially a proof of the familiar mathematical result that the powers of an element in a finite semigroup include a unique idempotent element: take $X_0 = a$, $f(x) = ax$.]

(c) Once n has been found, generate X_i and X_{n+i} for $i \geq 0$ until first finding $X_i = X_{n+i}$; then $\mu = i$. If none of the values of X_{n+i} for $0 \leq i \leq \mu$ is equal to X_n, it follows that $\lambda = n$, otherwise λ is the smallest such i.

7. (a) The least $n > 0$ such that $n - (\ell(n)-1)$ is a multiple of λ and $\ell(n)-1 \geq \mu$ is $n = 2^{\lceil \lg \max(\mu+1,\lambda)\rceil} - 1 + \lambda$. [This may be compared with the least $n > 0$ such that $X_{2n} = X_n$, namely $\lambda\delta_{\mu 0} + \mu + \lambda - 1 - ((\mu+\lambda-1) \bmod \lambda)$.]

(b) Start with $X = Y = X_0$, $k = m = 1$. (At key places in this algorithm we will have $X = X_{2m-k-1}$, $Y = X_{m-1}$, and $m = \ell(2m-k)$.) To generate the next random number, do the following steps: Set $X \leftarrow f(X)$ and $k \leftarrow k-1$. If $X = Y$, stop (the period length λ is equal to $m-k$). Otherwise if $k = 0$, set $Y \leftarrow X$, $m \leftarrow 2m$, $k \leftarrow m$. Output X.

Notes: Brent has also considered a more general method in which the successive values of $Y = X_{n_i}$ satisfy $n_1 = 0$, $n_{i+1} = 1 + \lfloor pn_i \rfloor$ where p is any number greater than 1. He showed that the best choice of p, approximately 2.4771, saves about 3 percent of the iterations by comparison with $p = 2$. (See exercise 4.5.4–4.)

The method in part (b) has a serious deficiency, however, since it might generate a lot of nonrandom numbers before shutting off. For example, we might have a particularly bad case such as $\lambda = 1$, $\mu = 2^k$. A method based on Floyd's idea in exercise 6(b), namely one that maintains $Y = X_{2n}$ and $X = X_n$ for $n = 0, 1, 2, \ldots$, will require a few more function evaluations than Brent's method, but it will stop before any number has been output twice.

On the other hand if f is unknown (e.g., if we are receiving the values $X_0, X_1, \ldots$ on-line from an outside source) or if f is difficult to apply, the following cycle detection algorithm due to R. W. Gosper will be preferable: Maintain an auxiliary table $T_0, T_1, \ldots, T_m$, where $m = \lfloor \lg n \rfloor$ when receiving X_n. Initially $T_0 \leftarrow X_0$. For $n = 1, 2, \ldots$, compare X_n with each of $T_0, \ldots, T_{\lfloor \lg n \rfloor}$; if no match is found, set $T_{e(n)} \leftarrow X_n$, where $e(n) = \max\{\, e \mid 2^e \text{ divides } n + 1 \,\}$. But if a match $X_n = T_k$ is found, then $\lambda = n - \max\{\, m \mid m < n \text{ and } e(m) = k \,\}$. This procedure does not stop before generating a number twice, but at most $\lceil \frac{2}{3}\lambda \rceil$ of the X's will have occurred more than once. [MIT AI Laboratory Memo 239 (Feb. 29, 1972), Hack 132.]

See also R. Sedgewick and T. G. Szymanski, *Proc. ACM Symp. Th. Comp.* **11** (1979), 74–80.

8. (a,b) $00, 00, \ldots$ [62 starting values]; $10, 10, \ldots$ [19]; $60, 60, \ldots$ [15]; $50, 50, \ldots$ [1]; $24, 57, 24, 57, \ldots$ [3]. (c) 42 or 69; these both lead to a set of fifteen distinct values, namely (42 or 69), 76, 77, 92, 46, 11, 12, 14, 19, 36, 29, 84, 05, 02, 00.

9. Since $X < b^n$, we have $X^2 < b^{2n}$, and the middle square is $\lfloor X^2/b^n \rfloor \le X^2/b^n$. If $X > 0$, then $X^2/b^n < Xb^n/b^n = X$.

10. If $X = ab^n$, the next number of the sequence has the same form; it is $(a^2 \bmod b^n)b^n$. If a is a multiple of b or of all the prime factors of b, the sequence will soon degenerate to zero; if not, the sequence will degenerate into a cycle of numbers having the same general form as X.

Further facts about the middle-square method have been found by B. Jansson, *Random Number Generators* (Stockholm: Almqvist & Wiksell, 1966), Section 3A. Numerologists will be interested to learn that the number 3792 is self-reproducing in the four-digit middle-square method, since $3792^2 = 14379264$; furthermore (as Jansson has observed), it is "self-reproducing" in another sense, too, since its prime factorization is $3 \cdot 79 \cdot 2^4$!

11. The probability that $\lambda = 1$ and $\mu = 0$ is the probability that $X_1 = X_0$, namely $1/m$. The probability that $\lambda = 1, \mu = 1$, or $\lambda = 2, \mu = 0$, is the probability that $X_1 \neq X_0$ and that X_2 has a certain value, so it is $(1 - 1/m)(1/m)$. Similarly, the probability that the sequence has any given μ and λ is a function only of $\mu + \lambda$, namely

$$P(\mu, \lambda) = \frac{1}{m} \prod_{1 \le k < \mu + \lambda} \left(1 - \frac{k}{m}\right).$$

For the probability that $\lambda = 1$, we have

$$\sum_{\mu \ge 0} \frac{1}{m} \prod_{1 \le k \le \mu} \left(1 - \frac{k}{m}\right) = \frac{1}{m} Q(m),$$

where $Q(m)$ is defined in Section 1.2.11.3, Eq. (2). By Eq. (25) in that section, the probability is approximately $6\sqrt{\pi/2m} \approx 1.25/\sqrt{m}$. The chance of Algorithm K converging as it did is only about one in 80000; the author was decidedly unlucky. But see exercise 15 for further comments on the "colossalness."

12. $$\sum_{\substack{1\le\lambda\le m\\ 0\le\mu<m}} \lambda P(\mu,\lambda) = \frac{1}{m}\Big(1+3\Big(1-\frac{1}{m}\Big)+6\Big(1-\frac{1}{m}\Big)\Big(1-\frac{2}{m}\Big)+\cdots\Big)$$
$$= \frac{1+Q(m)}{2}.$$

(See the previous answer. In general if $f(a_0,a_1,\dots) = \sum_{n\ge0} a_n \prod_{1\le k\le n}(1-k/m)$ then $f(a_0,a_1,\dots) = a_0 + f(a_1,a_2,\dots) - f(a_1,2a_2,\dots)/m$; apply this identity with $a_n = (n+1)/2$.) Therefore the average value of λ (and, by symmetry of $P(\mu,\lambda)$, also of $\mu+1$) is approximately $\sqrt{\pi m/8}+\frac{1}{3}$. The average value of $\mu+\lambda$ is exactly $Q(m)$, approximately $\sqrt{\pi m/2}-\frac{1}{3}$. [For alternative derivations and further results, including asymptotic values for the moments, see A. Rapoport, *Bull. Math. Biophysics* **10** (1948), 145–157, and B. Harris, *Annals Math. Stat.* **31** (1960), 1045–1062; see also I. M. Sobol', *Theory of Probability and its Applications* **9** (1964), 333–338. Sobol' discusses the asymptotic period length for the more general sequence $X_{n+1} = f(X_n)$ if $n \not\equiv 0$ (modulo m); $X_{n+1} = g(X_n)$ if $n \equiv 0$ (modulo m); with both f and g random.]

13. [Paul Purdom and John Williams, *Trans. Amer. Math. Soc.* **133** (1968), 547–551.] Let T_{mn} be the number of functions that have n one-cycles and no cycles of length greater than one. Then

$$T_{mn} = \binom{m-1}{n-1} m^{m-n}.$$

(See Section 2.3.4.4.) *Any* function is such a function followed by a permutation of the n elements that were the one-cycles. Hence $\sum_{n\ge1} T_{mn}\, n! = m^m$.

Let P_{nk} be the number of permutations of n elements in which the longest cycle is of length k. Then the number of functions with a maximum cycle of length k is $\sum_{n\ge1} T_{mn}P_{nk}$. To get the average value of k, we compute $\sum_{k\ge1}\sum_{n\ge1} kT_{mn}P_{nk}$, which by the result of exercise 1.3.3–23 is $\sum_{n\ge1} T_{mn}\, n!(n+\frac{1}{2}+\epsilon_n)c$ where $c \approx .62433$ and $\epsilon_n \to 0$ as $n\to\infty$. Summing, we get the average value $cQ(m) + \frac{1}{2}c + \delta_m$, where $\delta_m \to 0$ as $m\to\infty$. (This is not substantially larger than the average value when X_0 is selected at random. The average value of $\max(\mu+\lambda)$ is still unknown.)

14. Let $c_r(m)$ be the number of functions with exactly r different final cycles. From the recurrence $c_1(m) = (m-1)! - \sum_{k>0}\binom{m}{k}(-1)^k(m-k)^k c_1(m-k)$, which comes by counting the number of functions whose image contains at most $m-k$ elements, we find the solution $c_1(m) = m^{m-1}Q(m)$. (Cf. exercise 1.2.11.3–16.) Another way to obtain the value of $c_1(m)$, which is perhaps more elegant and revealing, is given in exercise 2.3.4.4–17. The value of $c_r(m)$ may be determined by solving the recurrence

$$c_r(m) = \sum_{0<k<m} \binom{m-1}{k-1} c_1(k)c_{r-1}(m-k),$$

which has the solution

$$c_r(m) = m^{m-1}\Big(\frac{1}{0!}\begin{bmatrix}1\\r\end{bmatrix} + \frac{1}{1!}\begin{bmatrix}2\\r\end{bmatrix}\frac{m-1}{m} + \frac{1}{2!}\begin{bmatrix}3\\r\end{bmatrix}\frac{m-1}{m}\frac{m-2}{m} + \cdots\Big).$$

The desired average value can now be computed; it is (cf. exercise 12)

$$E_m = \frac{1}{m}\Big(H_1 + 2H_2\frac{m-1}{m} + 3H_3\frac{m-1}{m}\frac{m-2}{m} + \cdots\Big)$$
$$= 1 + \frac{1}{2}\frac{m-1}{m} + \frac{1}{3}\frac{m-1}{m}\frac{m-2}{m} + \cdots.$$

This latter formula was obtained by quite different means by Martin D. Kruskal, *AMM* **61** (1954), 392–397. Using the integral representation

$$E_m = \int_0^\infty \Big(\Big(1+\frac{x}{m}\Big)^m - 1\Big)e^{-x}\,\frac{dx}{x},$$

he proved the asymptotic relation $\lim_{m\to\infty}(E_m - \frac{1}{2}\ln m) = \frac{1}{2}(\gamma + \ln 2)$. For further results and references, see John Riordan, *Annals Math. Stat.* **33** (1962), 178–185.

15. The probability that $f(x) \neq x$ for all x is $(m-1)^m/m$, which is approximately $1/e$. The existence of a self-repeating value in an algorithm like Algorithm K is therefore not "colossal" at all—it occurs with probability $1 - 1/e \approx .63212$. The only "colossal" thing was that the author happened to hit such a value when X_0 was chosen at random (see exercise 11).

16. The sequence will repeat when a pair of successive elements occurs for the second time. The maximum period is m^2. (Cf. next exercise.)

17. After selecting $X_0, \ldots, X_{k-1}$ arbitrarily, let $X_{n+1} = f(X_n, \ldots, X_{n-k+1})$, where $0 \le x_1, \ldots, x_k < m$ implies that $0 \le f(x_1, \ldots, x_k) < m$. The maximum period is m^k. This is an obvious upper bound, but it is not obvious that it can be attained; for a proof that it can always be attained for suitable f, see exercises 3.2.2–17 and 3.2.2–21, and for the number of ways to attain it see exercise 2.3.4.2–23.

18. Same as exercise 7, but use the k-tuple of elements $(X_n, \ldots, X_{n-k+1})$ in place of the single element X_n.

SECTION 3.2.1

1. Take X_0 even, a even, c odd. Then X_n is odd for $n > 0$.

2. Let X_r be the first repeated value in the sequence. If X_r were equal to X_k for some k where $0 < k < r$, we could prove that $X_{r-1} = X_{k-1}$, since X_n uniquely determines X_{n-1} when a is prime to m. Hence $k = 0$.

3. If d is the greatest common divisor of a and m, the quantity aX_n can take on at most m/d values. The situation can be even worse; e.g., if $m = 2^e$ and if a is even, Eq. (6) shows that the sequence is eventually constant.

4. Induction on k.

5. If a is relatively prime to m, there is a number a' for which $aa' \equiv 1$ (modulo m). Then $X_{n-1} = (a'X_n - a'c) \bmod m$, and in general,

$$X_{n-k} = \big((a')^k X_n - c(a' + \cdots + (a')^k)\big) \bmod m$$
$$= \left((a')^k X_n - c\frac{(a')^{k+1} - a'}{a' - 1}\right) \bmod m$$

when $k > 0$, $n - k \ge 0$. If a is not relatively prime to m, it is not possible to determine X_{n-1} when X_n is given; multiples of $m/\gcd(a, m)$ may be added to X_{n-1} without changing the value of X_n. (See also exercise 3.2.1.3–7.)

SECTION 3.2.1.1

1. Let c' be a solution to the congruence $ac' \equiv c$ (modulo m). (Thus, $c' = a'c \bmod m$, if a' is the number in the answer to exercise 3.2.1–5.) Then we have

```
LDA  X
ADD  CPRIME
MUL  A        ∎
```

Overflow is possible on this addition operation. (From results derived later in the chapter, it is probably best to save a unit of time, taking $c = a$ and replacing the ADD instruction by "INCA 1". Then if $X_0 = 0$, overflow will not occur until the end of the period, so it won't occur in practice.)

2.
```
RANDM STJ  1F
      LDA  XRAND
      MUL  A
      SLAX 5
      ADD  C      (or, INCA c, if c is small)
      STA  XRAND
1H    JNOV *
      JMP  *-1
XRAND CON  X0
A     CON  a
C     CON  c      ∎
```

Note: Locations A and C should probably be named 2H and 3H to avoid conflict with other symbols, if this subroutine is to be used by other programmers.

3. See WM1 at the end of Program 4.2.3D.

4. Define the operation $x \underline{\bmod} 2^e = y$ iff $x \equiv y$ (modulo 2^e) and $-2^{e-1} \le y < 2^{e-1}$. The congruential sequence $\langle Y_n \rangle$ defined by

$$Y_0 = X_0 \underline{\bmod} 2^{32}, \qquad Y_{n+1} = (aY_n + c) \underline{\bmod} 2^{32}$$

is easy to compute on 370-style machines, since the lower half of the product of y and z is $(yz) \underline{\bmod} 2^{32}$ for all two's complement numbers y and z, and since addition ignoring overflow also delivers its result $\underline{\bmod} 2^{32}$. This sequence has all the randomness properties of the standard linear congruential sequence $\langle X_n \rangle$, since $Y_n \equiv X_n$ (modulo 2^{32}). Indeed, the two's complement representation of Y_n is *identical* to the binary representation of X_n, for all n. [G. Marsaglia and T. A. Bray first pointed this out in *CACM* **11** (1968), 757–759.]

5. (a) Subtraction: LDA X; SUB Y; JANN *+2; ADD M. (b) Addition: LDA X; SUB M; ADD Y; JANN *+2; ADD M. (Note that if m is more than half the word size, the instruction "SUB M" must precede the instruction "ADD Y".)

6. The sequences are not essentially different, since adding the constant $(m - c)$ has the same effect as subtracting the constant c. The operation must be combined with multiplication, so a subtractive process has little merit over the additive one (at least in MIX's case), except when it is necessary to avoid affecting the overflow toggle.

7. The prime factors of $z^k - 1$ appear in the factorization of $z^{kr} - 1$. If r is odd, the prime factors of $z^k + 1$ appear in the factorization of $z^{kr} + 1$. And $z^{2k} - 1$ equals $(z^k - 1)(z^k + 1)$.

8.
```
JOV  *+1    (Ensure that overflow is off.)
LDA  X
MUL  A
STX  TEMP
ADD  TEMP   Add lower half to upper half.
JNOV *+2    If ≥ w, subtract w − 1.
INCA 1      (Overflow is impossible in this step.)
```
∎

Note: Since addition on an e-bit ones'-complement computer is mod $(2^e - 1)$, it is possible to combine the techniques of exercises 4 and 8, producing $(yz) \bmod (2^e - 1)$ by adding together the two e-bit halves of the product yz, for all ones' complement numbers y and z regardless of sign.

9. The pairs $(0, w - 2)$, $(1, w - 1)$ are treated as equivalent in input and output:

```
JOV  *+1
LDA  X
MUL  A      aX = qw + r.
SLC  5      rA ← r, rX ← q.
STX  TEMP
ADD  TEMP
JNOV *+2    Get (r + q) mod (w − 2).
INCA 2      Overflow is impossible.
ADD  TEMP
JNOV *+3    Get (r + 2q) mod (w − 2).
INCA 2      Overflow is possible.
JOV  *-1
```
∎

SECTION 3.2.1.2

1. Period length m, by Theorem A. (Cf. exercise 3.)

2. Yes, these conditions imply the conditions in Theorem A, since the only prime divisor of 2^e is 2, and any odd number is relatively prime to 2^e. (In fact, the conditions of the exercise are *necessary* and sufficient.)

3. By Theorem A, we need $a \equiv 1$ (modulo 4) and $a \equiv 1$ (modulo 5). By Law D of Section 1.2.4, this is equivalent to $a \equiv 1$ (modulo 20).

4. We know $X_{2^{e-1}} \equiv 0$ (modulo 2^{e-1}) by using Theorem A in the case $m = 2^{e-1}$. Also using Theorem A for $m = 2^e$, we know that $X_{2^{e-1}} \not\equiv 0$ (modulo 2^e). It follows that $X_{2^{e-1}} = 2^{e-1}$. More generally, we can use Eq. 3.2.1–6 to prove that the second half of the period is essentially like the first half, since $X_{n+2^{e-1}} = (X_n + 2^{e-1}) \bmod 2^e$. (The quarters are similar too, see exercise 21.)

5. We need $a \equiv 1$ (modulo p) for $p = 3, 11, 43, 281, 86171$. By Law D of Section 1.2.4, this is equivalent to $a \equiv 1$ (modulo $3 \cdot 11 \cdot 43 \cdot 281 \cdot 86171$), so the *only* solution is the terrible multiplier $a = 1$.

6. (Cf. previous exercise.) $a \equiv 1$ (modulo $3 \cdot 7 \cdot 11 \cdot 13 \cdot 37$) implies that the solutions are $a = 1 + 111111k$, for $0 \le k \le 8$.

7. Using the notation of the proof of Lemma Q, μ is the smallest value such that $X_{\mu+\lambda} = X_\mu$; so it is the smallest value such that $Y_{\mu+\lambda} = Y_\mu$ and $Z_{\mu+\lambda} = Z_\mu$. This shows that $\mu = \max(\mu_1, \ldots, \mu_t)$. The highest achievable μ is $\max(e_1, \ldots, e_t)$, but nobody really wants to achieve it.

8. We have $a^2 \equiv 1$ (modulo 8); so $a^4 \equiv 1$ (modulo 16), $a^8 \equiv 1$ (modulo 32), etc. If $a \bmod 4 = 3$, then $a-1$ is twice an odd number; so $(a^{2^{e-1}}-1)/2 \equiv 0$ (modulo $2^{e+1}/2$), and this yields the desired result.

9. Substitute for X_n in terms of Y_n and simplify. If $X_0 \bmod 4 = 3$, the formulas of the exercise do not apply; but they do apply to the sequence $Z_n = (-X_n) \bmod 2^e$, which has essentially the same behavior.

10. Only $m = 1$, 2, 4, p^e, and $2p^e$, for odd primes p. In all other cases, the result of Theorem B is an improvement over Euler's theorem (exercise 1.2.4–28).

11. (a) Either $x+1$ or $x-1$ (not both) will be a multiple of 4, so $x \mp 1 = q2^f$, where q is odd and f is greater than 1. (b) In the given circumstances, $f < e$ and so $e \ge 3$. We have $\pm x \equiv 1$ (modulo 2^f) and $\pm x \not\equiv 1$ (modulo 2^{f+1}) and $f > 1$. Hence by applying Lemma P, we find that $(\pm x)^{2e-f-1} \not\equiv 1$ (modulo 2^e), while $x^{2e-f} = (\pm x)^{2e-f} \equiv 1$ (modulo 2^e). So the order is a divisor of 2^{e-f}, but not a divisor of 2^{e-f-1}. (c) 1 has order 1; $2^e - 1$ has order 2; the maximum period when $e \ge 3$ is therefore 2^{e-2}, and for $e \ge 4$ it is necessary to have $f = 2$, that is, $x \equiv 4 \pm 1$ (modulo 8).

12. If k is a proper divisor of $p-1$ and if $a^k \equiv 1$ (modulo p), then by Lemma P we have $a^{kp^{e-1}} \equiv 1$ (modulo p^e). Similarly, if $a^{p-1} \equiv 1$ (modulo p^2), we find that $a^{(p-1)p^{e-2}} \equiv 1$ (modulo p^e). So in these cases a is *not* primitive. Conversely, if $a^{p-1} \not\equiv 1$ (modulo p^2), Theorem 1.2.4F and Lemma P tell us that $a^{(p-1)p^{e-2}} \not\equiv 1$ (modulo p^e), but $a^{(p-1)p^{e-1}} \equiv 1$ (modulo p^e). So the order is a divisor of $(p-1)p^{e-1}$ but not of $(p-1)p^{e-2}$; it therefore has the form kp^{e-1}, where k divides $p-1$. But if a is primitive modulo p, the congruence $a^{kp^{e-1}} \equiv a^k \equiv 1$ (modulo p) implies that $k = p-1$.

13. Let λ be the order of a modulo p. By Theorem 1.2.4F, λ is a divisor of $p-1$. If $\lambda < p-1$, then $(p-1)/\lambda$ has a prime factor, q.

14. Let $0 < k < p$. If $a^{p-1} \equiv 1$ (modulo p^2), then $(a+kp)^{p-1} \equiv a^{p-1} + (p-1) \times a^{p-2}kp$ (modulo p^2); and this is $\not\equiv 1$, since $(p-1)a^{p-2}k$ is not a multiple of p. By exercise 12, $a + kp$ is primitive modulo p^e.

15. (a) If $\lambda_1 = p_1^{e_1} \ldots p_t^{e_t}$, $\lambda_2 = p_1^{f_1} \ldots p_t^{f_t}$, let $\kappa_1 = p_1^{g_1} \ldots p_t^{g_t}$, $\kappa_2 = p_1^{h_1} \ldots p_t^{h_t}$, where

$$\begin{aligned} g_j = e_j \quad &\text{and} \quad h_j = 0, \qquad \text{if} \quad e_j < f_j, \\ g_j = 0 \quad &\text{and} \quad h_j = f_j, \qquad \text{if} \quad e_j \ge f_j. \end{aligned}$$

Now $a_1^{\kappa_1}, a_2^{\kappa_2}$ have periods $\lambda_1/\kappa_1, \lambda_2/\kappa_2$, and the latter are relatively prime. Furthermore $(\lambda_1/\kappa_1)(\lambda_2/\kappa_2) = \lambda$, so it suffices to consider the case when λ_1 is relatively prime to λ_2, that is, when $\lambda = \lambda_1\lambda_2$. Now since $(a_1a_2)^\lambda \equiv 1$, we have $1 \equiv (a_1a_2)^{\lambda\lambda_1} \equiv a_2^{\lambda\lambda_1}$; hence $\lambda\lambda_1$ is a multiple of λ_2. This implies that λ is a multiple of λ_2, since λ_1 is relatively prime to λ_2. Similarly, λ is a multiple of λ_1; hence λ is a multiple of $\lambda_1\lambda_2$. But obviously $(a_1a_2)^{\lambda_1\lambda_2} \equiv 1$, so $\lambda = \lambda_1\lambda_2$.

(b) If a_1 has order $\lambda(m)$ and if a_2 has order λ, by part (a) $\lambda(m)$ must be a multiple of λ, otherwise we could find an element of higher order, namely of order $\operatorname{lcm}(\lambda, \lambda(m))$.

16. (a) $f(x) = (x-a)(x^{n-1} + (a+c_1)x^{n-2} + \cdots + (a^{n-1} + \cdots + c_{n-1})) + f(a)$. (b) The statement is clear when $n = 0$. If a is one root, $f(x) \equiv (x-a)q(x)$; therefore if a' is any other root,

$$0 \equiv f(a') \equiv (a'-a)q(a'),$$

and since $a'-a$ is not a multiple of p, a' must be a root of $q(x)$. So if $f(x)$ has more than n distinct roots, $q(x)$ has more than $n-1$ distinct roots. (c) $\lambda(p) \geq p-1$, since $f(x)$ must have degree $\geq p-1$ in order to possess so many roots. But by Theorem 1.2.4F, $\lambda(p) \leq p-1$.

17. By Lemma P, $11^5 \equiv 1$ (modulo 25), $11^5 \not\equiv 1$ (modulo 125), etc.; so the order of 11 is 5^{e-1} (modulo 5^e), not the maximum value $\lambda(5^e) = 4 \cdot 5^{e-1}$. But by Lemma Q the total period length is the least common multiple of the period modulo 2^e (namely 2^{e-2}) and the period modulo 5^e (namely 5^{e-1}), and this is $2^{e-2}5^{e-1} = \lambda(10^e)$. The period modulo 5^e may be 5^{e-1} or $2 \cdot 5^{e-1}$ or $4 \cdot 5^{e-1}$, without affecting the length of period modulo 10^e, since the least common multiple is taken. The values that are primitive modulo 5^e are those congruent to 2, 3, 8, 12, 13, 17, 22, 23 modulo 25 (cf. exercise 12), namely 3, 13, 27, 37, 53, 67, 77, 83, 117, 123, 133, 147, 163, 173, 187, 197.

18. According to Theorem C, $a \bmod 8$ must be 3 or 5. Knowing the period of a modulo 5 and modulo 25 allows us to apply Lemma P to determine admissible values of a mod 25. Period $= 4 \cdot 5^{e-1}$: 2, 3, 8, 12, 13, 17, 22, 23; period $= 2 \cdot 5^{e-1}$: 4, 9, 14, 19; period $= 5^{e-1}$: 6, 11, 16, 21. Each of these 16 values yields one value of a, $0 \leq a < 200$, with $a \bmod 8 = 3$, and another value of a with $a \bmod 8 = 5$.

19. One example appears in Table 3.3.4–1, line 26.

20. (a) We have $AY_n + X_0 \equiv AY_{n+k} + X_0$ (modulo m) iff $Y_n \equiv Y_{n+k}$ (modulo m'). (b)(i) Obvious. (ii) Theorem A. (iii) $(a^n-1)/(a-1) \equiv 0$ (modulo 2^e) iff $a^n \equiv 1$ (modulo 2^{e+1}); if $a \not\equiv -1$, the order of a modulo 2^{e+1} is twice its order modulo 2^e. (iv) $(a^n-1)/(a-1) \equiv 0$ (modulo p^e) iff $a^n \equiv 1$.

21. $X_{n+s} \equiv X_n + X_s$ by Eq. 3.2.1–6; and s is a divisor of m, since s is a power of p when m is a power of p. Hence a given integer q is a multiple of m/s iff $X_{qs} \equiv 0$ iff q is a multiple of $m/\gcd(X_s, m)$.

SECTION 3.2.1.3

1. $c = 1$ is always relatively prime to B^5; and every prime dividing $m = B^5$ is a divisor of B, so it divides $b = B^2$ to at least the second power.

2. Only 3, so the generator is not recommended in spite of its long period.

3. The potency is 18 in both cases (see next exercise).

4. Since $a \bmod 4 = 1$, we must have $a \bmod 8 = 1$ or 5, so $b \bmod 8 = 0$ or 4. If b is an odd multiple of 4, and if b_1 is a multiple of 8, clearly $b^s \equiv 0$ (modulo 2^e) implies that $b_1^s \equiv 0$ (modulo 2^e), so b_1 cannot have higher potency.

5. The potency is the smallest value of s such that $f_j s \geq e_j$ for all j.

6. The modulus must be divisible by 2^7 or by p^4 (for odd prime p) in order to have a potency as high as 4. The only values are $m = 2^{27} + 1$ and $10^9 - 1$.

7. $a' = (1 - b + b^2 - \cdots) \bmod m$, where the terms in b^s, b^{s+1}, etc., are dropped (if s is the potency).

8. Since X_n is always odd,

$$X_{n+2} = (2^{34} + 3 \cdot 2^{18} + 9)X_n \bmod 2^{35} = (2^{34} + 6X_{n+1} - 9X_n) \bmod 2^{35}.$$

Given Y_n and Y_{n+1}, the possibilities for

$$Y_{n+2} \approx (5 + 6(Y_{n+1} + \epsilon_1) - 9(Y_n + \epsilon_2)) \bmod 10,$$

with $0 \le \epsilon_1 < 1$, $0 \le \epsilon_2 < 1$, are limited and nonrandom.

Note: If the multiplier suggested in exercise 3 were, say, $2^{33} + 2^{18} + 2^2 + 1$, instead of $2^{23} + 2^{14} + 2^2 + 1$, we would similarly find $X_{n+2} - 10X_{n+1} + 25X_n \equiv$ constant (modulo 2^{35}). In general, we do not want $a \pm \delta$ to be divisible by high powers of 2 when δ is small, else we get "second order impotency." See Section 3.3.4 for a more detailed discussion.

The generator that appears in this exercise is discussed in an article by MacLaren and Marsaglia, *JACM* **12** (1965), 83–89. The deficiencies of such generators were first demonstrated by M. Greenberger, *CACM* **8** (1965), 177–179. Yet generators like this were still in widespread use more than ten years later (cf. the discussion of RANDU in Section 3.3.4).

SECTION 3.2.2

1. The method is useful only with great caution. In the first place, aU_n is likely to be so large that the addition of c/m that follows will lose almost all significance, and the "mod 1" operation will nearly destroy any vestiges of significance that might remain. We conclude that double-precision floating point arithmetic is necessary. Even with double precision, one must be sure that no rounding, etc., occurs to affect the numbers of the sequence in any way, since that would destroy the theoretical grounds for the good behavior of the sequence. (But see exercise 23.)

2. X_{n+1} equals either $X_{n-1} + X_n$ or $X_{n-1} + X_n - m$. If $X_{n+1} < X_n$ we must have $X_{n+1} = X_{n-1} + X_n - m$; hence $X_{n+1} < X_{n-1}$.

3. (a) The underlined numbers are $V[j]$ after step M3.

Output: initial		0	4	5	6	2	0	3	(2	7	4	1	6	3	0	5)	and repeats.
$V[0]$:	0	$\underline{4}$	$\underline{7}$	7	7	7	7	7	7	$\underline{4}$	$\underline{7}$	7	7	7	7	7	7	$\underline{4}$	$\underline{7}$ ...
$V[1]$:	3	3	3	3	3	3	3	$\underline{2}$	$\underline{5}$	5	5	5	5	5	5	$\underline{2}$	$\underline{5}$	5	5 ...
$V[2]$:	2	2	2	2	2	$\underline{0}$	$\underline{3}$	3	3	3	3	3	3	$\underline{0}$	$\underline{3}$	3	3	3	3 ...
$V[3]$:	5	5	5	$\underline{6}$	$\underline{1}$	1	1	1	1	1	1	$\underline{6}$	$\underline{1}$	1	1	1	1	1	1 ...
X:		4	7	6	1	0	3	2	5	4	7	6	1	0	3	2	5	4	7 ...
Y:		0	1	6	7	4	5	2	3	0	1	6	7	4	5	2	3	0	1 ...

So the potency has been reduced to 1! (See further comments in the answer to exercise 15.)

(b) The underlined numbers are $V[j]$ after step B2.

Output: initial		2 3 6 5 7 0 0 5 3 ... 4 6(3 0 ... 4 7)...
$V[0]$:	0	0 0 0 0 0 0 $\underline{5}$ $\underline{4}$ 4 ... 1 1 1 1 ... 1 1 ...
$V[1]$:	3	3 $\underline{6}$ $\underline{1}$ 1 1 1 1 1 1 ... 0 0 0 $\underline{4}$ ... 0 0 ...
$V[2]$:	2	$\underline{7}$ 7 7 7 $\underline{3}$ 3 3 3 $\underline{7}$ ... 6 $\underline{2}$ 2 2 ... 7 $\underline{2}$ ...
$V[3]$:	5	5 5 5 $\underline{0}$ 0 $\underline{2}$ 2 2 2 ... $\underline{3}$ 3 $\underline{5}$ 5 ... $\underline{3}$ 3 ...
X:	4	7 6 1 0 3 2 5 4 7 ... 3 2 5 4 ... 3 2 ...

In this case the output is considerably better than the input; it enters a repeating cycle of length 40 after 46 steps: 236570 05314 72632 40110 37564 76025 12541 73625 03746 (30175 24061 52317 46203 74531 60425 16753 02647). The cycle can be found easily by applying the method of exercise 3.1–7 to the above array until a column is repeated.

4. The low-order byte of many random sequences (e.g., linear congruential sequences with $m =$ word size) is much less random than the high-order byte. See Section 3.2.1.1.

5. The randomizing effect would be quite minimized, because $V[j]$ would always contain a number in a certain range, essentially $j/k \le V[j]/m < (j+1)/k$. However, some similar approaches could be used: we could take $Y_n = X_{n-1}$, or we could choose j from X_n by extracting some digits from about the middle instead of at the extreme left. None of these suggestions would produce a lengthening of the period analogous to the behavior of Algorithm B.

6. For example, if $\mathtt{X}_n/m < \frac{1}{2}$, then $\mathtt{X}_{n+1} = 2\mathtt{X}_n$.

7. [W. Mantel, *Nieuw Arehief voor Wiskunde* (2) **1** (1897), 172–184.]

The subsequence of X values:	00...01 00...10 . . . 10...00 CONTENTS(A)	becomes:	00...01 00...10 . . . 10...00 00...00 CONTENTS(A)

8. We may assume that $X_0 = 0$ and $m = p^e$, as in the proof of Theorem 3.2.1.2A. First suppose that the sequence has period length p^e; it follows that the period of the sequence mod p^f has length p^f, for $1 \le f \le e$, otherwise some residues mod p^f would never occur. Clearly, c is not a multiple of p, for otherwise each X_n would be a multiple of p. If $p \le 3$, it is easy to establish the necessity of conditions (iii) and (iv) by trial and error, so we may assume that $p \ge 5$. If $d \not\equiv 0$ (modulo p) then $dx^2 + ax + c \equiv d(x + a_1)^2 + c_1$ (modulo p^e) for some integers a_1 and c_1 and for all integers x; this quadratic takes the same value at the points x and $-x - 2a_1$, so it cannot assume all values modulo p^e. Hence $d \equiv 0$ (modulo p); and if $a \not\equiv 1$, we would have $dx^2 + ax + c \equiv x$ (modulo p) for some x, contradicting the fact that the sequence mod p has period length p.

To show the sufficiency of the conditions, we may assume by Theorem 3.2.1.2A and consideration of some trivial cases that $m = p^e$ where $e \ge 2$. If $p = 2$, we have $X_{n+p} \equiv X_n + pc$ (modulo p^2), by trial; and if $p = 3$, we have either $X_{n+p} \equiv X_n + pc$ (modulo p^2), for all n, or $X_{n+p} \equiv X_n - pc$ (modulo p^2), for all n. For $p \ge 5$, we can prove that $X_{n+p} \equiv X_n + pc$ (modulo p^2): Let $d = pr$, $a = 1 + ps$. Then if

$X_n \equiv cn + pY_n$ (modulo p^2), we must have $Y_{n+1} \equiv n^2c^2r + ncs + Y_n$ (modulo p); hence $Y_n \equiv \binom{n}{3}2c^2r + \binom{n}{2}(c^2r + cs)$ (modulo p). Thus $Y_p \bmod p = 0$, and the desired relation has been proved.

Now we can prove that the sequence $\langle X_n \rangle$ of integers defined in the "hint" satisfies the relation

$$X_{n+p^f} \equiv X_n + tp^f \quad (\text{modulo } p^{f+1}), \qquad n \geq 0,$$

for some t with $t \bmod p \neq 0$, and for all $f \geq 1$. This suffices to prove that the sequence $\langle X_n \bmod p^e \rangle$ has period length p^e, for the length of the period is a divisor of p^e but not a divisor of p^{e-1}. The above relation has already been established for $f = 1$, and for $f > 1$ it can be proved by induction in the following manner: Let

$$X_{n+p^f} \equiv X_n + tp^f + Z_np^{f+1} \quad (\text{modulo } p^{f+2});$$

then the quadratic law for generating the sequence, with $d = pr$, $a = 1 + ps$, yields $Z_{n+1} \equiv 2rtnc + st + Z_n$ (modulo p). It follows that $Z_{n+p} \equiv Z_n$ (modulo p); hence

$$X_{n+kp^f} \equiv X_n + k(tp^f + Z_np^{f+1}) \quad (\text{modulo } p^{f+2})$$

for $k = 1, 2, 3, \ldots$; setting $k = p$ completes the proof.

Notes: If $f(x)$ is a polynomial of degree higher than 2 and $X_{n+1} = f(X_n)$, the analysis is more complicated, although we can use the fact that $f(m + p^k) = f(m) + p^kf'(m) + p^{2k}f''(m)/2! + \cdots$ to prove that many polynomial recurrences give the maximum period. For example, Coveyou has proved that the period is $m = 2^e$ if $f(0)$ is odd, $f'(j) \equiv 1$, $f''(j) \equiv 0$, and $f(j+1) \equiv f(j)+1$ (modulo 4) for $j = 0, 1, 2, 3$. [*Studies in Applied Math.* **3** (1967), 70–111.]

9. Let $X_n = 4Y_n+2$; then the sequence Y_n satisfies the quadratic recurrence $Y_{n+1} = (4Y_n^2 + 5Y_n + 1) \bmod 2^{e-2}$.

10. *Case 1:* $X_0 = 0$, $X_1 = 1$; hence $X_n \equiv F_n$. We seek the smallest n for which $F_n \equiv 0$ and $F_{n+1} \equiv 1$ (modulo 2^e). Since $F_{2n} = F_n(F_{n-1} + F_{n+1})$, $F_{2n+1} = F_n^2 + F_{n+1}^2$, we find by induction on e that, for $e > 1$, $F_{3\cdot 2^{e-1}} \equiv 0$ and $F_{3\cdot 2^{e-1}+1} \equiv 2^e + 1$ (modulo 2^{e+1}). This implies that the period is a divisor of $3 \cdot 2^{e-1}$ but not a divisor of $3 \cdot 2^{e-2}$, so it is either $3 \cdot 2^{e-1}$ or 2^{e-1}. But $F_{2^{e-1}}$ is always odd (since only F_{3n} is even).

Case 2: $X_0 = a$, $X_1 = b$. Then $X_n \equiv aF_{n-1} + bF_n$; we need to find the smallest positive n with $a(F_{n+1} - F_n) + bF_n \equiv a$ and $aF_n + bF_{n+1} \equiv b$. This implies that $(b^2 - ab - a^2)F_n \equiv 0$, $(b^2 - ab - a^2)(F_{n+1} - 1) \equiv 0$; and $b^2 - ab - a^2$ is odd (i.e., prime to m) so the condition is equivalent to $F_n \equiv 0$, $F_{n+1} \equiv 1$.

Methods to determine the period of F_n for any modulus appear in an article by D. D. Wall, *AMM* **67** (1960), 525–532. Further facts about the Fibonacci sequence mod 2^e have been derived by B. Jansson [*Random Number Generators* (Stockholm: Almqvist & Wiksell, 1966), Section 3C1].

11. (a) We have $z^\lambda = 1 + f(z)u(z) + p^ev(z)$ for some $u(z), v(z)$, where $v(z) \not\equiv 0$ (modulo $f(z)$ and p). By the binomial theorem

$$z^{\lambda p} = 1 + p^{e+1}v(z) + p^{2e+1}v(z)^2(p-1)/2$$

plus further terms congruent to zero (modulo $f(z)$ and p^{e+2}). Since $p^e > 2$, we have $z^{\lambda p} \equiv 1+p^{e+1}v(z)$ (modulo $f(z)$ and p^{e+2}). If $p^{e+1}v(z) \equiv 0$ (modulo $f(z)$ and p^{e+2}),

there must exist polynomials $a(z)$ and $b(z)$ such that $p^{e+1}(v(z)+pa(z)) = f(z)b(z)$. Since $f(0)=1$, this implies that $b(z)$ is a multiple of p^{e+1} (by Gauss's Lemma 4.6.1G); hence $v(z) \equiv 0$ (modulo $f(z)$ and p), a contradiction.

(b) If $z^\lambda - 1 = f(z)u(z) + p^e v(z)$, then

$$G(z) = u(z)/(z^\lambda - 1) + p^e v(z)/f(z)(z^\lambda - 1);$$

hence $A_{n+\lambda} \equiv A_n$ (modulo p^e) for large n. Conversely, if $\langle A_n \rangle$ has the latter property then $G(z) = u(z) + v(z)/(1-z^\lambda) + p^e H(z)$, for some polynomials $u(z)$ and $v(z)$, and some power series $H(z)$, all with integer coefficients. This implies the identity $1-z^\lambda = u(z)f(z)(1-z^\lambda) + v(z)f(z) + p^e H(z)f(z)(1-z^\lambda)$; and $H(z)f(z)(1-z^\lambda)$ is a polynomial since the other terms of the equation are polynomials.

(c) It suffices to prove that $\lambda(p^e) \neq \lambda(p^{e+1})$ implies that $\lambda(p^{e+1}) = p\lambda(p^e) \neq \lambda(p^{e+2})$. Applying (a) and (b), we know that $\lambda(p^{e+2}) \neq p\lambda(p^e)$, and that $\lambda(p^{e+1})$ is a divisor of $p\lambda(p^e)$ but not of $\lambda(p^e)$. Hence if $\lambda(p^e) = p^f q$, where $q \bmod p \neq 0$, then $\lambda(p^{e+1})$ must be $p^{f+1}d$, where d is a divisor of q. But now $X_{n+p^{f+1}} \equiv X_n$ (modulo p^e); hence $p^{f+1}d$ is a multiple of $p^f q$, hence $d = q$. [*Note:* The hypothesis $p^e > 2$ is necessary; for example, let $a_1 = 4$, $a_2 = -1$, $k = 2$; then $\langle A_n \rangle = 1, 4, 15, 56, 209, 780, \ldots$; $\lambda(2) = 2$, $\lambda(4) = 4$, $\lambda(8) = 4$.]

(d) $g(z) = X_0 + (X_1 - a_1X_0)z + \cdots$
$$+(X_{k-1} - a_1X_{k-2} - a_2X_{k-3} - \cdots - a_{k-1}X_0)z^{k-1}.$$

(e) The derivation in (b) can be generalized to the case $G(z) = g(z)/f(z)$; then the assumption of period length λ implies that $g(z)(1-z^\lambda) \equiv 0$ (modulo $f(z)$ and p^e); we treated only the special case $g(z) = 1$ above. But both sides of this congruence can be multiplied by Hensel's $b(z)$, and we obtain $1 - z^\lambda \equiv 0$ (modulo $f(z)$ and p^e).

Note: A more "elementary" proof of the result in (c) can be given without using generating functions, using methods analogous to those in the answer to exercise 8: If $A_{\lambda+n} = A_n + p^e B_n$, for $n = r, r+1, \ldots, r+k-1$ and some integers B_n, then this same relation holds for *all* $n \geq r$ if we define $B_{r+k}, B_{r+k+1}, \ldots$ by the given recurrence relation. Since the resulting sequence of B's is some linear combination of shifts of the sequence of A's, we will have $B_{\lambda+n} \equiv B_n$ (modulo p^e) for all large enough values of n. Now $\lambda(p^{e+1})$ must be some multiple of $\lambda = \lambda(p^e)$; for all large enough n we have $A_{n+j\lambda} = A_n + p^e(B_n + B_{n+\lambda} + B_{n+2\lambda} + \cdots + B_{n+(j-1)\lambda}) \equiv A_n + jp^e B_n$ (modulo p^{2e}) for $j = 1, 2, 3, \ldots$. No k consecutive B's are multiples of p; hence $\lambda(p^{e+1}) = p\lambda(p^e) \neq \lambda(p^{e+2})$ follows immediately when $e \geq 2$. We still must prove that $\lambda(p^{e+2}) \neq p\lambda(p^e)$ when p is odd and $e = 1$; here we let $B_{\lambda+n} = B_n + pC_n$, and observe that $C_{n+\lambda} \equiv C_n$ (modulo p) when n is large enough. Then $A_{n+p} \equiv A_n + p^2\binom{p}{2}C_n$ (modulo p^3), and the proof is readily completed.

For the history of this problem, see Morgan Ward, *Trans. Amer. Math. Soc.* **35** (1933), 600–628; see also D. W. Robinson, *AMM* **73** (1966), 619–621.

12. The period length mod 2 can be at most 4; and the period length mod 2^{e+1} is at most twice the maximum length mod 2^e, by the considerations of the previous exercise. So the maximum conceivable period length is 2^{e+1}; this is achievable, for example, in the trivial case $a = 0$, $b = c = 1$.

13, 14. Clearly $Z_{n+\lambda} = Z_n$, so λ' is certainly a divisor of λ. Let the least common multiple of λ' and λ_1 be λ_1', and define λ_2' similarly. $X_n + Y_n \equiv Z_n \equiv Z_{n+\lambda_1'} \equiv X_n + Y_{n+\lambda_1'}$, so λ_1' is a multiple of λ_2. Similarly, λ_2' is a multiple of λ_1. This yields the desired result. (The result is "best possible" in the sense that sequences for which $\lambda' = \lambda_0$ can be constructed, as well as sequences for which $\lambda' = \lambda$.)

15. Algorithm M generates (X_{n+k}, Y_n) in step M1 and outputs $Z_n = X_{n+k-q_n}$ in step M3, for all sufficiently large n. Thus $\langle Z_n \rangle$ has a period of length λ', where λ' is the least positive integer such that $X_{n+k-q_n} = X_{n+\lambda'+k-q_{n+\lambda'}}$ for all large n. Since λ is a multiple of λ_1 and λ_2, it follows that λ' is a divisor of λ. (These observations are due to Alan G. Waterman.)

We also have $n + k - q_n \equiv n + \lambda' + k - q_{n+\lambda'}$ (modulo λ_1) for all large n, by the distinctness of the X's. The bound on $\langle q_n \rangle$ implies that $q_{n+\lambda'} = q_n + c$ for all large n, where $c \equiv \lambda'$ (modulo λ_1) and $|c| < \frac{1}{2}\lambda_1$. But c must be 0 since $\langle q_n \rangle$ is bounded. Hence $\lambda' \equiv 0$ (modulo λ_1), and $q_{n+\lambda'} = q_n$ for all large n; it follows that λ' is a multiple of λ_2 and λ_1, so $\lambda' = \lambda$.

Note: The answer to exercise 3.2.1.2–4 implies that when $\langle Y_n \rangle$ is a linear congruential sequence of maximum period modulo $m = 2^e$, the period length λ_2 will be at most 2^{e-2} when k is a power of 2.

16. There are several methods of proof.

(1) Using the theory of finite fields. In the field with 2^k elements let ξ satisfy $\xi^k = a_1\xi^{k-1} + \cdots + a_k$. Let $f(b_1\xi^{k-1} + \cdots + b_k) = b_k$, where each b_j is either zero or one; this is a linear function. If word X in the generation algorithm is $(b_1 b_2 \ldots b_k)_2$ before (10) is executed, and if $b_1\xi^{k-1} + \cdots + b_k\xi^0 = \xi^n$, then word X represents ξ^{n+1} after (10) is executed. Hence the sequence is $f(\xi^n)$, $f(\xi^{n+1})$, $f(\xi^{n+2})$, ...; and $f(\xi^{n+k}) = f(\xi^n\xi^k) = f(a_1\xi^{n+k-1} + \cdots + a_k\xi^n) = a_1 f(\xi^{n+k-1}) + \cdots + a_k f(\xi^n)$.

(2) Using brute force, or elementary ingenuity. We are given a sequence X_{nj}, $n \geq 0$, $1 \leq j \leq k$, satisfying

$$X_{(n+1)j} \equiv X_{n(j+1)} + a_j X_{n1}, \qquad 1 \leq j < k; \qquad X_{(n+1)k} \equiv a_k X_{n1} \quad \text{(modulo 2)}.$$

We must show that this implies $X_{nk} \equiv a_1 X_{(n-1)k} + \cdots + a_k X_{(n-k)k}$, for $n \geq k$. Indeed, it implies $X_{nj} \equiv a_1 X_{(n-1)j} + \cdots + a_k X_{(n-k)j}$ when $1 \leq j \leq k \leq n$. This is clear for $j = 1$, since $X_{n1} \equiv a_1 X_{(n-1)1} + X_{(n-1)2} \equiv a_1 X_{(n-1)1} + a_2 X_{(n-2)2} + X_{(n-2)3}$, etc. For $j > 1$, we have by induction

$$\begin{aligned} X_{nj} &\equiv X_{(n+1)(j-1)} - a_{j-1}X_{n1} \\ &\equiv \sum_{1\leq i\leq k} a_i X_{(n+1-i)(j-1)} - a_{j-1} \sum_{1\leq i\leq k} a_i X_{(n-i)1} \\ &\equiv \sum_{1\leq i\leq k} a_i (X_{(n+1-i)(j-1)} - a_{j-1} X_{(n-i)1}) \\ &\equiv a_1 X_{(n-1)j} + \cdots + a_k X_{(n-k)j}. \end{aligned}$$

This proof does not depend on the fact that operations were done modulo 2, or modulo any prime number.

17. (a) When the sequence terminates, the $(k-1)$-tuple $(X_{n+1}, \ldots, X_{n+k-1})$ occurs for the $(m+1)$st time. A given $(k-1)$-tuple $(X_{r+1}, \ldots, X_{r+k-1})$ can have only m distinct predecessors X_r, so one of these occurrences must be for $r = 0$. (b) Since the $(k-1)$-tuple $(0, \ldots, 0)$ occurs $(m+1)$ times, each possible predecessor appears, so the k-tuple $(a_1, 0, \ldots, 0)$ appears for all a_1, $0 \leq a_1 < m$. Let $1 \leq s < k$ and suppose we have proved that all k-tuples $(a_1, \ldots, a_s, 0, \ldots, 0)$ appear in the sequence when $a_s \neq 0$. By the construction, this k-tuple would not be in the sequence unless $(a_1, \ldots, a_s, 0, \ldots, 0, y)$ had appeared earlier for $1 \leq y < m$. Hence the $(k-1)$-tuple

$(a_1, \ldots, a_s, 0, \ldots, 0)$ has appeared m times, and all m possible predecessors appear; this means $(a, a_1, \ldots, a_s, 0, \ldots, 0)$ appears for $0 \le a < m$. The proof is now complete by induction.

The result also follows from Theorem 2.3.4.2D, using the directed graph of exercise 2.3.4.2–23; the set of arcs from $(x_1, \ldots, x_j, 0, \ldots, 0)$ to $(x_2, \ldots, x_j, 0, \ldots, 0, 0)$, where $x_j \neq 0$ and $1 \le j \le k$, forms an oriented subtree related neatly to Dewey decimal notation.

18. The third-most-significant bit of U_{n+1} is completely determined by the first and third bits of U_n, so only 32 of the 64 possible pairs $(\lfloor 8U_n \rfloor, \lfloor 8U_{n+1} \rfloor)$ occur. (*Notes:* If we had used, say, 11-bit numbers $U_n = (.X_{11n}X_{11n+1}\ldots X_{11n+10})_2$, the sequence *would* be satisfactory for many applications. If another constant appears in A having more "one" bits, the generalized spectral test might give some indication of its suitability. See exercise 3.3.4–24; we could examine ν_t in dimensions $t = 36, 37, 38, \ldots$.)

21. [*J. London Math. Soc.* **21** (1946), 169–172.] Any sequence of period length $m^k - 1$ with no k consecutive zeros leads to a sequence of period length m^k by inserting a zero in the appropriate place, as in exercise 7; conversely, we can start with a sequence of period length m^k and delete an appropriate zero from the period, to form a sequence of the other type. Let us call these "(m, k) sequences" of types A and B. The hypothesis assures us of the existence of (p, k) sequences of type A, for all primes p and all $k \ge 1$; hence we have (p, k) sequences of type B for all such p and k.

To get a (p^e, k) sequence of type B, let $e = qr$, where q is a power of p and r is not a multiple of p. Start with a (p, qrk) sequence of type A, namely $X_0, X_1, X_2, \ldots$; then (using the p-ary number system) the grouped digits $(X_0 \ldots X_{q-1})_p, (X_q \ldots X_{2q-1})_p, \ldots$ form a (p^q, rk) sequence of type A, since q is relatively prime to $p^{qrk} - 1$ and the sequence therefore has a period length of $p^{qrk} - 1$. This leads to a (p^q, rk) sequence $\langle Y_n \rangle$ of type B; and $(Y_0Y_1 \ldots Y_{r-1})_{p^q}, (Y_rY_{r+1} \ldots Y_{2r-1})_{p^q}, \ldots$ is a (p^{qr}, k) sequence of type B by a similar argument, since r is relatively prime to p^{qk}.

To get an (m, k) sequence of type B for arbitrary m, we can combine (p^e, k) sequences for each of the prime power factors of m using the Chinese remainder theorem; but a simpler method is available. Let $\langle X_n \rangle$ be an (r, k) sequence of type B, and let $\langle Y_n \rangle$ be an (s, k) sequence of type B, where r and s are relatively prime; then $\langle sX_n + Y_n \rangle$ is an (rs, k) sequence of type B.

A simple, uniform construction that yields $(2, k)$ sequences for arbitrary k has been discovered by A. Lempel [*IEEE Trans.* **C–19** (1970), 1204–1209].

22. By the Chinese remainder theorem, we can find constants $a_1, \ldots, a_k$ having desired residues mod each prime divisor of m. If $m = p_1p_2 \ldots p_t$, the period length will be $\operatorname{lcm}(p_1^k - 1, \ldots, p_t^k - 1)$. In fact, we can achieve reasonably long periods for arbitrary m (not necessarily squarefree), as shown in exercise 11.

23. Period length at least $2^{55} - 1$; possibly faster than (7), see exercise 3.2.1.1–5. Furthermore, R. Brent has pointed out that the calculations can be done exactly on floating point numbers in $[0, 1)$.

24. Run the sequence backwards. In other words, if $Z_n = Y_{-n}$ we have $Z_n = (Z_{n-m+k} + Z_{n-m}) \bmod 2$.

25. This actually would be slower and more complicated, unless it can be used to save subroutine-calling overhead in high-level languages. (See the FORTRAN program in Section 3.6.)

27. Let $J_n = \lfloor kX_n/m \rfloor$. *Lemma:* After the $(k^2 + 7k - 2)/2$ consecutive values

$$0^{k+2}\,1\,0^{k+1}\,2\,0^{k}\ldots(k-1)\,0^{3}$$

occur in the $\langle J_n \rangle$ sequence, Algorithm B will have $V[i] < m/k$ for $0 \le j < k$, and also $Y < m/k$. *Proof.* Let S_n be the set of positions i such that $V[i] < m/k$ just before X_n is generated, and let j_n be the index such that $V[j_n] \leftarrow X_n$. If $j_n \notin S_n$ and $J_n = 0$, then $S_{n+1} = S_n \cup \{j_n\}$; if $j_n \in S_n$ and $J_n = 0$, then $S_{n+1} = S_n$ and $j_{n+1} = 0$. After $k+2$ successive 0's, we must therefore have $0 \in S_n$ and $j_{n+1} = 0$. Then after "$1\,0^{k+1}$" we must have $\{0,1\} \subseteq S_n$ and $j_{n+1} = 0$; after "$2\,0^{k}$" we must have $\{0,1,2\} \subseteq S_n$ and $j_{n+1} = 0$; and so on.

Corollary: For $\lambda \ge 2(k^2+7k-2)k^{(k^2+7k-2)/2}$, either Algorithm B yields a period of length λ or the sequence $\langle X_n \rangle$ is poorly distributed. *Proof.* The probability that any given length-l pattern of J's does not occur in a random sequence of length λ is less than $(1 - k^{-l})^{\lambda/l} < \exp(-k^{-l}\lambda/l)$. For $l = (k^2 + 7k - 2)/2$ this is at most e^{-4}; hence the stated pattern should appear. After it does, the subsequent behavior of Algorithm B will be the same each time it reaches this part of the period.

SECTION 3.3.1

1. There are $k = 11$ categories, so the line $\nu = 10$ should be used.

2. $\frac{2}{49}, \frac{3}{49}, \frac{4}{49}, \frac{5}{49}, \frac{6}{49}, \frac{9}{49}, \frac{6}{49}, \frac{5}{49}, \frac{4}{49}, \frac{3}{49}, \frac{2}{49}$.

3. $V = 7\frac{173}{240}$, only very slightly higher than that obtained from the good dice! There are two reasons why we do not detect the weighting: (a) The new probabilities (cf. exercise 2) are not really very far from the old ones in Eq. (1). The sum of the two dice tends to smooth out the probabilities; if we considered instead each of the 36 possible pairs of values, and counted these, we would probably detect the difference quite rapidly (assuming that the two dice are distinguishable). (b) A far more important reason is that n is too small for a significant difference to be detected. If the same experiment is done for large enough n, the faulty dice will be discovered (see exercise 12).

4. $p_s = \frac{1}{12}$ for $2 \le s \le 12$ and $s \ne 7$; $p_7 = \frac{1}{6}$. The value of V is $16\frac{1}{2}$, which falls between the 75% and 95% entries in Table 1; so it is reasonable, in spite of the fact that not too many sevens actually turned up.

5. $K_{20}^{+} = 1.15$; $K_{20}^{-} = 0.215$; these do not differ significantly from random behavior (being at about the 94% and 86% levels), but they are mighty close. (The data values in this exercise come from Appendix A, Table 1.)

6. The probability that $X_j \le x$ is $F(x)$, so we have the binomial distribution discussed in Section 1.2.10. $F_n(x) = s/n$ with probability $\binom{n}{s} F(x)^s(1 - F(x))^{n-s}$; the mean is $F(x)$; the standard deviation is $\sqrt{F(x)(1 - F(x))/n}$. [Cf. Eq. 1.2.10–19. This suggests that a slightly better statistic would be to define

$$K_n^{+} = \sqrt{n} \max_{-\infty < x < \infty} (F_n(x) - F(x))/\sqrt{F(x)(1 - F(x))};$$

see exercise 22. We can calculate the mean and standard deviation of $F_n(x) - F_n(y)$, for $x < y$, and obtain the covariance of $F_n(x), F_n(y)$. Using these facts, it can be

shown that for large values of n the function $F_n(x)$ behaves as a "Brownian motion," and techniques from this branch of probability theory may be used to study it. The situation is exploited in articles by J. L. Doob and M. D. Donsker, *Annals Math. Stat.* **20** (1949), 393–403 and **23** (1952), 277–281; this is generally regarded as the most enlightening way to study the KS tests.]

7. ((Cf. Eq. (13).) Take $j = n$ to see that K_n^+ is never negative and it can get as high as $\sqrt{n}$. Similarly, take $j = 1$ to make the same observations about K_n^-.

8. The new KS statistic was computed for 20 observations. The distribution of K_{10}^+ was used as $F(x)$ when the KS statistic was computed.

9. The idea is erroneous, because all of the observations must be *independent*. There is a relation between the statistics K_n^+ and K_n^- on the same data, so each test should be judged separately. (A high value of one tends to give a low value of the other.) Similarly, the entries in Figs. 2 and 5 (which show 15 tests for each generator) do not show 15 independent observations, because the maximum-of-5 test is not independent of the maximum-of-4 test. The three tests of each horizontal row are independent (because they were done on different parts of the sequence), but the five tests in a column are somewhat correlated. The net effect of this is that the 95-percent probability levels, etc., which apply to one test, cannot legitimately be applied to a whole group of tests on the same data. Moral: When testing a random number generator, we may expect it to "pass" each of several tests, e.g., the frequency test, maximum test, run test; but an array of data from several different tests should not be considered as a unit since the tests themselves may not be independent. The K_n^+ and K_n^- statistics should be considered as two separate tests; a good source of random numbers will pass both of the tests.

10. Each Y_s is doubled, and np_s is doubled, so the numerators of (6) are quadrupled while the denominators only double. Hence the new value of V is twice as high as the old one.

11. The empirical distribution function stays the same; the values of K_n^+ and K_n^- are multiplied by $\sqrt{2}$.

12. Let $Z_s = (Y_s - nq_s)/\sqrt{nq_s}$. The value of V is n times

$$\sum_{1 \le s \le k} (q_s - p_s + \sqrt{q_s/n}Z_s)^2/p_s,$$

and the latter quantity stays bounded away from zero as n increases (since $Z_s n^{-1/4}$ is bounded with probability 1). Hence the value of V will increase to a value that is extremely improbable under the p_s assumption.

For the KS test, let $F(x)$ be the assumed distribution, $G(x)$ the actual distribution, and let $h = \max|G(x) - F(x)|$. Take n large enough so that $|F_n(x) - G(x)| > h/2$ occurs with very small probability; then $|F_n(x) - F(x)|$ will be improbably high under the assumed distribution $F(x)$.

13. (The "max" notation should really be replaced by "sup" since a least upper bound is meant; however, "max" was used in the text to avoid confusing too many readers by the less familiar "sup" notation.) For convenience, let $X_0 = -\infty$, $X_{n+1} = +\infty$. When $X_j \le x < X_{j+1}$, we have $F_n(x) = j/n$; therefore $\max(F_n(x) - F(x)) = j/n - F(X_j)$ and $\max(F(x) - F_n(x)) = F(X_{j+1}) - j/n$ in this interval. As j varies

from 0 to n, all real values of x are considered; this proves that

$$K_n^+ = \sqrt{n} \max_{0\le j\le n}\left(\frac{j}{n} - F(X_j)\right);$$
$$K_n^- = \sqrt{n} \max_{1\le j\le n+1}\left(F(X_j) - \frac{j-1}{n}\right).$$

These are equivalent to (13), since the extra term under the maximum signs is nonpositive and it must be redundant by exercise 7.

14. The logarithm of the left-hand side simplifies to

$$-\sum_{1\le s\le k} Y_s \ln\left(1+\frac{Z_s}{\sqrt{np_s}}\right) + \frac{1-k}{2}\ln(2\pi n) - \frac{1}{2}\sum_{1\le s\le k}\ln p_s - \frac{1}{2}\sum_{1\le s\le k}\ln\left(1+\frac{Z_s}{\sqrt{np_s}}\right) + O\left(\frac{1}{n}\right),$$

and this quantity simplifies further (upon expanding $\ln(1 + Z_s/\sqrt{np_s})$ and realizing that $\sum_{1\le s\le k} Z_s\sqrt{np_s} = 0$) to

$$-\frac{1}{2}\sum_{1\le s\le k} Z_s^2 + \frac{1-k}{2}\ln(2\pi n) - \frac{1}{2}\ln(p_1\ldots p_k) + O\left(\frac{1}{\sqrt{n}}\right).$$

15. The corresponding Jacobian determinant is easily evaluated by (a) removing the factor r^{n-1} from the determinant, (b) expanding the resulting determinant by the cofactors of the row containing "$\cos\theta_1 \ -\sin\theta_1\ 0\ldots 0$" (each of the cofactor determinants may be evaluated by induction), and (c) recalling that $\sin^2\theta_1 + \cos^2\theta_1 = 1$.

16. $$\int_0^{z\sqrt{2x}+y} \exp\left(-\frac{u^2}{2x}+\cdots\right)du = ye^{-z^2} + O\left(\frac{1}{\sqrt{x}}\right) + \int_0^{z\sqrt{2x}} \exp\left(-\frac{u^2}{2x}+\cdots\right)du.$$

The latter integral is

$$\int_0^{z\sqrt{2x}} e^{-u^2/2x}\,du + \frac{1}{3x^2}\int_0^{z\sqrt{2x}} e^{-u^2/2x}u^3\,du + O\left(\frac{1}{\sqrt{x}}\right).$$

When all is put together, the final result is

$$\frac{\gamma(x+1, x+z\sqrt{2x}+y)}{\Gamma(x+1)} = \frac{1}{\sqrt{2\pi}}\int_{-\infty}^{z\sqrt{2}} e^{-u^2/2}\,du + \frac{e^{-z^2}}{\sqrt{2\pi x}}(y - \tfrac{2}{3} - \tfrac{2}{3}z^2) + O\left(\frac{1}{x}\right).$$

If we set $z\sqrt{2} = x_p$ and write

$$\frac{1}{\sqrt{2\pi}}\int_{-\infty}^{z\sqrt{2}} e^{-u^2/2}\,du = p, \qquad x+1 = \frac{\nu}{2}, \qquad \gamma\left(\frac{\nu}{2}, \frac{t}{2}\right)\Big/\Gamma\left(\frac{\nu}{2}\right) = p,$$

where $t/2 = x + z\sqrt{2x} + y$, we can solve for y to obtain $y = \frac{2}{3}(1+z^2) + O(1/\sqrt{x})$, which is consistent with the above analysis. The solution is therefore $t = \nu + 2\sqrt{\nu}z + \frac{4}{3}z^2 - \frac{2}{3} + O(1/\sqrt{\nu})$.

17. (a) Change of variable, $x_j \leftarrow x_j + t$. (b) Induction on n; by definition,

$$P_{n0}(x-t) = \int_n^x P_{(n-1)0}(x_n - t)\,dx_n.$$

(c) The left-hand side is

$$\int_n^{x+t} dx_n \ldots \int_{k+1}^{x_{k+2}} dx_{k+1} \qquad \text{times} \qquad \int_t^k dx_k \int_t^{x_k} dx_{k-1} \ldots \int_t^{x_2} dx_1.$$

(d) From (b), (c) we have

$$P_{nk}(x) = \sum_{0 \le r \le k} \frac{(r-t)^r}{r!} \frac{(x+t-r)^{n-r-1}}{(n-r)!}(x+t-n).$$

The numerator in (24) is $P_{n\lfloor t \rfloor}(n)$.

18. We may assume that $F(x) = x$ for $0 \le x \le 1$, as remarked in the text's derivation of (24). If $0 \le X_1 \le \cdots \le X_n \le 1$, let $Z_j = 1 - X_{n+1-j}$. We have $0 \le Z_1 \le \cdots \le Z_n \le 1$; and K_n^+ evaluated for $X_1, \ldots, X_n$ equals K_n^- evaluated for $Z_1, \ldots, Z_n$. This symmetrical relation gives a one-to-one correspondence between sets of equal volume for which K_n^+ and K_n^- fall in a given range.

23. Let m be any number $\ge n$. (a) If $\lfloor mF(X_i) \rfloor = \lfloor mF(X_j) \rfloor$ and $i > j$, then $i/n - F(X_i) > j/n - F(X_j)$. (b) Start with $a_k = 1.0$, $b_k = 0.0$, and $c_k = 0$ for $0 \le k < m$. Then do the following for each observation X_j: Set $Y \leftarrow F(X_j)$, $k \leftarrow \lfloor mY \rfloor$, $a_k \leftarrow \min(a_k, Y)$, $b_k \leftarrow \max(b_k, Y)$, $c_k \leftarrow c_k + 1$. (Assume that $F(X_j) < 1$ so that $k < m$.) Then set $j \leftarrow 0$, $r^+ \leftarrow r^- \leftarrow 0$, and for $k = 0, 1, \ldots, m-1$ (in this order) do the following whenever $c_k > 0$: Set $r^- \leftarrow \max(r^-, a_k - j/n)$, $j \leftarrow j + c_k$, $r^+ \leftarrow \max(r^+, j/n - b_k)$. Finally set $K_n^+ \leftarrow \sqrt{n}\,r^+$, $K_n^- \leftarrow \sqrt{n}\,r^-$. The time required is $O(m+n)$, and the precise value of n need not be known in advance. (If the estimate $(k + \frac{1}{2})/m$ is used for a_k and b_k, so that only the values c_k are actually computed for each k, we obtain estimates of K_n^+ and K_n^- good to within $\frac{1}{2}\sqrt{n}/m$, even when $m < n$.) [*ACM Trans. Math. Software* **3** (1977), 60–64.]

SECTION 3.3.2

1. The observations for a chi-square test must be independent, and in the second sequence successive observations are manifestly dependent, since the second component of one equals the first component of the next.

2. Form t-tuples $(Y_{jt}, \ldots, Y_{jt+t-1})$, for $0 \le j < n$, and count how many of these equal each possible value. Apply the chi-square test with $k = d^t$ and with probability $1/d^t$ in each category. The number of observations, n, should be at least $5d^t$.

3. The probability that j values are examined, i.e., the probability that U_{j-1} is the nth element of the sequence lying in the range $\alpha \le U_{j-1} < \beta$, is easily seen to be

$$\binom{j-1}{n-1} p^n (1-p)^{j-n},$$

by enumeration of the possible places in which the other $n-1$ occurrences can appear and by evaluating the probability of such a pattern. The generating function is $G(z) = (pz/(1-(1-p)z))^n$, which makes sense since the given distribution is the n-fold convolution of the same thing for $n = 1$. Hence the mean and variance are proportional to n; the number of U's to be examined is now easily found to have the characteristics (min n, ave n/p, max ∞, dev $\sqrt{n(1-p)}/p$). A more detailed discussion of this probability distribution when $n = 1$ may be found in the answer to exercise 3.4.1–17; see also the considerably more general results of exercise 2.3.4.2–26.

4. The probability of a gap of length $\ge r$ is the probability that r consecutive U's lie outside the given range, i.e., $(1-p)^r$. The probability of a gap of length exactly r is the above value for length $\ge r$ minus the value for length $\ge (r+1)$.

5. As N goes to infinity, so does n (with probability 1), hence this test is just the same as the gap test described in the text except for the length of the very last gap. And the text's gap test certainly is asymptotic to the chi-square distribution stated, since the length of each gap is independent of the length of the others. [*Notes:* A quite complicated proof of this result by E. Bofinger and V. J. Bofinger appears in *Annals Math. Stat.* **32** (1961), 524–534. Their paper is noteworthy because it discusses several interesting variations of the gap test; they show, for example, that the quantity

$$\sum_{0 \le r \le t} \frac{(Y_r - (Np)p_r)^2}{(Np)p_r}$$

does *not* approach a chi-square distribution, although others had suggested this statistic as a "stronger" test because Np is the expected value of n.]

7. 5, 3, 5, 6, 5, 5, 4.

8. See exercise 10, with $w = d$.

9. (Change d to w in steps C1 and C4.) We have

$$p_r = \frac{d(d-1)\ldots(d-w+1)}{d^r} \left\{ {r-1 \atop w-1} \right\}, \qquad \text{for } w \le r < t;$$

$$p_t = 1 - \frac{d!}{d^{t-1}} \left(\frac{1}{0!} \left\{ {t-1 \atop d} \right\} + \cdots + \frac{1}{(d-w)!} \left\{ {t-1 \atop w} \right\} \right).$$

10. As in exercise 3, we really need consider only the case $n = 1$. The generating function for the probability that a coupon set has length r is

$$G(z) = \frac{d!}{(d-w)!} \sum_{r>0} \left\{ {r-1 \atop w-1} \right\} \left(\frac{z}{d}\right)^r = z^w \left(\frac{d-1}{d-z}\right) \cdots \left(\frac{d-w+1}{d-(w-1)z}\right)$$

by the previous exercise and Eq. 1.2.9–28. The mean and variance are readily computed using Theorem 1.2.10A and exercise 3.4.1–17. We find that

$$\text{mean}(G) = w + \left(\frac{d}{d-1} - 1\right) + \cdots + \left(\frac{d}{d-w+1} - 1\right) = d(H_d - H_{d-w}) = \mu;$$
$$\text{var}(G) = d^2(H_d^{(2)} - H_{d-w}^{(2)}) - d(H_d - H_{d-w}) = \sigma^2.$$

The number of U's examined, as the search for a coupon set is repeated n times, therefore has the characteristics (min wn, ave μn, max ∞, dev $\sigma\sqrt{n}$).

11. $\big|\,1\,\big|\,2\,\big|\,9\;\;8\;\;5\;\;3\,\big|\,6\,\big|\,7\;\;0\,\big|\,4\,\big|$.

12. Algorithm R (*Data for run test*).

R1. [Initialize.] Set $j \leftarrow -1$, and set COUNT[1] $\leftarrow$ COUNT[2] $\leftarrow \cdots \leftarrow$ COUNT[6] $\leftarrow 0$. Also set $U_n \leftarrow U_{n-1}$, for convenience in terminating the algorithm.

R2. [Set r zero.] Set $r \leftarrow 0$.

R3. [Is $U_j < U_{j+1}$?] Increase r and j by 1. If $U_j < U_{j+1}$, repeat this step.

R4. [Record the length.] If $r \geq 6$, increase COUNT[6] by one, otherwise increase COUNT[r] by one.

R5. [Done?] If $j < n-1$, return to step R2. ∎

13. There are $(p+q+1)\binom{p+q}{p}$ ways to have $U_{i-1} \gtrless U_i < \cdots < U_{i+p-1} \gtrless U_{i+p} < \cdots < U_{i+p+q-1}$; subtract $\binom{p+q+1}{p+1}$ of these in which $U_{i-1} < U_i$, and subtract $\binom{p+q+1}{1}$ for those in which $U_{i+p-1} < U_{i+p}$; then add in 1 for the case that both $U_{i-1} < U_i$ and $U_{i+p-1} < U_{i+p}$, since this case has been subtracted out twice. (This is a special case of the "inclusion-exclusion" principle, which is explained further in Section 1.3.3.)

14. A run of length r occurs with probability $1/r! - 1/(r+1)!$, assuming distinct U's.

15. This is always true of $F(X)$ when F is continuous and S has distribution F; see Section 3.3.1C.

16. (a) $Z_{jt} = \max(Z_{j(t-1)}, Z_{(j+1)(t-1)})$. If the $Z_{j(t-1)}$ are stored in memory, it is therefore a simple matter to transform this array into the set of Z_{jt} with no auxiliary storage required. (b) With his "improvement," each of the V's should indeed have the stated distribution, but the observations are no longer independent. In fact, when U_j is a relatively large value, all of Z_{jt}, $Z_{(j-1)t}$, ..., $Z_{(j-t+1)t}$ will be equal to U_j; so we almost have the effect of repeating the same data t times (and that would multiply V by t, cf. exercise 3.3.1–10).

17. (b) By Lagrange's identity, the difference is $\sum_{0\leq k<j<n}(U'_kV'_j - U'_jV'_k)^2$, and this is certainly positive. (c) Therefore if $D^2 = N^2$, we must have $U'_kV'_j - U'_jV'_k = 0$, for all pairs j, k. This means that the matrix

$$\begin{pmatrix} U'_1 & U'_2 \ldots U'_{n-1} \\ V'_1 & V'_2 \ldots V'_{n-1} \end{pmatrix}$$

has rank < 2, so its rows are linearly dependent. (A more elementary proof can be given, using the fact that $U'_0V'_j - U'_jV'_0 = 0$ for $1 \leq j < n$ implies the existence of constants α, β such that $\alpha U'_j + \beta V'_j = 0$ for all j, provided that U'_0 and V'_0 are not both zero; the latter case can be avoided by a suitable renumbering.)

18. (a) The numerator is $-(U_0 - U_1)^2$, the denominator is $(U_0 - U_1)^2$. (b) The numerator in this case is $-(U_0^2 + U_1^2 + U_2^2 - U_0U_1 - U_1U_2 - U_2U_0)$; the denominator is $2(U_0^2 + \cdots - U_2U_0)$. (c) The denominator always equals $\sum_{0\le j<k<n}(U_j - U_k)^2$, by exercise 1.2.3–30 or 1.2.3–31.

21. The successive values of $c_{r-1} = s - 1$ in step P2 are 2, 3, 7, 6, 4, 2, 2, 1, 0; hence $f = 886862$.

22. $1024 = 6! + 2\cdot 5! + 2\cdot 4! + 2\cdot 3! + 2\cdot 2! + 0\cdot 1!$, so we want the successive values of $s - 1$ in step P2 to be 0, 0, 0, 1, 2, 2, 2, 2, 0; working backwards, the permutation is $(9, 6, 5, 2, 3, 4, 0, 1, 7, 8)$.

SECTION 3.3.3

1. $y((x/y)) + \frac{1}{2}y - \frac{1}{2}y\delta(x/y)$.

2. See exercises 1.2.4–38 and 1.2.4–39(a), (b), (g).

3. $f(x) = \sum_{n\ge 1}(-\sin 2\pi nx)/n$, which converges for all x. (The representation in Eq. (24) may be considered a "finite" Fourier series, for the case when x is rational.)

4. $d = 2^{10}\cdot 5$. Note that we have $X_{n+1} < X_n$ with probability $\frac{1}{2} + \epsilon$, where

$$|\epsilon| < d/(2\cdot 10^{10}) = 1/(2\cdot 5^9);$$

hence *every* potency-10 generator is respectable from the standpoint of Theorem P.

5. An intermediate result:

$$\sum_{0\le x<m} \frac{x}{m}\frac{s(x)}{m} = \frac{1}{12}\sigma(a, m, c) + \frac{m}{4} - \frac{c}{2m} - \frac{x'}{2m}.$$

6. (a) Use induction and the formula

$$\left(\!\!\left(\frac{hj+c}{k}\right)\!\!\right) - \left(\!\!\left(\frac{hj+c-1}{k}\right)\!\!\right) = \frac{1}{k} - \frac{1}{2}\delta\left(\frac{hj+c}{k}\right) - \frac{1}{2}\delta\left(\frac{hj+c-1}{k}\right).$$

(b) Use the fact that $-\left(\!\!\left(\frac{h'j}{k}\right)\!\!\right) = -\left(\!\!\left(\frac{j}{hk} - \frac{k'j}{h}\right)\!\!\right) = \left(\!\!\left(\frac{k'j}{h}\right)\!\!\right) - \frac{j}{hk} + \frac{1}{2}\delta\left(\frac{k'j}{h}\right)$.

7. Take $m = h$, $n = k$, $k = 2$ in the second formula of exercise 1.2.4–45:

$$\sum_{0<j<k}\left(\frac{hj}{k} - \left(\!\!\left(\frac{hj}{k}\right)\!\!\right) + \frac{1}{2}\right)\left(\frac{hj}{k} - \left(\!\!\left(\frac{hj}{k}\right)\!\!\right) - \frac{1}{2}\right) + 2\sum_{0<j<h}\left(\frac{kj}{h} - \left(\!\!\left(\frac{kj}{h}\right)\!\!\right) + \frac{1}{2}\right)j = kh(h-1).$$

The sums on the left simplify, and by standard manipulations we get

$$h^2k - hk - \frac{h}{2} + \frac{h^2}{6k} + \frac{k}{12} + \frac{1}{4} - \frac{h}{6}\sigma(h, k, 0) - \frac{h}{6}\sigma(k, h, 0) + \frac{1}{12}\sigma(1, k, 0) = h^2k - hk.$$

Since $\sigma(1, k, 0) = (k-1)(k-2)/k$, this reduces to the reciprocity law.

8. See *Duke Math. J.* **21** (1954), 391–397.

9. Begin with the handy identity $\sum_{0\le k<r}\lfloor kp/r\rfloor\lfloor kq/r\rfloor+\sum_{0\le k<p}\lfloor kq/p\rfloor\lfloor kr/p\rfloor+\sum_{0\le k<q}\lfloor kr/q\rfloor\lfloor kp/q\rfloor=(p-1)(q-1)(r-1)$ for which a simple geometric proof is possible. [U. Dieter, *Abh. Math. Sem. Univ. Hamburg* **21** (1957), 109–125.]

10. Obviously $\sigma(k-h,k,c)=-\sigma(h,k,-c)$, cf. (8). Replace j by $k-j$ in definition (16), to deduce that $\sigma(h,k,c)=\sigma(h,k,-c)$.

11. (a) $\displaystyle\sum_{0\le j<dk}\left(\!\left(\frac{j}{dk}\right)\!\right)\left(\!\left(\frac{hj+c}{k}\right)\!\right)=\sum_{\substack{0\le i<d\\0\le j<k}}\left(\!\left(\frac{ik+j}{dk}\right)\!\right)\left(\!\left(\frac{hj+c}{k}\right)\!\right)$; use (10) to sum on i. (b) $\displaystyle\left(\!\left(\frac{hj+c+\theta}{k}\right)\!\right)=\left(\!\left(\frac{hj+c}{k}\right)\!\right)+\frac{\theta}{k}-\frac{1}{2}\delta\left(\frac{hj+c}{k}\right)$; now sum.

12. Since $((\frac{hj+c}{k}))$ runs through the same values as $((\frac{j}{k}))$ in some order, Cauchy's inequality implies that $\sigma(h,k,c)^2\le\sigma(h,k,0)^2$; and $\sigma(1,k,0)$ may be summed directly, cf. exercise 7.

13. $\displaystyle\sigma(h,k,c)+\frac{3(k-1)}{k}=\frac{12}{k}\sum_{0<j<k}\frac{\omega^{-cj}}{(\omega^{-hj}-1)(\omega^{j}-1)}+\frac{6}{k}(c \bmod k)-6\left(\!\left(\frac{h'c}{k}\right)\!\right)$,

if $hh'\equiv 1$ (modulo k).

14. $(2^{38}-3\cdot 2^{20}+5)/(2^{70}-1)\approx 2^{-32}$. An extremely satisfactory global value, in spite of the local nonrandomness!

15. Replace c^2 where it appears in (19) by $\lfloor c\rfloor\lceil c\rceil$.

16. The hinted identity is equivalent to $m_1=p_rm_{r+1}+p_{r-1}m_{r+2}$ for $1\le r\le t$; this follows by induction, cf. also exercise 4.5.3–32. Now replace c_j by $\sum_{j\le r\le t}b_rm_{r+1}$ and compare coefficients of b_ib_j on both sides of the identity to be proved.

Note: For all exponents $e\ge 1$ we have

$$\sum_{1\le j\le t}(-1)^{j+1}\frac{c_j^e}{m_jm_{j+1}}=\frac{1}{m_1}\sum_{1\le j\le t}(-1)^{j+1}b_j\frac{(c_j^e-c_{j+1}^e)}{c_j-c_{j+1}}p_{j-1}$$

by a similar argument.

17. During this algorithm we will have $k=m_j$, $h=m_{j+1}$, $c=c_j$, $p=p_j-1$, $p'=p_{j-2}$, $s=(-1)^{j+1}$ for $j=1,2,\ldots,t+1$.

D1. [Initialize.] Set $A\leftarrow 0$, $B\leftarrow h$, $p\leftarrow 1$, $p'\leftarrow 0$, $s\leftarrow 1$.

D2. [Divide.] Set $a\leftarrow\lfloor k/h\rfloor$, $b\leftarrow\lfloor c/h\rfloor$, $r\leftarrow c \bmod h$. (Now $a=a_j$, $b=b_j$, and $r=c_{j+1}$.)

D3. [Accumulate.] Set $A\leftarrow A-(a-6b)s$, $B\leftarrow B+6bp(c+r)s$. If $r\ne 0$ or $c=0$, set $A\leftarrow A-3s$. If $h=1$, set $B\leftarrow B+ps$. (This subtracts $3e(m_{j+1},c_j)$ and also takes care of the $\sum(-1)^{j+1}/m_jm_{j+1}$ terms.)

D4. [Prepare for next iteration.] Set $c\leftarrow r$, $s\leftarrow -s$; set $r\leftarrow k-ah$, $k\leftarrow h$, $h\leftarrow r$; set $r\leftarrow ap+p'$, $p'\leftarrow p$, $p\leftarrow r$. If $h>0$, return to D2. ∎

At the conclusion of this algorithm, p will be equal to the original value k_0 of k, so the desired answer will be $A+B/p$. The final value of p' will be h' if $s < 0$, otherwise p' will be $k_0 - h'$. It would be possible to maintain B in the range $0 \le B < k_0$, by making appropriate adjustments to A, thereby requiring only single-precision operations (with double-precision products and dividends) if k_0 is a single-precision number.

18. A moment's thought shows that the formula

$$S(h,k,c,z) = \sum_{0\le j<k}(\lfloor j/k\rfloor - \lfloor (j-z)/k\rfloor)(((hj+c)/k))$$

is in fact valid for all z, not only when $k \ge z$. Writing $\lfloor j/k\rfloor - \lfloor (j-z)/k\rfloor = \frac{z}{k} + ((\frac{j-z}{k})) - ((\frac{j}{k})) + \frac{1}{2}\delta_{j0} - \frac{1}{2}\delta(\frac{j-z}{k})$ and carrying out the sums yields $S(h,k,c,z) = zd((c/d))/k + \frac{1}{12}\sigma(h,k,hz+c) - \frac{1}{12}\sigma(h,k,c) + \frac{1}{2}((c/k)) - \frac{1}{2}(((hz+c)/k))$, where $d = \gcd(h,k)$. [This formula allows us to express the probability that $X_{n+1} < X_n < \alpha$ in terms of generalized Dedekind sums, given α.]

19. The desired probability is

$$\begin{aligned}
&\sum_{0\le x<m}(\lfloor (x-\alpha)/m\rfloor - \lfloor (x-\beta)/m\rfloor)(\lfloor (s(x)-\alpha')/m\rfloor - \lfloor (s(x)-\beta')/m\rfloor)/m\\
&\quad= \sum_{0\le x<m}\Big(\tfrac{\beta-\alpha}{m} + ((\tfrac{x-\beta}{m})) - ((\tfrac{x-\alpha}{m})) + \tfrac{1}{2}\delta(\tfrac{x-\alpha}{m}) - \tfrac{1}{2}\delta(\tfrac{x-\beta}{m})\Big)\\
&\qquad\times\big(\tfrac{\beta'-\alpha'}{m} + ((\tfrac{ax+c-\beta'}{m})) - ((\tfrac{ax+c-\alpha'}{m})) + \tfrac{1}{2}\delta(\tfrac{ax+c-\alpha'}{m}) - \tfrac{1}{2}\delta(\tfrac{ax+c-\beta'}{m})\big)/m\\
&\quad= \tfrac{\beta-\alpha}{m}\tfrac{\beta'-\alpha'}{m} + \tfrac{1}{12m}(\sigma(a,m,c+a\alpha-\alpha') - \sigma(a,m,c+a\alpha-\beta')\\
&\qquad\qquad + \sigma(a,m,c+a\beta-\beta') - \sigma(a,m,c+a\beta-\alpha')) + \epsilon,
\end{aligned}$$

where $|\epsilon| \le 2.5/m$.

[This approach is due to U. Dieter. The discrepancy between the true probability and the ideal value $\frac{\beta-\alpha}{m}\frac{\beta'-\alpha'}{m}$ is bounded by $\sum_{1\le j\le t} a_j/4m$, according to Theorem K; conversely, by choosing α, β, α', β' appropriately we will obtain a discrepancy of at least half this bound when there are large partial quotients, by the fact that Theorem K is "best possible." Note that when $a \approx \sqrt{m}$ the discrepancy cannot exceed $O(1/\sqrt{m}\,)$, so even the locally nonrandom generator of exercise 14 will look good on the serial test over the full period; it appears that we should insist on an *extremely* small discrepancy.]

20. $\sum_{0\le x<m}\lceil (x-s(x))/m\rceil\lceil (s(x)-s(s(x)))/m\rceil/m = \sum_{0\le x<m}((x-s(x))/m + (((bx+c)/m)) + \frac{1}{2})((s(x)-s(s(x)))/m + ((a(bx+c)/m)) + \frac{1}{2})/m$; and $x/m = ((x/m)) + \frac{1}{2} - \frac{1}{2}\delta(x/m)$, $s(x)/m = (((ax+c)/m)) + \frac{1}{2} - \frac{1}{2}\delta((ax+c)/m)$, $s(s(x))/m = (((a^2x + ac + c)/m)) + \frac{1}{2} - \frac{1}{2}\delta((a^2x+ac+c)/m)$. Let $s(x') = s(x'') = 0$ and $d = \gcd(b,m)$. The sum now reduces to

$$\begin{aligned}
&\frac{1}{4} + \frac{1}{12m}(S_1 - S_2 + S_3 - S_4 + S_5 - S_6 + S_7 - S_8 + S_9) + \frac{d}{2m}\Big(\big((\tfrac{c}{d})\big) + \big((\tfrac{ac}{d})\big)\Big)\\
&\quad+ \frac{1}{2m}\Big(\big((\tfrac{x'-x''}{m})\big) - \big((\tfrac{x'}{m})\big) + \big((\tfrac{x''}{m})\big) + \big((\tfrac{ac+c}{m})\big) - \big((\tfrac{ac}{m})\big) - \big((\tfrac{c}{m})\big) - \frac{1}{2}\Big),
\end{aligned}$$

where $S_1 = \sigma(a,m,c)$, $S_2 = \sigma(a^2,m,ac+c)$, $S_3 = \sigma(ab,m,ac)$, $S_4 = \sigma(1,m,0) = (m-1)(m-2)/m$, $S_5 = \sigma(a,m,c)$, $S_6 = \sigma(b,m,c)$, $S_7 = -\sigma(a'-1,m,a'c)$, and

$S_8 = -\sigma(a'(a'-1), m, (a')^2 c)$, if $a'a \equiv 1$ (modulo m); and finally

$$\begin{aligned} S_9 &= 12 \sum_{0\le x<m} \left(\!\!\left(\frac{bx+c}{m}\right)\!\!\right)\left(\!\!\left(\frac{a(bx+c)}{m}\right)\!\!\right) \\ &= 12d \sum_{0\le x<m/d} \left(\!\!\left(\frac{x+c_0/d}{m/d}\right)\!\!\right)\left(\!\!\left(\frac{a(x+c_0/d}{m/d}\right)\!\!\right) \\ &= 12d \sum_{0\le x<m/d} \left(\!\!\left(\frac{x}{m/d}\right)\!\!\right) + \frac{c_0}{m} - \frac{1}{2}\delta_{x0}\left(\!\!\left(\frac{a(x+c_0/d)}{m/d}\right)\!\!\right) \\ &= d\left(\sigma(ad, m, ac_0) + 12\frac{c_0}{m}\left(\!\!\left(\frac{ac_0}{d}\right)\!\!\right) - 6\left(\!\!\left(\frac{ac_0}{m}\right)\!\!\right)\right) \end{aligned}$$

where $c_0 = c \bmod d$. The grand total will be near $\frac{1}{6}$ when d is small and when the fractions a/m, $(a^2 \bmod m)/m$, $(ab \bmod m)/m$, b/m, $(a'-1)/m$, $(a'(a'-1) \bmod m)/m$, $((ad) \bmod m)/m$ all have small partial quotients. (Note that $a' - 1 \equiv -b + b^2 - \cdots$, cf. exercise 3.2.1.3–7.)

21. $C = (s - (\frac{1}{2})^2)/(\frac{1}{3} - (\frac{1}{2})^2)$, where

$$\begin{aligned} s_n &= \int_{x_n}^{x_{n+1}} x\{ax+\theta\}\,dx = \frac{1}{a^2}\left(\frac{1}{3} - \frac{\theta}{2} + \frac{n}{2}\right), \qquad \text{if } x_n = \frac{n-\theta}{a}; \\ s &= \int_0^1 x\{ax+\theta\}\,dx = s_0 + s_1 + \cdots + s_{a-1} + \int_{-\theta/a}^0 (ax+\theta)\,dx \\ &= \frac{1}{3a} - \frac{\theta}{2a} + \frac{a-1}{4a} + \frac{\theta^2}{2a}. \end{aligned}$$

Therefore $C = (1 - 6\theta + 6\theta^2)/a$.

22. Let $[u, v)$ denote the set $\{\, x \mid u \le x < v \,\}$. We have $s(x) < x$ in the disjoint intervals

$$\left[\frac{1-\theta}{a}, \frac{1-\theta}{a-1}\right), \quad \left[\frac{2-\theta}{a}, \frac{2-\theta}{a-1}\right), \quad \ldots, \quad \left[\frac{a-\theta}{a}, 1\right),$$

which have total length

$$1 + \sum_{0<j\le a-1} \left(\frac{j-\theta}{a-1}\right) - \sum_{0<j\le a} \left(\frac{j-\theta}{a}\right) = 1 + \frac{a}{2} - \theta - \frac{a+1}{2} + \theta = \frac{1}{2}.$$

23. We have $s(s(x)) < s(x) < x$ when x is in $\left[\frac{k-\theta}{a}, \frac{k-\theta}{a-1}\right)$ and $ax + \theta - k$ is in $\left[\frac{j-\theta}{a}, \frac{j-\theta}{a-1}\right)$, for $0 < j \le k < a$; or when x is in $\left[\frac{a-\theta}{a}, 1\right)$ and $ax + \theta - a$ is either in $\left[\frac{j-\theta}{a}, \frac{j-\theta}{a-1}\right)$ for $0 < j \le \lfloor a\theta \rfloor$ or in $\left[\frac{\lfloor a\theta\rfloor + 1 - \theta}{a}, \theta\right)$. The desired probability is

$$\begin{aligned} &\sum_{0<j\le k<a} \frac{j-\theta}{a^2(a-1)} + \sum_{0<j\le \lfloor a\theta\rfloor} \frac{j-\theta}{a^2(a-1)} + \frac{1}{a^2}\max(0, \{a\theta\} + \theta - 1) \\ &\qquad = \frac{1}{6} + \frac{1}{6a} - \frac{\theta}{2a} + \frac{1}{a^2}\left(\frac{\lfloor a\theta\rfloor(\lfloor a\theta\rfloor + 1 - 2\theta)}{2(a-1)} + \max(0, \{a\theta\} + \theta - 1)\right), \end{aligned}$$

which is $\frac{1}{6} + (1 - 3\theta + 3\theta^2)/6a + O(1/a^2)$ for large a. Note that $1 - 3\theta + 3\theta^2 \ge \frac{1}{4}$, so θ can't be chosen to make this probability come out right.

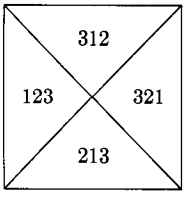

Fig. A–1. Permutation regions for Fibonacci generator.

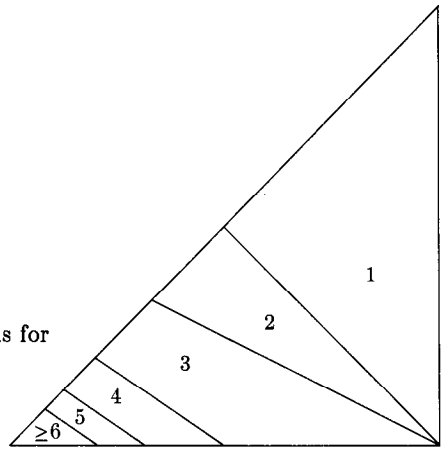

Fig. A–2. Run-length regions for Fibonacci generator.

24. Proceed as in the previous exercise; the sum of the interval lengths is

$$\sum_{0<j_1\le\cdots\le j_{t-1}<a} \frac{j_1}{a^{t-1}(a-1)} = \frac{1}{a^{t-1}(a-1)}\binom{a+t-2}{t}.$$

To compute the average length, let p_k be the probability of a run of length $\ge k$; the average is

$$\sum_{k\ge1} p_k = \sum_{k\ge1}\binom{a+k-2}{k}\frac{1}{a^{k-1}(a-1)} = \left(\frac{a}{a-1}\right)^a - \frac{a}{a-1}.$$

The value for a truly random sequence would be $e-1$; and our value is $e-1+(e/2-1)/a+O(1/a^2)$. [*Note:* The same result holds for an ascending run, since we have $U_n > U_{n+1}$ if and only if $1-U_n < 1-U_{n+1}$. This would lead us to suspect that runs in linear congruential sequences might be slightly longer than normal, so the run test should be applied to such generators.]

25. x must be in the interval $[(k+\alpha'-\theta)/a, (k+\beta'-\theta)/a)$ for some k, and also in the interval $[\alpha,\beta)$. Let $k_0 = \lceil a\alpha+\theta-\beta'\rceil$, $k_1 = \lceil a\beta+\theta-\beta'\rceil$. With due regard to boundary conditions, we get the probability

$$(k_1-k_0)(\beta'-\alpha')/a + \max(0,\beta-(k_1+\alpha'-\theta)/a) - \max(0,\alpha-(k_0+\alpha'-\theta)/a).$$

This is $(\beta-\alpha)(\beta'-\alpha')+\epsilon$, where $|\epsilon| < 2(\beta'-\alpha')/a$.

26. See Fig. A–1; the orderings $U_1 < U_3 < U_2$ and $U_2 < U_3 < U_1$ are impossible; the other four each have probability $\frac{1}{4}$.

27. $U_n = \{F_{n-1}U_0 + F_nU_1\}$. We need to have both $F_{k-1}U_0 + F_kU_1 < 1$ and $F_kU_0 + F_{k+1}U_1 > 1$. The half-unit-square in which $U_0 > U_1$ is broken up as shown in Fig. A–2, with various values of k indicated. The probability for a run of length k is $\frac{1}{2}$, if $k=1$; $1/F_{k-1}F_{k+1} - 1/F_kF_{k+2}$, if $k>1$. The corresponding probabilities for a random sequence are $2k/(k+1)! - 2(k+1)/(k+2)!$; the following table compares the first few values.

k:	1	2	3	4	5
Probability in Fibonacci case:	$\frac{1}{2}$	$\frac{1}{3}$	$\frac{1}{10}$	$\frac{1}{24}$	$\frac{1}{65}$
Probability in random case:	$\frac{1}{3}$	$\frac{5}{12}$	$\frac{11}{60}$	$\frac{19}{360}$	$\frac{29}{2520}$

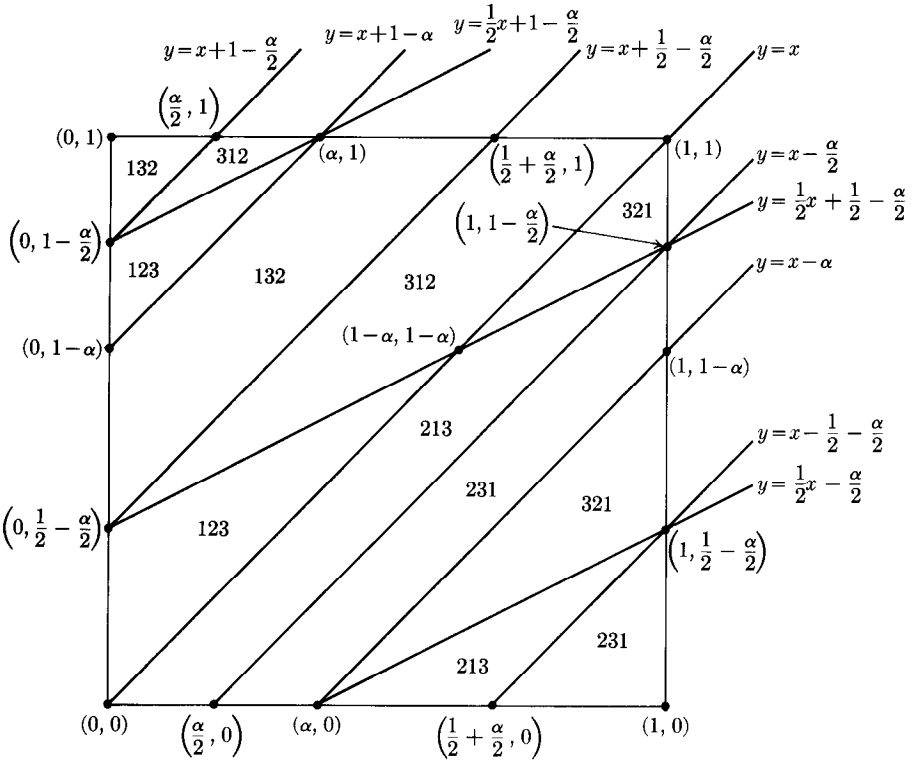

Fig. A–3. Permutation regions for a generator with potency 2; $\alpha = (a-1)c/m$.

28. Fig. A–3 shows the various regions in the general case. The "213" region means $U_2 < U_1 < U_3$, if U_1 and U_2 are chosen at random; the "321" region means that $U_3 < U_2 < U_1$, etc. The probabilities for 123 and 321 are $\frac{1}{4} - \alpha/2 + \alpha^2/2$; the probabilities for all other cases are $\frac{1}{8} + \alpha/4 - \alpha^2/4$. To have all equal to $\frac{1}{6}$, we must have $1 - 6\alpha + 6\alpha^2 = 0$. [This exercise establishes a theorem due to J. N. Franklin, *Math. Comp.* **17** (1963), 28–59, Theorem 13; other results of Franklin's paper are related to exercises 22 and 23.]

SECTION 3.3.4

1. ν_1 is always m and $\mu_1 = 2$, for generators of maximum period.

2. Let V be the matrix whose rows are $V_1, \ldots, V_t$. To minimize $Y \cdot Y$, subject to the condition that $Y \neq (0, \ldots, 0)$ and VY is an integer column vector X, is equivalent to minimizing $(V^{-1}X)\cdot(V^{-1}X)$, subject to the condition that X is a nonzero integer column vector. The columns of V^{-1} are $U_1, \ldots, U_t$.

3. $a^2 \equiv 2a - 1$ and $a^3 \equiv 3a - 2$ (modulo m). By considering all short solutions of (15), we find that $\nu_3^2 = 6$ and $\nu_4^2 = 4$, for the respective vectors $(1, -2, 1)$ and $(1, -1, -1, 1)$, except in the following cases: $m = 2^e q$, q odd, $e \geq 3$, $a \equiv 2^{e-1}$ (modulo 2^e), $a \equiv 1$ (modulo q), $\nu_3^2 = \nu_4^2 = 2$; $m = 3^e q$, $\gcd(3, q) = 1$, $e \geq 2$, $a \equiv 1 \pm 3^{e-1}$ (modulo 3^e), $a \equiv 1$ (modulo q), $\nu_4^2 = 2$; $m = 9$, $a = 4$ or 7, $\nu_2^2 = \nu_3^2 = 5$.

4. (a) The unique choice for (x_1, x_2) is $\frac{1}{m}(y_1 u_{22} - y_2 u_{21}, -y_1 u_{12} + y_2 u_{11})$, and this is $\equiv \frac{1}{m}(y_1 u_{22} + y_2 a u_{22}, -y_1 u_{12} - y_2 a u_{12}) \equiv (0, 0)$ (modulo 1); i.e., x_1 and x_2 are integers. (b) When $(x_1, x_2) \neq (0, 0)$, we have $(x_1 u_{11} + x_2 u_{21})^2 + (x_1 u_{12} + x_2 u_{22})^2 = x_1^2(u_{11}^2 + u_{12}^2) + x_2^2(u_{21}^2 + u_{22}^2) + 2x_1 x_2(u_{11} u_{21} + u_{12} u_{22})$, and by hypothesis this is $\geq (x_1^2 + x_2^2 - |x_1 x_2|)(u_{11}^2 + u_{12}^2) \geq u_{11}^2 + u_{12}^2$. [Note that this is a stronger result than Lemma A, which tells us only that $x_1^2 \leq (u_{11}^2 + u_{12}^2)(u_{21}^2 + u_{22}^2)/m^2$ and that $x_2^2 \leq (u_{11}^2 + u_{12}^2)^2/m^2$, where the latter can be ≥ 1. The idea is essentially Gauss's notion of a reduced binary quadratic form, *Disq. Arith.* (Leipzig: 1801), §171.]

5. Conditions (30) remain invariant; hence h cannot be zero in step S2, when a is relatively prime to m. Since h always decreases in that step, S2 eventually terminates with $u^2 + v^2 \geq s$. Note that $pp' \leq 0$ throughout the calculation.

The hinted inequality surely holds the first time step S2 is performed. The integer q' that minimizes $(h' - qh)^2 + (p' - qp')^2$ is $q' = \text{round}((h'h + p'p)/(h^2 + p^2))$, by (24). If $(h' - q'h)^2 + (p' - q'p)^2 < h^2 + p^2$ we must have $q' \neq 0$, $q' \neq -1$, hence $(p' - q'p)^2 \geq p^2$, hence $(h' - q'h)^2 < h^2$, i.e., $|h' - q'h| < h$, i.e., q' is q or $q + 1$. We have $hu + pv \geq h(h' - q'h) + p(p' - q'p) \geq -\frac{1}{2}(h^2 + p^2)$, so if $u^2 + v^2 < s$ the next iteration of step S2 will preserve the assumption in the hint. If $u^2 + v^2 \geq s > (u - h)^2 + (v - p)^2$, we have $2|h(u - h) + p(v - p)| = 2(h(h - u) + p(p - v)) = (u - h)^2 + (v - p)^2 + h^2 + p^2 - (u^2 + v^2) \leq (u - h)^2 + (v - p)^2 \leq h^2 + p^2$, hence $(u-h)^2+(v-p)^2$ is minimal by exercise 4. Finally if both u^2+v^2 and $(u-h)^2+(v-p)^2$ are $\geq s$, let $u' = h' - q'h$, $v' = p' - q'p$; then $2|hu' + pv'| \leq h^2 + p^2 \leq u'^2 + v'^2$, and $h^2 + p^2$ is minimal by exercise 4.

6. If $u^2+v^2 \geq s > (u-h)^2+(v-p)^2$ in the previous answer, we have $(v-p)^2 > v^2$, hence $(u - h)^2 < u^2$; and if $q = a_j$, so that $h' = a_j h + u$, we must have $a_{j+1} = 1$. It follows that $\nu_2^2 = \min_{0 \leq j < t}(m_j^2 + p_{j-1}^2)$, in the notation of exercise 3.3.3–16.

Now we have $m_0 = m_j p_j + m_{j+1} p_{j-1} = a_j m_j p_{j-1} + m_j p_{j-2} + m_{j+1} p_{j-1} < (a_j + 1 + 1/a_j) m_j p_{j-1} \leq (A + 1 + 1/A) m_j p_{j-1}$, and $m_j^2 + p_{j-1}^2 \geq 2 m_j p_{j-1}$, hence the result.

7. We shall prove, using condition (19), that $U_j \cdot U_k = 0$ for all $k \neq j$ iff $V_j \cdot V_k = 0$ for all $k \neq j$. Assume that $U_j \cdot U_k = 0$ for all $k \neq j$, and let $U_j = \alpha_1 V_1 + \cdots + \alpha_t V_t$. Then $U_j \cdot U_k = \alpha_k$ for all k, hence $U_j = \alpha_j V_j$, and $V_j \cdot V_k = \alpha_j^{-1}(U_j \cdot V_k) = 0$ for all $k \neq j$. A symmetric argument proves the converse.

8. Clearly $\nu_{t+1} \leq \nu_t$ (a fact used implicitly in Algorithm S, since s is not changed when t increases). For $t = 2$ this is equivalent to $(m\mu_2/\pi)^{1/2} \geq (\frac{3}{4} m \mu_3/\pi)^{1/3}$, i.e., $\mu_3 \leq \frac{4}{3}\sqrt{m/\pi}\,\mu_2^{3/2}$. This reduces to $\frac{4}{3} 10^{-4}/\sqrt{\pi}$ with the given parameters, but for large m and fixed μ_2 the bound (39) is better.

9. Let $f(y_1, \ldots, y_t) = \theta$; then $\gcd(y_1, \ldots, y_t) = 1$, so there is an integer matrix W of determinant 1 having $(w_1, \ldots, w_t)$ as its first row. (Prove the latter fact by induction on the magnitude of the smallest nonzero entry in the row.) Now if $X = (x_1, \ldots, x_t)$ is a row vector, we have $XW = X'$ iff $X = X'W^{-1}$, and W^{-1} is an integer matrix of determinant 1, hence the form g defined by WU satisfies $g(x_1, \ldots, x_t) = f(x_1', \ldots, x_t')$; furthermore $g(1, 0, \ldots, 0) = \theta$.

Without loss of generality, assume that $f = g$. If now S is any orthogonal matrix, the matrix US defines the same form as U, since $(XUS)(XUS)^T = (XU)(XU)^T$. Choosing S so that its first column is a multiple of V_1 and its other columns are any suitable vectors, we have

$$US = \begin{pmatrix} \alpha_1 & \alpha_2 & \ldots & \alpha_t \\ 0 & & & \\ \vdots & & U' & \\ 0 & & & \end{pmatrix}$$

for some $\alpha_1, \alpha_2, \ldots, \alpha_t$ and some $(t-1) \times (t-1)$ matrix U'. Hence $f(x_1, \ldots, x_t) = (\alpha_1 x_1 + \cdots + \alpha_t x_t)^2 + h(x_2, \ldots, x_t)$. It follows that $\alpha_1 = \sqrt{\theta}$ [in fact, $\alpha_j = (U_1 \cdot U_j)/\sqrt{\theta}$ for $1 \le j \le t$], and that h is a positive definite quadratic form defined by U', where $\det U' = (\det U)/\sqrt{\theta}$. By induction on t, there are integers $(x_2, \ldots, x_t)$ with $h(x_2, \ldots, x_t) \le (\frac{4}{3})^{(t-2)/2} |\det U|^{2/(t-1)}/\theta^{1/(t-1)}$, and for these integer values we can choose x_1 so that $|x_1 + (\alpha_2 x_2 + \cdots + \alpha_t x_t)/\alpha_1| \le \frac{1}{2}$, i.e., $(\alpha_1 x_1 + \cdots + \alpha_t x_t)^2 \le \frac{1}{4}\theta$. Hence $\theta \le f(x_1, \ldots, x_t) \le \frac{1}{4}\theta + (\frac{4}{3})^{(t-2)/2} |\det U|^{2/(t-1)}/\theta^{1/(t-1)}$ and the desired inequality follows immediately.

[*Note:* For $t = 2$ the result is best possible. For general t, Hermite's theorem implies that $\mu_t \le \pi^{t/2}(4/3)^{t(t-1)/4}/(t/2)!$. A fundamental theorem due to Minkowski ("Every t-dimensional convex set symmetric about the origin with volume $\ge 2^t$ contains a nonzero integer point") gives $\mu_t \le 2^t$; this is stronger than Hermite's theorem for $t \ge 9$. Even stronger results are known, cf. (41).]

10. Since y_1 and y_2 are relatively prime, we can solve $u_1 y_2 - u_2 y_1 = m$; furthermore $(u_1 + q y_1) y_2 - (u_2 + q y_2) y_1 = m$ for all q, so we can ensure that $2|u_1 y_1 + u_2 y_2| \le y_1^2 + y_2^2$ by choosing an appropriate integer q. Now $y_2(u_1 + a u_2) \equiv y_2 u_1 - y_1 u_2 \equiv 0$ (modulo m), and y_2 must be relatively prime to m, hence $u_1 + a u_2 \equiv 0$. Finally let $|u_1 y_1 + u_2 y_2| = \alpha m$, $u_1^2 + u_2^2 = \beta m$, $y_1^2 + y_2^2 = \gamma m$; we have $0 \le \alpha \le \frac{1}{2}\gamma$, and it remains to be shown that $\alpha \le \frac{1}{2}\beta$ and $\beta\gamma \ge 1$. The identity $(u_1 y_2 - u_2 y_1)^2 + (u_1 y_1 + u_2 y_2)^2 = (u_1^2 + u_2^2)(y_1^2 + y_2^2)$ implies that $1 + \alpha^2 = \beta\gamma$. If $\alpha > \frac{1}{2}\beta$, we have $2\alpha\gamma > 1 + \alpha^2$, i.e., $\gamma - \sqrt{\gamma^2 - 1} < \alpha \le \frac{1}{2}\gamma$. But $\frac{1}{2}\gamma < \sqrt{\gamma^2 - 1}$ implies that $\gamma^2 > \frac{4}{3}$, a contradiction.

11. Since a is odd, $y_1 + y_2$ must be even. To avoid solutions with y_1 and y_2 both even, let $y_1 = x_1 + x_2$, $y_2 = x_1 - x_2$, and solve $x_1^2 + x_2^2 = m/\sqrt{3} - \epsilon$, with (x_1, x_2) relatively prime and x_1 even; the corresponding multiplier a will be the solution to $(x_2 - x_1)a \equiv x_2 + x_1$ (modulo 2^e). It is not difficult to prove that $a \equiv 1$ (modulo 2^{k+1}) iff $x_1 \equiv 0$ (modulo 2^k), so we get the best potency when $x_1 \bmod 4 = 2$. The problem reduces to finding relatively prime solutions to $x_1^2 + x_2^2 = N$ where N is a large integer of the form $4k+1$. By factoring N over the Gaussian integers, we can see that solutions exist if and only if each prime factor of N (over the usual integers) has the form $4k + 1$.

According to a famous theorem of Fermat, every prime p of the form $4k + 1$ can be written $p = u^2 + v^2 = (u + iv)(u - iv)$, v even, in a unique way except for the signs of u and v. The numbers u and v can be calculated efficiently by solving $x^2 \equiv -1$ (modulo p), then calculating $u + iv = \gcd(x + i, p)$ by Euclid's algorithm over the Gaussian integers. [We can take $x = n^{(p-1)/4} \bmod p$ for almost half of all integers n. This application of a Euclidean algorithm is essentially the same as finding the least nonzero $u^2 + v^2$ such that $u \pm xv \equiv 0$ (modulo p).] If the prime factorization of N is $p_1^{e_1} \ldots p_r^{e_r} = (u_1 + iv_1)^{e_1}(u_1 - iv_1)^{e_1} \ldots (u_r + iv_r)^{e_r}(u_r - iv_r)^{e_r}$, we get 2^{r-1} distinct solutions to $x_1^2 + x_2^2 = N$, $\gcd(x_1, x_2) = 1$, x_1 even, by letting $|x_2| + i|x_1| = (u_1 + iv_1)^{e_1}(u_2 \pm iv_2)^{e_2} \ldots (u_r \pm iv_r)^{e_r}$; and all such solutions are obtained in this way.

Note: When $m = 10^e$, a similar procedure can be used, but it is five times as much work since we must keep trying until finding a solution with $x_1 \equiv 0$ (modulo 10). For example, when $m = 10^{10}$ we have $\lfloor m/\sqrt{3} \rfloor = 5773502691$, and $5773502689 = 53 \cdot 108934013 = (7+2i)(7-2i)(2203+10202i)(2203-10202i)$. Of the two solutions $|x_2| + i|x_1| = (7+2i)(2203+10202i)$ or $(7+2i)(2203-10202i)$, the former gives $|x_1| = 67008$ (no good) and the latter gives $|x_1| = 75820$, $|x_2| = 4983$ (which is usable). Line 9 of Table 1 was obtained by taking $x_1 = 75820$, $x_2 = -4983$.

Line 20 of the table was obtained as follows: $\lfloor 2^{35}/\sqrt{3} \rfloor = 19837604196$; we drop down to 19837604193, which is divisible by 3 so it is ineligible. Similarly, 19837604189 is divisible by 19, and 19837604185 by 7, and 19837604181 by 3; but 19837604177 is prime and equals $131884^2 + 49439^2$. The corresponding multiplier is 1175245817; a better one could be found if we continued searching. The multiplier on line 24 is the best of the first sixteen multipliers found by this procedure when $m = 2^{32}$.

12. $U_j' \cdot U_j' = U_j \cdot U_j + 2\sum_{i \neq j} q_i (U_i \cdot U_j) + \sum_{i \neq j} \sum_{k \neq j} q_i q_k (U_i \cdot U_k)$. The partial derivative with respect to q_k is twice the left-hand side of (26). If the minimum can be achieved, these partial derivatives must all vanish.

13. $u_{11} = 1$, $u_{21} =$ irrational, $u_{12} = u_{22} = 0$.

14. After three Euclidean steps we find $\nu_2^2 = 5^2 + 5^2$, then S4 produces

$$U = \begin{pmatrix} -5 & 5 & 0 \\ -18 & -2 & 0 \\ 1 & -2 & 1 \end{pmatrix}, \qquad V = \begin{pmatrix} -2 & 18 & 38 \\ -5 & -5 & -5 \\ 0 & 0 & 100 \end{pmatrix}.$$

Transformations $(j, q_1, q_2, q_3) = (1, *, 0, 2)$, $(2, -4, *, 1)$, $(3, 0, 0, *)$, $(1, *, 0, 0)$ result in

$$U = \begin{pmatrix} -3 & 1 & 2 \\ -5 & -8 & -7 \\ 1 & -2 & 1 \end{pmatrix}, \qquad V = \begin{pmatrix} -22 & -2 & 18 \\ -5 & -5 & -5 \\ 9 & -31 & 29 \end{pmatrix}, \qquad Z = (0 \quad 0 \quad 1).$$

Thus $\nu_3 = \sqrt{6}$, as we already knew from exercise 3.

15. The largest achievable q in (11), minus the smallest achievable, plus 1, is $|u_1| + \cdots + |u_t| - \delta$, where $\delta = 1$ if $u_i u_j < 0$ for some i and j, otherwise $\delta = 0$. For example if $t = 5$, $u_1 > 0$, $u_2 > 0$, $u_3 > 0$, $u_4 = 0$, and $u_5 < 0$, the largest achievable value is $q = u_1 + u_2 + u_3 - 1$ and the smallest is $q = u_5 + 1 = -|u_5| + 1$.

[Note that the number of hyperplanes is unchanged when c varies, hence the same answer applies to the problem of covering L instead of L_0. However, the stated formula is *not* always exact for covering L_0, since the hyperplanes that intersect the unit hypercube may not all contain points of L_0. In the example above, we can never achieve the value $q = u_1 + u_2 + u_3 - 1$ in L_0 if $u_1 + u_2 + u_3 > m$; it is achievable iff there is a solution to $m - u_1 - u_2 - u_3 = x_1 u_1 + x_2 u_2 + x_3 u_3 + x_4 |u_5|$ in nonnegative integers (x_1, x_2, x_3, x_4). It may be true that the stated limits are always achievable when $|u_1| + \cdots + |u_t|$ is minimal, but this does not appear to be obvious.]

16. It suffices to determine all solutions to (15) having minimum $|u_1| + \cdots + |u_t|$, subtracting 1 if any one of these solutions has components of opposite sign.

Instead of positive definite quadratic forms, we work with the somewhat similar function $f(x_1, \ldots, x_t) = |x_1 U_1 + \cdots + x_t U_t|$, defining $|Y| = |y_1| + \cdots + |y_t|$. Inequality (21) can be replaced by $|x_k| \leq (\max_{1 \leq j \leq t} |v_{kj}|)\, f(y_1, \ldots, y_t)$.

Thus a workable algorithm can be obtained as follows. Replace steps S1 through S3 by: "Set $U \leftarrow (m)$, $V \leftarrow (1)$, $r \leftarrow 1$, $s \leftarrow m$, $t \leftarrow 1$." (Here U and V are 1×1

matrices; thus the two-dimensional case will be handled by the general method. A special procedure for $t = 2$ could, of course, be devised.) In steps S4 and S8, set $s \leftarrow \min(s, |U_k|)$. In step S8, set $z_k \leftarrow \lfloor \max_{1\le j\le t} |v_{kj}|\, s/m \rfloor$. In step S10, set $s \leftarrow \min(s, |Y| - \delta)$; and in step S11, output $s = N_t$. Otherwise leave the algorithm as it stands, since it already produces suitably short vectors. [*Math. Comp.* **29** (1975), 827–833.]

17. When $k > t$ in S10, and if $Y \cdot Y \le s$, output Y and $-Y$; furthermore if $Y \cdot Y < s$, take back the previous output of vectors for this t. [In the author's experience preparing Table 1, there was exactly one vector (and its negative) output for each ν_t, except when $y_1 = 0$ or $y_t = 0$.]

18. (a) Let $x = m$, $y = (1 - m)/3$, $v_{ij} = y + x\delta_{ij}$, $u_{ij} = -y + \delta_{ij}$. Then $V_j \cdot V_k = \frac{1}{3}(m^2 - 1)$ for $j \ne k$, $V_k \cdot V_k = \frac{2}{3}(m^2 + \frac{1}{2})$, $U_j \cdot U_j = \frac{1}{3}(m^2 + 2)$, $z_k \approx \sqrt{\frac{2}{9}}\, m$. (This example satisfies (28) with $a = 1$ and works for all $m \equiv 1$ (modulo 3).)

(b) Interchange the rôles of U and V in step S5. Also set $s \leftarrow \min(s, U_i \cdot U_i)$ for all U_i that change. For example, when $m = 64$ this transformation with $j = 1$, applied to the matrices of (a), reduces

$$V = \begin{pmatrix} 43 & -21 & -21 \\ -21 & 43 & -21 \\ -21 & -21 & 43 \end{pmatrix}, \quad U = \begin{pmatrix} 22 & 21 & 21 \\ 21 & 22 & 21 \\ 21 & 21 & 22 \end{pmatrix}$$

to

$$V = \begin{pmatrix} 1 & 1 & 1 \\ -21 & 43 & -21 \\ -21 & -21 & 43 \end{pmatrix}, \quad U = \begin{pmatrix} 22 & 21 & 21 \\ -1 & 1 & 0 \\ -1 & 0 & 1 \end{pmatrix}.$$

[Since the transformation can increase the length of V_j, an algorithm that incorporates both transformations must be careful to avoid infinite looping. See also exercise 23.]

19. No, since a product of non-identity matrices with all off-diagonal elements non-negative and all diagonal elements 1 cannot be the identity.

[However, looping would be possible if a subsequent transformation with $q = -1$ were performed when $-2V_i \cdot V_j = V_j \cdot V_j$; the rounding rule must be asymmetric with respect to sign if non-shortening transformations are allowed.]

20. Use the ordinary spectral test for a and $m = 2^{e-2}$; cf. exercise 3.2.1.2–9. [On intuitive grounds, the same answer should apply also when $a \bmod 8 = 3$.]

21. $X_{4n+4} \equiv X_{4n}$ (modulo 4), so it is now appropriate to let $V_1 = (4, 4a^2, 4a^3)/m$, $V_2 = (0, 1, 0)$, $V_3 = (0, 0, 1)$ define the corresponding lattice L_0.

24. Let $m = p$; an analysis paralleling the text can be given. For example, when $t = 4$ we have $X_{n+3} = ((a^2 + b)X_{n+1} + abX_n) \bmod n$, and we want to minimize $u_1^2 + u_2^2 + u_3^2 + u_4^2 \ne 0$ such that $u_1 + bu_3 + abu_4 \equiv u_2 + au_3 + (a^2 + b)u_4 \equiv 0$ (modulo m).

Replace steps S1 through S3 by the operations of setting

$$U \leftarrow \begin{pmatrix} m & 0 \\ 0 & m \end{pmatrix}, \quad V \leftarrow \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}, \quad R \leftarrow \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}, \quad s \leftarrow m^2, \quad t \leftarrow 2,$$

and outputting $\nu_2 = m$. Replace step S4 by

S4′. [Advance t.] If $t = T$, the algorithm terminates. Otherwise set $t \leftarrow t+1$ and $R \leftarrow R\left(\begin{smallmatrix} 0 & b \\ 1 & a \end{smallmatrix}\right) \bmod m$. Set U_t to the new row $(-r_{12}, -r_{22}, 0, \ldots, 0, 1)$ of t elements, and set $u_{it} \leftarrow 0$ for $1 \le i < t$. Set V_t to the new row $(0, \ldots, 0, m)$. For $1 \le i < t$, set $q \leftarrow \text{round}((v_{i1}r_{12} + v_{i2}r_{22})/m)$, $v_{it} \leftarrow v_{i1}r_{12} + v_{i2}r_{22} - qm$, and $U_t \leftarrow U_t + qU_i$. Finally set $s \leftarrow \min(s, U_t \cdot U_t)$, $k \leftarrow t$, $j \leftarrow 1$.

[A similar generalization applies to all sequences of length $p^k - 1$ defined by Eq. 3.2.2–8. Additional numerical examples have been given by A. Grube, *Zeitschrift für angewandte Math. und Mechanik* **53** (1973), T223–T225.]

25. The given sum is at most two times the quantity $\sum_{0 \le k \le m/2d} r(dk) = 1 + \frac{1}{d} f(m/d)$, where

$$f(m) = \frac{1}{m} \sum_{1 \le k \le m/2} \csc(\pi k/m)$$
$$= \frac{1}{m} \int_1^{m/2} \csc(\pi x/m)\, dx + O\Big(\frac{1}{m}\Big) = \frac{1}{\pi} \ln \tan\Big(\frac{\pi}{2m} x\Big)\Big|_1^{m/2} + O\Big(\frac{1}{m}\Big).$$

[When $d = 1$, we have $\sum_{0 \le k < m} r(k) = (2/\pi)\ln m + 1 + (2/\pi)\ln(2e/\pi) + O(1/m)$.]

26. When $m = 1$, we cannot use (52) since k will be zero. If $\gcd(q, m) = d$, the same derivation goes through with m replaced by m/d. Suppose we have $m = p_1^{e_1} \ldots p_r^{e_r}$ and $\gcd(a-1, m) = p_1^{f_1} \ldots p_r^{f_r}$ and $d = p_1^{d_1} \ldots p_r^{d_r}$. If m is replaced by m/d, then s is replaced by $p_1^{\max(0, e_1 - f_1 - d_1)} \ldots p_r^{\max(0, e_r - f_r - d_r)}$.

27. It is convenient to use the following functions: $\rho(x) = 1$ if $x = 0$, $\rho(x) = x$ if $0 < x \le m/2$, $\rho(x) = m - x$ if $m/2 < x < m$; $\text{trunc}(x) = \lfloor x/2 \rfloor$ if $0 \le x \le m/2$, $\text{trunc}(x) = m - \lfloor (m-x)/2 \rfloor$ if $m/2 < x < m$; $L(x) = 0$ if $x = 0$, $L(x) = \lfloor \lg x \rfloor + 1$ if $0 < x \le m/2$, $L(x) = -(\lfloor \lg(m-x) \rfloor + 1)$ if $m/2 < x < m$; and $l(x) = \max(1, 2^{|x|-1})$. Note that $l(L(x)) \le \rho(x) < 2l(L(x))$ and $\rho(x) \le m \sin(\pi x/m) < \pi\rho(x)$ for $0 < x < m$.

Say that a vector $(u_1, \ldots, u_t)$ is *bad* if it is nonzero and satisfies (15); and let $\rho_{\max}$ be the maximum value of $\rho(u_1) \ldots \rho(u_t)$ over all bad $(u_1, \ldots, u_t)$. The vector $(u_1, \ldots, u_t)$ is said to be in class $(L(u_1), \ldots, L(u_t))$. Thus there are at most $(2 \lg m + 1)^t$ classes, and class $(L_1, \ldots, L_t)$ contains at most $l(L_1) \ldots l(L_t)$ vectors. Our proof is based on showing that the bad vectors in each fixed class contribute only $O(1/\rho_{\max})$ to $\sum r(u_1, \ldots, r_t)$; this proves even more than was asked, since $1/\rho_{\max} \le \pi^t r_{\max}$.

Let $\mu = \lfloor \lg \rho_{\max} \rfloor$. The *$\mu$-fold truncation operator* on a vector is defined to be the following operation repeated μ times: "Let j be minimal such that $\rho(u_j) > 1$, and replace u_j by $\text{trunc}(u_j)$; but do nothing if $\rho(u_j) = 1$ for all j." (This operation essentially throws away one bit of information about $(u_1, \ldots, u_t)$.) If $(u_1', \ldots, u_t')$ and $(u_1'', \ldots, u_t'')$ are two vectors of the same class having the same μ-fold truncation, we say they are *similar*; in this case it follows that $\rho(u_1' - u_1'') \ldots \rho(u_t' - u_t'') < 2^\mu \le \rho_{\max}$. For example, any two vectors of the form $((1x_2x_1)_2, 0, m - (1x_3)_2, (101x_5x_4)_2, (1101)_2)$ are similar when m is large and $\mu = 5$; the μ-fold truncation operator successively removes x_1, x_2, x_3, x_4, x_5. Since the difference of two bad vectors satisfies (15), it is impossible for two unequal bad vectors to be similar. Therefore class $(L_1, \ldots, L_t)$ can contain at most $\max(1, l(L_1) \ldots l(L_t)/2^\mu)$ bad vectors. If class $(L_1, \ldots, L_t)$ contains exactly one bad vector $(u_1, \ldots, u_t)$, we have $r(u_1, \ldots, u_t) \le r_{\max} \le 1/\rho_{\max}$; if it contains $\le l(L_1) \ldots l(L_t)/2^\mu$ bad vectors, each of them has $r(u_1, \ldots, u_t) \le 1/\rho(u_1) \ldots \rho(u_t) \le 1/l(L_1) \ldots l(L_t)$.

28. Let $\zeta = e^{2\pi i/(m-1)}$ and let $S_{kl} = \sum_{0\le j<m-1} \omega^{x_{j+l}}\zeta^{jk}$. The analog of (51) is $|S_{k0}| = \sqrt{m}$, hence the analog of (53) is $|N^{-1}\sum_{0\le n<N}\omega^{x_n}| = O((\sqrt{m}\log m)/N)$. The analogous theorem now states that

$$D_N^{(t)} = O\left(\frac{\sqrt{m}(\log m)^{t+1}}{N}\right) + O\big((\log m)^t\, r_{\max}\big), \qquad D_{m-1}^{(t)} = O\big((\log m)^t\, r_{\max}\big).$$

In fact, $D_{m-1}^{(t)} \le \frac{m-2}{m-1}\sum r(u_1,\ldots,u_t)$ [summed over nonzero solutions of (15)] + $\frac{1}{m-1}\sum r(u_1,\ldots,u_t)$ [summed over all nonzero $(u_1,\ldots,u_t)$]. The latter sum is $O(\log m)^t$ by exercise 25 with $d=1$, and the former sum is treated as in exercise 27.

Let us now consider the quantity $R(a) = \sum r(u_1,\ldots,u_t)$ summed over nonzero solutions of (15). Since m is prime, each $(u_1,\ldots,u_t)$ can be a solution to (15) for at most $t-1$ values of a, hence $\sum_{0<a<m} R(a) \le (t-1)\sum r(u_1,\ldots,u_t) = O(t(\log m)^t)$. It follows that the average value of $R(a)$ taken over all $\varphi(m-1)$ primitive roots is $O(t(\log m)^t/\varphi(m-1))$.

Note: In general $1/\varphi(n) = O(\log\log n/n)$; we have therefore proved that *for all prime m and for all T there exists a primitive root a modulo m such that the linear congruential sequence $(1,a,0,m)$ has discrepancy $D_{m-1}^{(t)} = O(m^{-1}T(\log m)^T\log\log m)$ for $1\le t\le T$.* This method of proof does *not* extend to a similar result for linear congruential generators of period 2^e modulo 2^e, since for example the vector $(1,-3,3,-1)$ solves (15) for about $2^{2e/3}$ values of a.

29. $u_1^2+\cdots+u_t^2 \ge \nu_t^2 \ge 2(t-1)$ implies that $\rho(u_1)\ldots\rho(u_t) \ge \sqrt{\nu_t^2-(t-1)} \ge \nu_t/\sqrt{2}$, in the notation of exercise 27.

30. We wish to minimize $q|aq-mp|$ for $1\le q<m$ and $0\le p<a$. In the notation of exercise 4.5.3–42, we have $aq_n - mp_n = (-1)^n Q_{s-n-1}(a_{n+2},\ldots,a_s)$ for $0\le n\le s$. In the range $q_{n-1}\le q<q_n$ we have $|aq-mp| \ge |aq_{n-1}-mp_{n-1}|$; consequently $q|aq-mp| \ge q_{n-1}|aq_{n-1}-mp_{n-1}|$, and the minimum is $\min_{0\le n<s} q_n|aq_n-mp_n| = \min_{0\le n<s} Q_n(a_1,\ldots,a_n)Q_{s-n-1}(a_{n+2},\ldots,a_s)$. By exercise 4.5.3–32 we have $m = Q_n(a_1,\ldots,a_n)a_{n+1}Q_{s-n-1}(a_{n+2},\ldots,a_s) + Q_n(a_1,\ldots,a_n)Q_{s-n-2}(a_{n+3},\ldots,a_s) + Q_{n-1}(a_1,\ldots,a_{n-1})Q_{s-n-1}(a_{n+2},\ldots,a_s)$; and our problem is essentially that of maximizing the quantity $m/Q_n(a_1,\ldots,a_n)Q_{s-n-1}(n+2,\ldots,a_s)$, which lies between a_{n+1} and $a_{n+1}+2$.

31. Equivalently, the conjecture is that all large m can be written $m = Q_n(a_1,\ldots,a_n)$ for some n and some $a_i\in\{1,2,3\}$. For fixed n the 3^n numbers $Q_n(a_1,\ldots,a_n)$ have an average value of order $(1+\sqrt{2}\,)^n$, and their standard deviation is of order $(2.51527)^n$; so the conjecture is almost surely true. S. K. Zaremba conjectured in 1972 that all m can be represented with $a_i\le 5$; T. W. Cusick made some progress on this problem in *Mathematika* **24** (1977), 166–172. It appears that only the cases $m=54$ and $m=150$ require $a_i=5$, and the largest m's that require 4's are 2052, 2370, 5052, and 6234; at least, the author has found representations with $a_i\le 3$ for all other integers less than 2000000. When we require $a_i\le 2$, the average of $Q_n(a_1,\ldots,a_n)$ is $\frac{4}{5}2^n + \frac{1}{5}(-2)^{-n}$, while the standard deviation grows as $(2.04033)^n$. The density of such numbers in the author's experiments (which considered 2^6 blocks of 2^{14} numbers each, for $m\le 2^{20}$) appears to vary between .50 and .65.

[See I. Borosh and H. Niederreiter, to appear, for a computational method that finds multipliers with small partial quotients. They have found 2-bounded solutions with $m=2^e$ for $25\le e\le 35$.]

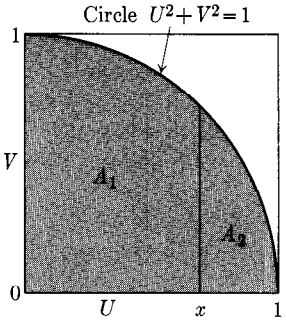

Fig. A–4. Region of "acceptance" for the algorithm of exercise 6.

SECTION 3.4.1

1. $\alpha + (\beta - \alpha)U$.

2. Let $U = X/m$; $\lfloor kU \rfloor = r$ iff $r \le kX/m < r + 1$ iff $mr/k \le X < m(r + 1)/k$ iff $\lceil mr/k \rceil \le X < \lceil m(r + 1)/k \rceil$. The exact probability is given by the formula $(1/m)(\lceil m(r + 1)/k \rceil - \lceil mr/k \rceil) = 1/k + \epsilon$, where $|\epsilon| < 1/m$.

3. If full-word random numbers are given, the result will be sufficiently random as in exercise 2. But if a linear congruential sequence is used, k must be relatively prime to the modulus m, lest the numbers have a very short period, by the results of Section 3.2.1.1. For example, if $k = 2$ and m is even, the numbers will at best be alternately 0 and 1. The method is slower than (1) in nearly every case, so it is not recommended.

4. $\max(X_1, X_2) \le x$ if and only if $X_1 \le x$ and $X_2 \le x$; $\min(X_1, X_2) \ge x$ if and only if $X_1 \ge x$ and $X_2 \ge x$. The probability that two independent events both happen is the product of the individual probabilities.

5. Obtain independent uniform deviates U_1, U_2. Set $X \leftarrow U_2$. If $U_1 \ge p$, set $X \leftarrow \max(X, U_3)$, where U_3 is a third uniform deviate. If $U_1 \ge p + q$, also set $X \leftarrow \max(X, U_4)$, where U_4 is a fourth uniform deviate. This method can obviously be generalized to any polynomial, and indeed even to infinite power series (as shown for example in Algorithm S, which uses minimization instead of maximization).

We could also proceed as follows (suggested by M. D. MacLaren): If $U_1 < p$, set $X \leftarrow U_1/p$; otherwise if $U_1 < p + q$, set $X \leftarrow \max((U_1 - p)/q, U_2)$; otherwise set $X \leftarrow \max((U_1 - p - q)/r, U_2, U_3)$. This method requires less time than the other to obtain the uniform deviates, although it involves further arithmetical operations and it is slightly less stable numerically.

6. $F(x) = A_1/(A_1 + A_2)$, where A_1 and A_2 are the areas in Fig. A–4; so

$$F(x) = \frac{\int_0^x \sqrt{1 - y^2}\, dy}{\int_0^1 \sqrt{1 - y^2}\, dy} = \frac{2}{\pi} \arcsin x + \frac{2}{\pi} x\sqrt{1 - x^2}.$$

The probability of termination at step 2 is $p = \pi/4$, each time step 2 is encountered, so the number of executions of step 2 has the geometric distribution. The characteristics of this number are (min 1, ave $4/\pi$, max ∞, dev $(4/\pi)\sqrt{1 - \pi/4}$), by exercise 17.

7. If $k = 1$, then $n_1 = n$ and the problem is trivial. Otherwise it is always possible to find $i \neq j$ such that $n_i \leq n \leq n_j$. Fill B_i with n_i cubes of color C_i and $n - n_i$ of color C_j, then decrease n_j by $n - n_i$ and eliminate color C_i. We are left with the same sort of problem but with k reduced by 1; by induction, it's possible.

The following algorithm can be used to compute the P and Y tables: Form a list of pairs $(p_1, 1) \ldots (p_k, k)$ and sort it by first components, obtaining a list $(q_1, a_1) \ldots (q_k, a_k)$ where $q_1 \leq \cdots \leq q_k$ and $n = k$. Repeat the following operation until $n = 0$: Set $P[a_1 - 1] \leftarrow kq_1$ and $Y[a_1 - 1] \leftarrow x_{a_n}$. Delete (q_1, a_1) and (q_n, a_n), then insert the new entry $(q_n - (1/k - q_1), a_n)$ into its proper place in the list and decrease n by 1.

(If $p_j \leq 1/k$ the algorithm will never put x_j in the Y table; this fact is used implicitly in Algorithm M. The algorithm attempts to maximize the probability that $V < P_K$ in (3), by always robbing from the richest remaining element and giving it to the poorest. However, it is very difficult to determine the absolute minimum of this probability, since such a task is at least as difficult as the "bin-packing problem"; cf. Chapter 7.)

8. Replace P_j by $(j + P_j)/k$ for $0 \leq j < k$.

9. Consider the sign of $f''(x) = \sqrt{2/\pi}\,(x^2 - 1)e^{-x^2/2}$.

10. Let $S_j = (j - 1)/5$ for $1 \leq j \leq 16$ and $p_{j+15} = F(S_{j+1}) - F(S_j) - p_j$ for $1 \leq j \leq 15$; also let $p_{31} = 1 - F(3)$ and $p_{32} = 0$. (Eq. (15) defines $p_1, \ldots, p_{15}$.) The algorithm of exercise 7 can now be used with $k = 32$ to compute P_j and Y_j, after which we will have $1 \leq Y_j \leq 15$ for $1 \leq j \leq 32$. Set $P_0 \leftarrow P_{32}$ (which is 0) and $Y_0 \leftarrow Y_{32}$. Then set $Z_j \leftarrow 1/(5 - 5P_j)$ and $Y_j \leftarrow \frac{1}{5}Y_j - Z_j$ for $0 \leq j < 32$; $Q_j \leftarrow 1/(5P_j)$ for $1 \leq j \leq 15$.

Let $h = \frac{1}{5}$ and $f_{j+15}(x) = \sqrt{2/\pi}\left(e^{-x^2/2} - e^{-j^2/50}\right)/p_{j+15}$ for $S_j \leq x \leq S_j + h$. Then let $a_j = f_{j+15}(S_j)$ for $1 \leq j \leq 5$, $b_j = f_{j+15}(S_j)$ for $6 \leq j \leq 15$; also $b_j = -hf'_{j+15}(S_j + h)$ for $1 \leq j \leq 5$, and $a_j = f_{j+15}(x_j) + (x_j - S_j)b_j/h$ for $6 \leq j \leq 15$, where x_j is the root of the equation $f'_{j+15}(x_j) = -b_j/h$. Finally set $D_{j+15} \leftarrow a_j/b_j$ for $1 \leq j \leq 15$ and $E_{j+15} \leftarrow 25/j$ for $1 \leq j \leq 5$, $E_{j+15} \leftarrow 1/(e^{(2j-1)/50} - 1)$ for $6 \leq j \leq 15$.

Table 1 was computed while making use of the following intermediate values: $(p_1, \ldots, p_{31}) = (.156, .147, .133, .116, .097, .078, .060, .044, .032, .022, .014, .009, .005, .003, .002, .002, .005, .007, .009, .010, .009, .009, .008, .006, .005, .004, .002, .002, .001, .001, .003)$; $(x_6, \ldots, x_{15}) = (1.115, 1.304, 1.502, 1.700, 1.899, 2.099, 2.298, 2.497, 2.697, 2.896)$; $(a_1, \ldots, a_{15}) = (7.5, 9.1, 9.5, 9.8, 9.9, 10.0, 10.0, 10.1, 10.1, 10.1, 10.1, 10.2, 10.2, 10.2, 10.2)$; $b_1, \ldots, b_{15}) = (14.9, 11.7, 10.9, 10.4, 10.1, 10.1, 10.2, 10.3, 10.4, 10.5, 10.6, 10.7, 10.7, 10.8, 10.9)$.

11. Let $g(t) = e^{9/2}te^{-t^2/2}$ for $t \geq 3$. Since $G(x) = \int_0^x g(t)\,dt = 1 - e^{-(x^2-9)/2}$, a random variable X with density g can be computed by setting $X \leftarrow G^{-1}(1 - V) = \sqrt{9 - 2\ln V}$. Now $e^{-t^2/2} \leq (t/3)e^{-t^2/2}$ for $t \geq 3$, so we obtain a valid rejection method if we accept X with probability $f(X)/cg(X) = 3/X$.

12. We have $f'(x) = xf(x) - 1 < 0$ for $x \geq 0$, since $f(x) = x^{-1} - e^{x^2/2}\int_x^\infty e^{-t^2/2}\,dt/t^2$ for $x > 0$. Let $x = a_{j-1}$ and $y^2 = x^2 + 2\ln 2$; then

$$\sqrt{2/\pi}\int_y^\infty e^{-t^2/2}\,dt = \tfrac{1}{2}\sqrt{2/\pi}\,e^{-x^2/2}f(y) < \tfrac{1}{2}\sqrt{2/\pi}\,e^{-x^2/2}f(x) = 2^{-j},$$

hence $y > a_j$.

13. Take $b_j = \mu_j$; consider now the problem with $\mu_j = 0$ for each j. In matrix notation, if $Y = AX$, where $A = (a_{ij})$, we need $AA^T = C = (c_{ij})$. (In other notation, if $Y_j = \sum a_{jk}X_k$, then the average value of Y_iY_j is $\sum a_{ik}a_{jk}$.) If this matrix equation can be solved for A, it can be solved when A is triangular, since $A = BU$ for some orthogonal matrix U and some triangular B, and $BB^T = C$. The desired triangular solution can be obtained by solving the equations $a_{11}^2 = c_{11}$, $a_{11}a_{21} = c_{12}$, $a_{21}^2 + a_{22}^2 = c_{22}$, $a_{11}a_{31} = c_{13}$, $a_{21}a_{31} + a_{22}a_{32} = c_{23}$, ..., successively for a_{11}, a_{21}, a_{22}, a_{31}, a_{32}, etc. [*Note:* The covariance matrix must be positive semidefinite, since the average value of $(\sum y_jY_j)^2$ is $\sum c_{ij}y_iy_j$, which must be nonnegative. And there is always a solution when C is positive semidefinite, since $C = U^{-1}\mathrm{diag}(\lambda_1, \ldots, \lambda_n)U$, where the eigenvalues λ_j are nonnegative, and $U^{-1}\mathrm{diag}(\sqrt{\lambda_1}, \ldots, \sqrt{\lambda_n})U$ is a solution.]

14. $F(x/c)$ if $c > 0$, a step function if $c = 0$, and $1 - F(x/c)$ if $c < 0$.

15. Distribution $\int_{-\infty}^{\infty} F_1(x-t)\,dF_2(t)$. Density $\int_{-\infty}^{\infty} f_1(x-t)f_2(t)\,dt$. This is called the *convolution* of the given distributions.

16. It is clear that $f(t) \le cg(t)$ for all t as required. Since $\int_0^\infty g(t)\,dt = 1$ we have $g(t) = Ct^{a-1}$ for $0 \le t < 1$, Ce^{-t} for $t \ge 1$, where $C = ae/(a+e)$. A random variable with density g is easy to obtain as a mixture of two distributions, $G_1(x) = x^a$ for $0 \le x < 1$, and $G_2(x) = 1 - e^{1-x}$ for $x \ge 1$:

G1. [Initialize.] Set $p \leftarrow e/(a+e)$. (This is the probability that G_1 should be used.)

G2. [Generate G deviate.] Generate independent uniform deviates U, V, where $V \neq 0$. If $U < p$, set $X \leftarrow V^{1/a}$ and $q \leftarrow e^{-X}$; otherwise set $X \leftarrow 1 - \ln V$ and $q \leftarrow X^{a-1}$. (Now X has density g, and $q = f(X)/cg(X)$.)

G3. [Reject?] Generate a new uniform deviate U. If $U \ge q$, return to G2. ∎

The average number of iterations is $c = (a+e)/(e\,\Gamma(a+1)) < 1.4$.

It is possible to streamline this procedure in several ways. First, we can replace V by an exponential deviate Y of mean 1, generated by Algorithm S, say, and then we set $X \leftarrow e^{-Y/a}$ or $X \leftarrow 1 + Y$ in the two cases. Moreover, if we set $q \leftarrow pe^{-X}$ in the first case and $q \leftarrow p + (1-p)X^{a-1}$ in the second, we can use the original U instead of a newly generated one in step G3. Finally if $U < p/e$ we can accept $V^{1/a}$ immediately, avoiding the calculation of q about 30 percent of the time.

17. (a) $F(x) = 1 - (1-p)^{\lfloor x \rfloor}$, for $x \ge 0$. (b) $G(z) = pz/(1-(1-p)z)$. (c) Mean $1/p$, standard deviation $\sqrt{1-p}/p$. To do the latter calculation, observe that if $H(z) = q + (1-q)z$, then $H'(1) = 1 - q$ and $H''(1) + H'(1) - (H'(1))^2 = q(1-q)$, so the mean and variance of $1/H(z)$ are $q - 1$ and $q(q-1)$, respectively. (See Section 1.2.10.) In this case, $q = 1/p$; the extra factor z in the numerator of $G(z)$ increases the mean by one.

18. Set $N \leftarrow N_1 + N_2 - 1$, where N_1 and N_2 independently have the geometric distribution for probability p. (Consider the generating function.)

19. Set $N \leftarrow N_1 + \cdots + N_t - t$, where the N_j have the geometric distribution for p. (This is the number of failures before the tth success, when a sequence of independent trials are made each of which succeeds with probability p.)

For $t = p = \frac{1}{2}$, and in general when the mean value (namely $t(1-p)/p$) of the distribution is small, we can simply evaluate the probabilities $p_n = \binom{t-1+n}{n} p^t(1-p)^n$ consecutively for $n = 0, 1, 2, \ldots$ as in the following algorithm:

B1. [Initialize.] Set $N \leftarrow 0$, $q \leftarrow p^t$, $r \leftarrow q$, and generate a random uniform deviate U. (We will have $q = p_N$ and $r = p_0 + \cdots + p_N$ during this algorithm, which stops as soon as $U < r$.)

B2. [Search.] If $U \geq r$, set $N \leftarrow N+1$, $q \leftarrow q(1-p)(t-1+N)/N$, $r \leftarrow r+q$, and repeat this step. ∎

[An interesting technique for the negative binomial distribution, for arbitrarily large real values of t, has been suggested by R. Léger: First generate a random gamma deviate X of order t, then let N be a random Poisson deviate of mean $X(1-p)/p$.]

20. R1 $= 1 + (1 - A/R) \cdot$ R1. When R2 is performed, the algorithm terminates with probability I/R; when R3 is performed, it goes to R1 with probability E/R. We have

R1	R/A	R/A	R/A	R/A
R2	0	R/A	0	R/A
R3	0	0	R/A	$R/A - I/A$
R4	R/A	$R/A - I/A$	$R/A - E/A$	$R/A - I/A - E/A$

21. $R = \sqrt{8/e} \approx 1.71153$; $A = \sqrt{\pi/2} \approx 1.25331$. Since

$$\int u\sqrt{a-bu}\,du = (a-bu)^{3/2}(\tfrac{2}{5}(a-bu) - \tfrac{2}{3})/b^2,$$

we have $I = \int_0^{a/b} u\sqrt{a-bu}\,du = \frac{4}{15}a^{5/2}/b^2$ where $a = 4(1+\ln c)$ and $b = 4c$; when $c = e^{1/4}$, I has its maximum value $\frac{5}{6}\sqrt{5/e} \approx 1.13020$. Finally the following integration formulas are needed for E:

$$\int \sqrt{bu-au^2}\,du = \tfrac{1}{8}b^2a^{-3/2}\arcsin(2ua/b-1) + \tfrac{1}{4}ba^{-1}\sqrt{bu-au^2}\,(2ua/b-1),$$

$$\int \sqrt{bu+au^2}\,du = -\tfrac{1}{8}b^2a^{-3/2}\ln\bigl(\sqrt{bu+au^2} + u\sqrt{a} + b/2\sqrt{a}\bigr) + \tfrac{1}{4}ba^{-1}\sqrt{bu+au^2}\,(2ua/b+1),$$

where $a, b > 0$. Let the test in step R3 be "$X^2 \geq 4e^{x-1}/U - 4x$"; then the exterior region hits the top of the rectangle when $u = r(x) = (e^x - \sqrt{e^{2x} - 2ex})/2ex$. (Incidentally, $r(x)$ reaches its maximum value at $x = 1/2$, a point where it is *not* differentiable!) We have $E = \int_0^{r(x)}(\sqrt{2/e} - \sqrt{bu-au^2})\,du$ where $b = 4e^{x-1}$ and $a = 4x$. The maximum value of E occurs near $x = -.35$, where we have $E \approx .29410$.

22. (Solution by G. Marsaglia.) Consider the "continuous Poisson distribution" defined by $G(x) = \int_\mu^\infty e^{-t}t^{x-1}\,dt/\Gamma(x)$, for $x > 0$; if X has this distribution then $\lfloor X \rfloor$ is Poisson distributed, since $G(x+1) - G(x) = e^{-\mu}\mu^x/x!$. If μ is large, G is approximately normal, hence $G^{-1}(F_\mu(x))$ is approximately linear, where $F_\mu(x)$ is the distribution function for a normal deviate with mean and variance μ; i.e., $F_\mu(x) = F((x-\mu)/\sqrt{\mu})$, where $F(x)$ is the normal distribution function (10). Let $g(x)$ be an efficiently computable function such that $|G^{-1}(F_\mu(x)) - g(x)| < \epsilon$ for $-\infty < x < \infty$; we can now generate Poisson deviates efficiently as follows: Generate a normal deviate X, and set $Y \leftarrow g(\mu + \sqrt{\mu}X)$, $N \leftarrow \lfloor Y \rfloor$, $M \leftarrow \lfloor Y + \frac{1}{2} \rfloor$. If $|Y - M| > \epsilon$, output N; otherwise output $M-1$ or M, according as $G^{-1}(F(X)) < M$ or not.

This approach applies also to the binomial distribution, with

$$G(x) = \int_p^1 u^{x-1}(1-u)^{n-x}\,du\,\Gamma(t+1)/\Gamma(x)\Gamma(t+1-x),$$

since $\lfloor G^{-1}(U) \rfloor$ is binomial with parameters (t,p) and G is approximately normal.

[See also the alternative method proposed by Ahrens and Dieter in *Computing* (1980), to appear.]

23. Yes. The second method calculates $|\cos 2\theta|$, where θ is uniformly distributed between 0 and $\pi/2$. (Let $U = r\cos\theta$, $V = r\sin\theta$.)

25. $\frac{21}{32} = (.10101)_2$. In general, the binary representation is formed by using 1 for $\vee$ and 0 for $\wedge$, from left to right, then suffixing 1. This technique [cf. K. D. Tocher, *J. Roy. Stat. Soc.* **B-16** (1954), 49] can lead to efficient generation of independent bits having a given probability p, and it can also be applied to the geometric and binomial distributions.

26. (a) True, $\sum_k \Pr(N_1 = k)\Pr(N_2 = n-k) = e^{-\mu_1-\mu_2}(\mu_1+\mu_2)^n/n!$. (b) False, unless $\mu_2 = 0$; otherwise $N_1 - N_2$ might be negative.

27. Let the binary representation of p be $(.b_1b_2b_3\ldots)_2$, and proceed according to the following rules:

B1. [Initialize.] Set $m \leftarrow t$, $N \leftarrow 0$, $j \leftarrow 1$. (During this algorithm, m represents the number of simulated uniform deviates whose relation to p is still unknown, since they match p in their leading $j-1$ bits; and N is the number of simulated deviates known to be less than p.)

B2. [Look at next column of bits.] Generate a random integer M with the binomial distribution $(m, \frac{1}{2})$. (Now M represents the number of unknown deviates that fail to match b_j.) Set $m \leftarrow m - M$, and if $b_j = 1$ set $N \leftarrow N + M$.

B3. [Done?] If $m = 0$, or if the remaining bits $(.b_{j+1}b_{j+2}\ldots)_2$ of p are all zero, the algorithm terminates. Otherwise, set $j \leftarrow j+1$ and return to step B2. ∎

[When $b_j = 1$ for infinitely many j, the average number of iterations A_t satisfies

$$A_0 = 0; \qquad A_n = 1 + \frac{1}{2^n}\sum_k \binom{n}{k} A_k, \quad \text{for } n \geq 1.$$

Letting $A(z) = \sum A_n z^n/n!$, we have $A(z) = e^z - 1 + A(\frac{1}{2}z)e^{z/2}$. Therefore $A(z)e^{-z} = 1 - e^{-z} + A(\frac{1}{2}z)e^{-z/2} = \sum_{k\geq 0}(1-e^{-z/2^k}) = 1 - e^{-z} - \sum_{n\geq 1}(-z)^n/(n!(2^n-1))$, and

$$A_m = 1 + \sum_{k\geq 1}\binom{n}{k}\frac{(-1)^{k+1}}{2^k-1} = 1 + \frac{V_{n+1}}{n+1} = \lg n + \frac{\gamma}{\ln 2} + \frac{1}{2} + f_0(n) + O(n^{-1})$$

in the notation of exercise 5.2.2–48.]

28. Generate a random point $(y_1,\ldots,y_n)$ on the unit sphere, and let $\rho = \sqrt{\sum a_k y_k^2}$. Generate an independent uniform deviate U, and if $\rho^{n+1}U < K\sqrt{\sum a_k^2 y_k^2}$, output the point $(y_1/\rho,\ldots,y_n/\rho)$; otherwise start over. Here $K^2 = \min\{(\sum a_k y_k^2)^{n+1}/(\sum a_k^2 y_k^2) \mid \sum y_k^2 = 1\} = a_n^{n-1}$ if $na_n \geq a_1$, $((n+1)/(a_1+a_n))^{n+1}(a_1a_n/n)^n$ otherwise.

29. Let $X_{n+1} = 1$, then set $X_k \leftarrow X_{k+1}U_k^{1/k}$ or $X_k \leftarrow X_{k+1}e^{-Y_k/k}$ for $k = n, n-1, \ldots, 1$, where U_k is uniform or Y_k is exponential. [*ACM Trans. Math. Software*, to appear.]

SECTION 3.4.2

1. There are $\binom{N-t}{n-m}$ ways to pick $n-m$ records from the last $N-t$; $\binom{N-t-1}{n-m-1}$ ways to pick $n-m-1$ from $N-t-1$ after selecting the $(t+1)$st item.

2. Step S3 will never go to step S5 when the number of records left to be examined is equal to $n-m$.

3. We should not confuse "conditional" and "unconditional" probabilities. The quantity m depends randomly on the selections that took place among the first t elements; if we take the average over all possible choices that could have occurred among these elements, we will find that $(n-m)/(N-t)$ is exactly n/N on the average. For example, consider the second element; if the first element was selected in the sample (this happens with probability n/N), the second element is selected with probability $(n-1)/(N-1)$; if the first element was not selected, the second is selected with probability $n/(N-1)$. The overall probability of selecting the second element is $(n/N)((n-1)/(N-1)) + (1-n/N)(n/(N-1)) = n/N$.

4. From the algorithm,

$$p(m, t+1) = \Big(1 - \frac{n-m}{N-t}\Big)p(m,t) + \frac{n-(m-1)}{N-t}\,p(m-1,t).$$

The desired formula can be proved by induction on t. In particular, $p(n, N) = 1$.

5. In the notation of exercise 4, the probability that $t = k$ at termination is $q_k = p(n,k) - p(n,k-1) = \binom{k-1}{n-1}/\binom{N}{n}$. The average is $\sum_{0\le k\le N} kq_k = (N+1)n/(n+1)$.

6. Similarly, $\sum_{0\le k\le N} k(k+1)q_k = (N+2)(N+1)n/(n+2)$; the variance is therefore $(N+1)(N-n)n/(n+2)(n+1)^2$.

7. Suppose the choice is $1 \le x_1 < x_2 < \cdots < x_n \le N$. Let $x_0 = 0$, $x_{n+1} = N+1$. The choice is obtained with probability $p = \prod_{1\le t\le N} p_t$, where

$$p_t = \frac{N-(t-1)-n+m}{N-(t-1)}, \qquad \text{for } x_m < t < x_{m+1};$$
$$p_t = \frac{n-m}{N-(t-1)}, \qquad \text{for } t = x_{m+1}.$$

The denominator of the product p is $N!$; the numerator contains the terms $N-n$, $N-n-1, \ldots, 1$ for those t's that are not x's, and the terms $n, n-1, \ldots, 1$ for those t's that are x's. Hence $p = (N-n)!n!/N!$. *Example:* $n = 3$, $N = 8$, $(x_1, x_2, x_3) = (2, 3, 7)$; $p = \frac{5}{8}\frac{3}{7}\frac{2}{6}\frac{2}{5}\frac{4}{4}\frac{3}{3}\frac{2}{2}\frac{1}{1}\frac{1}{1}$.

9. The reservoir gets seven records: 1, 2, 3, 5, 9, 13, 16. The final sample consists of records 2, 5, 16.

10. Delete step R6 and the variable m. Replace the I table by a table of records, initialized to the first n records in step R1, and with the new record replacing the Mth table entry in step R4.

11. Arguing as in Section 1.2.10, which considers the special case $n = 1$, we see that the generating function is

$$G(z) = z^n\left(\frac{1}{n+1} + \frac{n}{n+1}z\right)\left(\frac{2}{n+2} + \frac{n}{n+2}z\right)\ldots\left(\frac{N-n}{N} + \frac{n}{N}z\right).$$

The mean is $n + \sum_{n<t\le N}(n/t) = n(1 + H_N - H_n)$; and the variance turns out to be $n(H_N - H_n) - n^2(H_N^{(2)} - H_n^{(2)})$.

12. (Note that $\pi^{-1} = (b_t t)\ldots(b_3 3)(b_2 2)$, so we seek an algorithm that goes from the representation of π to that for π^{-1}.) Set $b_j \leftarrow j$ for $1 \le j \le t$. Then for $j = 2$, 3, ..., t (in this order) interchange $b_j \leftrightarrow b_{a_j}$. Finally for $j = t$, ..., 3, 2 (in this order) set $b_{a_j} \leftarrow b_j$. (The algorithm is based on the fact that $(a_t t)\pi_1 = \pi_1(b_t t)$.)

13. Renumbering the deck 0, 1, ..., $2n - 2$, we find that s takes card number x into card number $(2x) \bmod (2n-1)$, while c takes card x into $(x+1) \bmod (2n-1)$. We have (c followed by s) $= cs = sc^2$. Therefore any product of c's and s's can be transformed into the form $s^i c^k$. Also $2^{\varphi(2n-1)} \equiv 1$ (modulo $(2n-1)$); since $s^{\varphi(2n-1)}$ and c^{2n-1} are the identity permutation, at most $(2n-1)\varphi(2n-1)$ arrangements are possible. (The *exact* number of different arrangements is $(2n-1)k$, where k is the order of 2 modulo $(2n-1)$. For if $s^k = c^j$, then c^j fixes the card 0, so $s^k = c^j =$ identity.) For further details, see *SIAM Review* **3** (1961), 293–297.

14. Set $Y_j \leftarrow j$ for $t - n < j \le t$. Then for $j = t$, $t-1$, ..., $t - n + 1$ do the following operations: Set $k \leftarrow \lfloor jU \rfloor + 1$. If $k > t - n$ then set $X_j \leftarrow Y_k$ and $Y_k \leftarrow Y_j$; otherwise if $k = X_i$ for some $i > j$ (a symbol table algorithm could be used), then set $X_j \leftarrow Y_i$ and $Y_i \leftarrow Y_j$; otherwise set $X_j \leftarrow k$. (The idea is to let $Y_{t-n+1}, \ldots, Y_j$ represent $X_{t-n+1}, \ldots, X_j$, and if $i > j$ and $X_i \le t - n$ also to let Y_i represent X_{X_i}, in the execution of Algorithm P.)

15. We may assume that $n \le \frac{1}{2}N$, otherwise it suffices to find the $N - n$ elements *not* in the sample. Using a hash table of size $2n$, the idea is to generate random numbers between 1 and N, storing them in the table and discarding duplicates, until n distinct numbers have been generated. The average number of random numbers generated is $N/N + N/(N-1) + \cdots + N/(N-n+1) < 2n$, by exercise 3.3.2–10, and the average time to process each number is $O(1)$. We want to output the results in increasing order, and this can be done as follows: Using an ordered hash table (exercise 6.4–66) with linear probing, the hash table will appear as if the values had been inserted in increasing order. Thus if we use a monotonic hash address such as $\lceil nk/N \rceil$ for the key k, it will be a simple matter to output the keys in sorted order by making at most two passes over the table.

16. In most cases it will be best simply to select n records one at a time by Walker's alias method, with probabilities proportional to their weights, rejecting an element that occurs more than once. But if some weights are significantly larger than others, the following algorithm will sometimes be better [cf. Wong and Easton, *SIAM J. Comput.* **9** (1980), 111–113]. Begin with a "complete binary tree" of weights x_i, where $x_i = x_{2i} + x_{2i+1}$ for $1 \le i < N$ and $x_{N+i-1} = w_i$ for $1 \le i \le N$; then do the following operation n times: "Set $j \leftarrow 1$, and generate $X = Ux_1$. If $X < x_{2j}$, set $j \leftarrow 2j$, otherwise set $X \leftarrow X - x_{2j}$ and $j \leftarrow 2j + 1$; repeat this until $j \ge N$. Then select element $j - N + 1$, set $i \leftarrow \lfloor j/2 \rfloor$, and while $i \ge 1$ set $x_i \leftarrow x_i - x_j$ and $i \leftarrow \lfloor i/2 \rfloor$. Finally set $x_j \leftarrow 0$."

SECTION 3.5

1. A b-ary sequence, yes (cf. exercise 2); a $[0, 1)$ sequence, no (since only finitely many values are assumed by the elements).

2. It is 1-distributed and 2-distributed, but not 3-distributed (the binary number 111 never appears).

3. Cf. exercise 3.2.2–17; repeat the sequence there with a period of length 27.

4. The sequence begins $\frac{1}{3}, \frac{2}{3}, \frac{2}{3}, \frac{1}{3}, \frac{1}{3}, \frac{1}{3}, \frac{1}{3}, \frac{2}{3}, \frac{2}{3}, \frac{2}{3}, \frac{2}{3}, \frac{2}{3}, \frac{2}{3}, \frac{2}{3}, \frac{2}{3}$, etc. When $n = 1, 3, 7, 15, \ldots$ we have $\nu(n) = 1, 1, 5, 5, \ldots$ so that $\nu(2^{2k-1} - 1) = \nu(2^{2k} - 1) = (2^{2k} - 1)/3$; hence $\nu(n)/n$ oscillates between $\frac{1}{3}$ and approximately $\frac{2}{3}$, and no limit exists. The probability is undefined.

[The methods of Section 4.2.4 show, however, that a numerical value *can* meaningfully be assigned to

$$\Pr(U_n < \frac{1}{2}) = \Pr(\text{leading digit of the radix-4 representation of } n+1 \text{ is } 1),$$

namely $\log_4 2 = \frac{1}{2}$.]

5. If $\nu_1(n)$, $\nu_2(n)$, $\nu_3(n)$, $\nu_4(n)$ are the counts corresponding to the four probabilities, we have $\nu_1(n) + \nu_2(n) = \nu_3(n) + \nu_4(n)$ for all n. So the desired result follows by addition of limits.

6. By exercise 5 and induction,

$$\Pr(S_j(n) \text{ for some } j,\ 1 \le j \le k) = \sum_{1 \le j \le k} \Pr(S_j(n)).$$

As $k \to \infty$, the latter is a monotone sequence bounded by 1, so it converges; and

$$\underline{\Pr}(S_j(n) \text{ for some } j \ge 1) \ge \sum_{1 \le j \le k} \Pr(S_j(n))$$

for all k. For a counterexample to equality, it is not hard to arrange things so that $S_j(n)$ is always true for *some* j, yet $\Pr(S_j(n)) = 0$ for *all* j.

7. Let $p_i = \sum_{j \ge 1} \Pr(S_{ij}(n))$. The result of the preceding exercise can be generalized to $\underline{\Pr}(S_j(n) \text{ for some } j \ge 1) \ge \sum_{j \ge 1} \underline{\Pr}(S_j(n))$, for *any* disjoint statements $S_j(n)$. So we have $1 = \Pr(S_{ij}(n) \text{ for some } i, j \ge 1) \ge \sum_{i \ge 1} \underline{\Pr}(S_{ij}(n) \text{ for some } j \ge 1) \ge \sum_{i \ge 1} p_i = 1$, and hence $\underline{\Pr}(S_{ij}(n) \text{ for some } j \ge 1) = p_i$. Given $\epsilon > 0$, let I be large enough so that $\sum_{1 \le i \le I} p_i \ge 1 - \epsilon$. Let

$$\phi_i(N) = (\text{number of } n < N \text{ with } S_{ij}(n) \text{ true for some } j \ge 1)/N.$$

Clearly $\sum_{1 \le i \le I} \phi_i(N) \le 1$, and for all large enough N we have $\sum_{2 \le i \le I} \phi_i(N) \ge \sum_{2 \le i \le I} p_i - \epsilon$; hence $\phi_1(N) \le 1 - \phi_2(N) - \cdots - \phi_I(N) \le 1 - p_2 - \cdots - p_I + \epsilon \le 1 - (1 - \epsilon - p_1) + \epsilon = p_1 + 2\epsilon$. This proves that $\overline{\Pr}(S_{1j}(n) \text{ for some } j \ge 1) \le p_1 + 2\epsilon$; hence $\Pr(S_{1j}(n) \text{ for some } j \ge 1) = p_1$, and the desired result holds for $i = 1$. By symmetry of the hypotheses, it holds for any value of i.

8. Add together the probabilities for j, $j + d$, $j + 2d$, ... in Definition E.

9. $\limsup_{n\to\infty}(a_n+b_n)\le\limsup_{n\to\infty}a_n+\limsup_{n\to\infty}b_n$; hence we find that

$$\limsup_{n\to\infty}((y_{1n}-\alpha)^2+\cdots+(y_{mn}-\alpha)^2)\le m\alpha^2-2m\alpha^2+m\alpha^2=0,$$

and this can happen only if each $(y_{jn}-\alpha)$ tends to zero.

10. In the evaluation of the sum in Eq. (22).

11. $\langle U_{2n}\rangle$ is k-distributed if $\langle U_n\rangle$ is $(2,2k)$-distributed.

12. Let $f(x_1,\ldots,x_k)=1$ if $u\le\max(x_1,\ldots,x_k)<v$; $f(x_1,\ldots,x_k)=0$ otherwise. Then apply Theorem B.

13. Let

$$\begin{aligned}p_k&=\Pr(U_n\text{ begins a gap of length }k-1)\\&=\Pr(U_{n-1}\in[\alpha,\beta),\ U_n\notin[\alpha,\beta),\ \ldots,\ U_{n+k-2}\notin[\alpha,\beta),\ U_{n+k-1}\in[\alpha,\beta))\\&=p^2(1-p)^{k-1}.\end{aligned}$$

It remains to translate this into the probability that $f(n)-f(n-1)=k$. Let $\nu_k(n)=$ (number of $j\le n$ with $f(j)-f(j-1)=k$); let $\mu_k(n)=$ (number of $j\le n$ with U_j the beginning of a gap of length $k-1$); and let $\mu(n)$ similarly count the number of $1\le j\le n$ with $U_j\in[\alpha,\beta)$. We have $\mu_k(f(n))=\nu_k(n)$, $\mu(f(n))=n$. As $n\to\infty$, we must have $f(n)\to\infty$, hence

$$\nu_k(n)/n=(\mu_k(f(n))/f(n))\cdot(f(n)/\mu(f(n)))\to p_k/p=p(1-p)^{k-1}.$$

[We have only made use of the fact that the sequence is $(k+1)$-distributed.]

14. Let

$$\begin{aligned}p_k&=\Pr(U_n\text{ begins a run of length }k)\\&=\Pr(U_{n-1}>U_n<\cdots<U_{n+k-1}>U_{n+k})\\&=\frac{1}{(k+2)!}\left(\binom{k+2}{1}\binom{k+1}{1}-\binom{k+2}{1}-\binom{k+2}{1}+1\right)\\&=\frac{k}{(k+1)!}-\frac{k+1}{(k+2)!}\end{aligned}$$

(cf. exercise 3.3.2–13). Now proceed as in the previous exercise to transfer this to $\Pr(f(n)-f(n-1)=k)$. [We have assumed only that the sequence is $(k+2)$-distributed.]

15. For $s,t\ge0$ let

$$\begin{aligned}p_{st}&=\Pr(X_{n-2t-3}=X_{n-2t-2}\ne X_{n-2t-1}\ne\cdots\ne X_{n-1}\\&\qquad\qquad\text{and }X_n=\cdots=X_{n+s}\ne X_{n+s+1})\\&=2^{-s-2t-3};\end{aligned}$$

for $t\ge0$ let $q_t=\Pr(X_{n-2t-2}=X_{n-2t-1}\ne\cdots\ne X_{n-1})=2^{-2t-1}$. By exercise 7, $\Pr(X_n$ is not the beginning of a coupon set$)=\sum_{t\ge0}q_t=\frac{2}{3}$; $\Pr(X_n$ is the beginning of coupon set of length $s+2)=\sum_{t\ge0}p_{st}=\frac{1}{3}\cdot2^{-s-1}$. Now proceed as in exercise 13.

16. (Solution by R. P. Stanley.) Whenever the subsequence $S = (b-1), (b-2), \ldots, 1, 0, 0, 1, \ldots, (b-2), (b-1)$ appears, a coupon set must end at the right of S, since some coupon set is completed in the first half of S. We now proceed to calculate the probability that a coupon set begins at position n by manipulating the probabilities that the last prior appearance of S ends at position $n-1$, $n-2$, etc., as in exercise 15.

18. Proceed as in the proof of Theorem A to calculate $\underline{\Pr}$ and $\overline{\Pr}$.

19. (Solution by T. Herzog.) Yes; e.g., the sequence $\langle U_{\lfloor n/2 \rfloor} \rangle$ when $\langle U_n \rangle$ satisfies R4 (or even its weaker version), cf. exercise 33.

21. $\Pr(Z_n \in M_1, \ldots, Z_{n+k-1} \in M_k) = p(M_1) \ldots p(M_k)$, for all $M_1, \ldots, M_k \in \mathcal{M}$.

22. If the sequence is k-distributed, the limit is zero by integration and Theorem B. Conversely, note that if $f(x_1, \ldots, x_k)$ has an absolutely convergent Fourier series

$$f(x_1, \ldots, x_k) = \sum_{-\infty < c_1, \ldots, c_k < \infty} a(c_1, \ldots, c_k) \exp(2\pi i(c_1 x_1 + \cdots + c_k x_k)),$$

we have $\lim_{N \to \infty} \frac{1}{N} \sum_{0 \le n < N} f(U_n, \ldots, U_{n+k-1}) = a(0, \ldots, 0) + \epsilon_r$, where

$$|\epsilon_r| \le \sum_{|c_1|, \ldots, |c_k| > r} |a(c_1, \ldots, c_k)|,$$

so ϵ_r can be made arbitrarily small. Hence this limit is equal to

$$a(0, \ldots, 0) = \int_0^1 \cdots \int_0^1 f(x_1, \ldots, x_k)\, dx_1 \ldots dx_k,$$

and Eq. (8) holds for all sufficiently smooth functions f. The remainder of the proof shows that the function in (9) can be approximated by smooth functions to any desired accuracy.

23. See *AMM* **75** (1968), 260–264.

24. This follows immediately from exercise 22.

25. If the sequence is equidistributed, the denominator in Corollary S approaches $\frac{1}{12}$, and the numerator approaches the quantity in this exercise.

26. See *Math. Comp.* **17** (1963), 50–54. [Consider also the following example by A. G. Waterman: Let $\langle U_n \rangle$ be an equidistributed $[0, 1)$ sequence and $\langle X_n \rangle$ an ∞-distributed binary sequence. Let $V_n = U_{\lceil \sqrt{n} \rceil}$ or $1 - U_{\lceil \sqrt{n} \rceil}$ according as X_n is 0 or 1. Then $\langle V_n \rangle$ is equidistributed and white, but $\Pr(V_n = V_{n+1}) = \frac{1}{2}$. Let $W_n = (V_n - \epsilon_n) \bmod 1$ where $\langle \epsilon_n \rangle$ is any sequence that decreases monotonically to 0; then $\langle W_n \rangle$ is equidistributed and white, yet $\Pr(W_n < W_{n+1}) = \frac{3}{4}$.]

28. Let $\langle U_n \rangle$ be ∞-distributed, and consider the sequence $\langle \frac{1}{2}(X_n + U_n) \rangle$. This is 3-distributed, using the fact that $\langle U_n \rangle$ is $(16, 3)$-distributed.

29. If $x = x_1x_2\ldots x_t$ is any binary number, we can consider the number $\nu_x^E(n)$ of times $X_p\ldots X_{p+t-1} = x$, where $1 \le p \le n$ and p is even. Similarly, let $\nu_x^O(n)$ count the number of times when p is odd. Let $\nu_x^E(n) + \nu_x^O(n) = \nu_x(n)$. Now

$$\nu_0^E(n) = \sum \nu^E_{0**\ldots*}(n) \approx \sum \nu^O_{*0*\ldots*}(n) \approx \sum \nu^E_{**0\ldots*}(n) \approx \cdots \approx \sum \nu^O_{***\ldots0}(n)$$

where the ν's in these summations have $2k$ subscripts, $2k-1$ of which are asterisks (meaning that they are being summed over—each sum is taken over 2^{2k-1} combinations of zeros and ones), and where "$\approx$" denotes approximate equality (except for an error of at most $2k$ due to end conditions). Therefore we find that

$$\frac{1}{n}2k\nu_0^E(n) = \frac{1}{n}\Big(\sum \nu_{*0*\ldots*}(n) + \cdots + \sum \nu_{***\ldots0}(n)\Big) + \frac{1}{n}\sum_x (r(x) - s(x))\nu_x^E(n) + O\Big(\frac{1}{n}\Big),$$

where $x = x_1\ldots x_{2k}$ contains $r(x)$ zeros in odd positions and $s(x)$ zeros in even positions. By $(2k)$-distribution, the parenthesized quantity tends to $k(2^{2k-1})/2^{2k} = k/2$. The remaining sum is clearly a maximum if $\nu_x^E(n) = \nu_x(n)$ when $r(x) > s(x)$, and $\nu_x^E(n) = 0$ when $r(x) < s(x)$. So the maximum of the right-hand side becomes

$$\frac{k}{2} + \sum_{0\le s<r\le k} (r-s)\binom{k}{r}\binom{k}{s}\Big/2^{2k} = \frac{k}{2} + k\binom{2k-1}{k}\Big/2^{2k}.$$

Now $\overline{\Pr}(X_{2n} = 0) \le \limsup_{n\to\infty} \nu_0^E(2n)/n$, so the proof is complete. *Note:*

$$\sum_{r,s}\binom{n}{r}\binom{n}{s}\max(r,s) = 2n2^{2n-2} + n\binom{2n-1}{n};$$
$$\sum_{r,s}\binom{n}{r}\binom{n}{s}\min(r,s) = 2n2^{2n-2} - n\binom{2n-1}{n}.$$

30. Let $f(x_1, x_2, \ldots, x_{2k}) = \operatorname{sign}(x_1 - x_2 + x_3 - x_4 + \cdots - x_{2k})$. Construct a directed graph with 2^{2k} nodes labeled $(E; x_1, \ldots, x_{2k-1})$ and $(O; x_1, \ldots, x_{2k-1})$, where each x is either 0 or 1. Let there be $1 + f(x_1, x_2, \ldots, x_{2k})$ directed arcs from $(E; x_1, \ldots, x_{2k-1})$ to $(O; x_2, \ldots, x_{2k})$, and $1 - f(x_1, x_2, \ldots, x_{2k})$ directed arcs leading from $(O; x_1, \ldots, x_{2k-1})$ to $(E; x_2, \ldots, x_{2k})$. We find that each node has the same number of arcs leading into it as there are leading out; for example, $(E; x_1, \ldots, x_{2k-1})$ has $1 - f(0, x_1, \ldots, x_{2k-1}) + 1 - f(1, x_1, \ldots, x_{2k-1})$ leading in and $1 + f(x_1, \ldots, x_{2k-1}, 0) + 1 + f(x_1, \ldots, x_{2k-1}, 1)$ leading out, and $f(x, x_1, \ldots, x_{2k-1}) = -f(x_1, \ldots, x_{2k-1}, x)$. Drop all nodes that have no paths leading either in or out, i.e., $(E; x_1, \ldots, x_{2k-1})$ if $f(0, x_1, \ldots, x_{2k-1}) = +1$, or $(O; x_1, \ldots, x_{2k-1})$ if $f(1, x_1, \ldots, x_{2k-1}) = -1$. The resulting directed graph is seen to be connected, since we can get from any node to $(E; 1, 0, 1, 0, \ldots, 1)$ and from this to any desired node. By Theorem 2.3.4.2G, there is a cyclic path traversing each arc; this path has length 2^{2k+1}, and we may assume that it starts at node $(E; 0, \ldots, 0)$. Construct a cyclic sequence with $X_1 = \cdots = X_{2k-1} = 0$, and $X_{n+2k-1} = x_{2k}$ if the nth arc of the path is from $(E; x_1, \ldots, x_{2k-1})$ to $(O; x_2, \ldots, x_{2k})$ or from $(O; x_1, \ldots, x_{2k-1})$ to $(E; x_2, \ldots, x_{2k})$. For example, the graph for $k = 2$ is shown in Fig. A–5; the arcs of

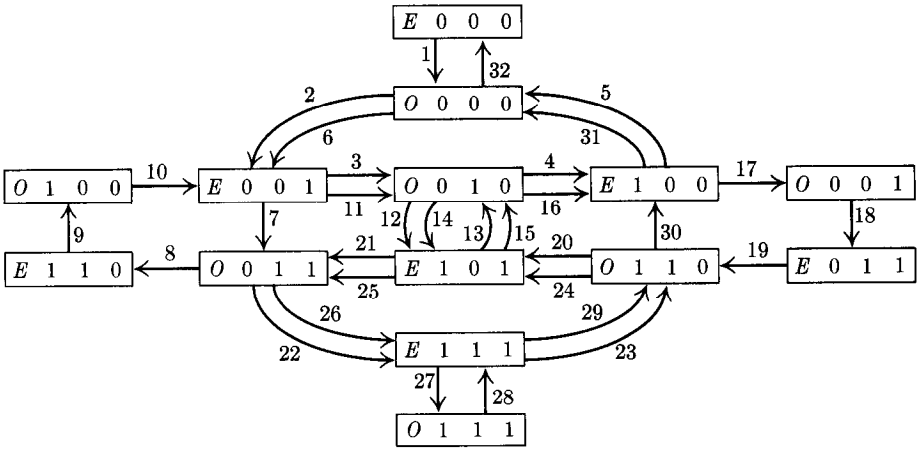

Fig. A–5. Directed graph for the construction in exercise 30.

the cyclic path are numbered from 1 to 32, and the cyclic sequence is

$$(00001000110010101001101110111110)(00001\ldots).$$

Note that $\Pr(X_{2n} = 0) = \frac{11}{16}$ in this sequence. The sequence is clearly $(2k)$-distributed, since each $(2k)$-tuple $x_1x_2\ldots x_{2k}$ occurs $1 + f(x_1, \ldots, x_{2k}) + 1 - f(x_1, \ldots, x_{2k}) = 2$ times in the cycle. The fact that $\Pr(X_{2n} = 0)$ has the desired value comes from the fact that the maximum value on the right-hand side in the proof of the preceding exercise has been achieved by this construction.

31. Use Algorithm W with rule $\mathcal{R}_1$ selecting the entire sequence. [For a generalization of this type of nonrandom behavior in R5-sequences, see Jean Ville, *Étude Critique de la notion de Collectif* (Paris, 1939), 55–62. Perhaps R6 is also too weak, from this standpoint.]

32. If $\mathcal{R}, \mathcal{R}'$ are computable subsequence rules, so is $\mathcal{R}'' = \mathcal{R}\mathcal{R}'$ defined by the following functions: $f''_n(x_0, \ldots, x_{n-1}) = 1$ iff $\mathcal{R}$ defines the subsequence $x_{r_1}, \ldots, x_{r_k}$ of $x_0, \ldots, x_{n-1}$, where $k \geq 0$ and $0 \leq r_1 < \cdots < r_k < n$ and $f'_k(x_{r_1}, \ldots, x_{r_k}) = 1$.

Now $\langle X_n\rangle\mathcal{R}\mathcal{R}'$ is $(\langle X_n\rangle\mathcal{R})\mathcal{R}'$. The result follows immediately.

33. Given $\epsilon > 0$, find N_0 such that $N > N_0$ implies that both $|\nu_r(N)/N - p| < \epsilon$ and $|\nu_s(N)/N - p| < \epsilon$. Then find N_1 such that $N > N_1$ implies that t_N is r_M or s_M for some $M > N_0$. Now $N > N_1$ implies that

$$\left|\frac{\nu_t(N)}{N} - p\right| = \left|\frac{\nu_r(N_r) + \nu_s(N_s)}{N} - p\right| = \left|\frac{\nu_r(N_r) - pN_r + \nu_s(N_s) - pN_s}{N_r + N_s}\right| < \epsilon.$$

34. For example, if the binary representation of t is $(1\,0^{b-2}\,1\,0^{a_1}\,1\,1\,0^{a_2}\,1\ldots1\,0^{a_k})_2$, where "$0^a$" stands for a sequence of a consecutive zeros, let the rule $\mathcal{R}_t$ accept U_n if and only if $\lfloor bU_{n-k}\rfloor = a_1, \ldots, \lfloor bU_{n-1}\rfloor = a_k$.

35. Let $a_0 = s_0$ and $a_{m+1} = \max\{\, s_k \mid 0 \leq k < 2^{a_m} \,\}$. Construct a subsequence rule that selects element X_n if and only if $n = s_k$ for some $k < 2^{a_m}$, when n is in the range $a_m \leq n < a_{m+1}$. Then $\lim_{m\to\infty} \nu(a_m)/a_m = \frac{1}{2}$.

36. Let b and k be arbitrary but fixed integers greater than 1. Let $Y_n = \lfloor bU_n \rfloor$. An arbitrary infinite subsequence $\langle Z_n \rangle = \langle Y_{s_n} \rangle \mathcal{R}$ determined by algorithms $\mathcal{S}$ and $\mathcal{R}$ (as in the proof of Theorem M) corresponds in a straightforward but notationally hopeless manner to algorithms $\mathcal{S}'$ and $\mathcal{R}'$ that inspect X_t, X_{t+1}, ..., X_{t+s} and/or select X_t, X_{t+1}, ..., $X_{t+\min(k-1,s)}$ of $\langle X_n \rangle$ if and only if $\mathcal{S}$ and $\mathcal{R}$ inspect and/or select Y_s, where $U_s = (0.X_tX_{t+1}\ldots X_{t+s})_2$. Algorithms $\mathcal{S}'$ and $\mathcal{R}'$ determine an infinite 1-distributed subsequence of $\langle X_n \rangle$ and in fact (as in exercise 32) this subsequence is ∞-distributed so it is $(k, 1)$-distributed. Hence we find that $\underline{\Pr}(Z_n = a)$ and $\overline{\Pr}(Z_n = a)$ differ from $1/b$ by less than $1/2^k$.

[The result of this exercise is true if "R6" is replaced consistently by "R4" or "R5"; but it is false if "R1" is used, since $X_{\binom{n}{2}}$ might be identically zero.]

37. For $n \geq 2$ replace U_{n^2} by $\frac{1}{2}(U_{n^2} + \delta_n)$, where $\delta_n = 0$ or 1 according as the set $\{U_{(n-1)^2+1}, \ldots, U_{n^2-1}\}$ contains an even or odd number of elements less than $\frac{1}{2}$. [*Advances in Math.* **14** (1974), 333–334.]

39. See *Acta Arithmetica* **21** (1972), 45–50. The best possible value of c is unknown.

40. If every one-digit change to a random table yields a random table, all tables are random (or none are). If we don't allow degrees of randomness, the answer must therefore be, "Not always."

```

2. Putting a random number generator into a program makes the results essentially unpredictable to the programmer. If the behavior of the machine on each problem were known in advance, few programs would ever be written. As Turing has said, the actions of a computer quite often *do* surprise its programmer, especially when a program is being debugged.

So the world had better watch out.

7. In fact, you only need the 2-bit values $\lfloor X_n/2^{16} \rfloor \bmod 4$; see D. E. Knuth, "Deciphering a linear congruential encryption," to appear. See also J. Reeds, *Cryptologia* **1** (1977), 20–26, **3** (1979), 83–95, for solutions to related problems.

SECTION 4.1

1. 1010, 1011, 1000, ..., 11000, 11001, 11110.

2. (a) -110001, $-11.001001001001\ldots$, $11.0010010000111111\ldots$.
(b) 11010011, 1101.001011001011... , 111.011001000100000....
(c) $\overline{1}11\overline{1}1$, $\overline{1}0.0\overline{1}10110\overline{1}1011\ldots$, $10.011\overline{1}111\overline{1}\ldots$.
(d) -9.4, $-\ldots 7582417582413$, $\ldots 562951413$.

3. $(1010113.2)_{2i}$.

4. (a) Between rA and rX. (b) The remainder in rX has radix point between bytes 3 and 4; the quotient in rA has radix point one byte to the right of the least significant portion of the register.

5. It has been subtracted from $999\ldots9 = 10^p - 1$, instead of from $1000\ldots0 = 10^p$.

6. (a,c) $2^{p-1} - 1$, $-(2^{p-1} - 1)$; (b) $2^{p-1} - 1$, -2^{p-1}.

7. A ten's complement representation for a negative number x can be obtained by considering $10^n + x$ (where n is large enough for this to be positive) and extending it on the left with infinitely many nines. The nines' complement representation can be obtained in the usual manner. (These two representations are equal for nonterminating decimals, otherwise the nines' complement representation has the form $\ldots(a)99999\ldots$ while the ten's complement representation has the form $\ldots(a+1)0000\ldots$.) The representations may be considered sensible if we regard the value of the infinite sum $N = 9 + 90 + 900 + 9000 + \cdots$ as -1, since $N - 10N = 9$.

See also exercise 31, which considers p-adic number systems. The latter agree with the p's complement notations considered here, for numbers whose radix-p representation is terminating, but there is no simple relation between the field of p-adic numbers and the field of real numbers.

8. $\sum_j a_j b^j = \sum_j (a_{kj+k-1} b^{k-1} + \cdots + a_{kj}) b^{kj}$.

9. A BAD ADOBE FACADE FADED. [*Note:* Other possible "number sentences" would be DO A DEED A DECADE; A CAD FED A BABE BEEF, COCOA, COFFEE; BOB FACED A DEAD DODO.]

10. $\begin{bmatrix} \ldots, a_3, a_2, a_1, a_0; a_{-1}, a_{-2}, \ldots \\ \ldots, b_3, b_2, b_1, b_0; b_{-1}, b_{-2}, \ldots \end{bmatrix} = \begin{bmatrix} \ldots, A_3, A_2, A_1, A_0; A_{-1}, A_{-2}, \ldots \\ \ldots, B_3, B_2, B_1, B_0; B_{-1}, B_{-2}, \ldots \end{bmatrix}$, if

$$A_j = \begin{bmatrix} a_{k_j+1}-1, a_{k_j+1}-2, \ldots, a_{k_j} \\ b_{k_j+1}-2, \ldots, b_{k_j} \end{bmatrix}, \qquad B_j = b_{k_j+1}-1 \ldots b_{k_j},$$

where $\langle k_n \rangle$ is any infinite sequence of integers with $k_{j+1} > k_j$.

11. (The following algorithm works both for addition or subtraction, depending on whether the plus or minus sign is chosen.)

Start by setting $k \leftarrow a_{n+1} \leftarrow a_{n+2} \leftarrow b_{n+1} \leftarrow b_{n+2} \leftarrow 0$; then for $m = 0, 1, \ldots, n+2$ do the following: Set $c_m \leftarrow a_m \pm b_m + k$; then if $c_m \geq 2$, set $k \leftarrow -1$ and $c_m \leftarrow c_m - 2$; otherwise if $c_m < 0$, set $k \leftarrow 1$ and $c_m \leftarrow c_m + 2$; otherwise (i.e., if $0 \leq c_m \leq 1$), set $k \leftarrow 0$.

12. (a) Subtract $\pm(\ldots a_3 0 a_1 0)_{-2}$ from $\pm(\ldots a_4 0 a_2 0 a_0)_{-2}$ in the negabinary system. (See also exercise 7.1–18 for a trickier solution that uses full-word logical operations.) (b) Subtract $(\ldots b_3 0 b_1 0)_2$ from $(\ldots b_4 0 b_2 0 b_0)_2$ in the binary system.

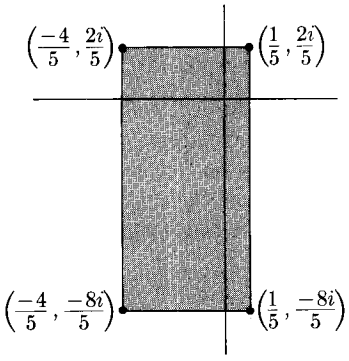

Fig. A–6. Fundamental region for quater-imaginary numbers.

13. $(1.909090\ldots)_{-10} = (0.090909\ldots)_{-10} = \frac{1}{11}$.

14.

$$\begin{array}{rrrrrrrrrrl}
 & & & & 1 & 1 & 3 & 2 & 1 & & [5-4i] \\
 & & & & 1 & 1 & 3 & 2 & 1 & & [5-4i] \\
\hline
 & & & & 1 & 1 & 3 & 2 & 1 & & \\
 & & & 1 & 1 & 2 & 0 & 2 & & & \\
 & & 1 & 2 & 1 & 2 & 3 & & & & \\
 & 1 & 1 & 3 & 2 & 1 & & & & & \\
1 & 1 & 3 & 2 & 1 & & & & & & \\
\hline
0 & 1 & 0 & 3 & 1 & 1 & 2 & 0 & 1 & & [9-40i]
\end{array}$$

15. $[-\frac{10}{11}, \frac{1}{11}]$, and the rectangle shown in Fig. A–6.

16. It is tempting to try to do this in a very simple way, by using the rule $2 = (1100)_{i-1}$ to take care of carries; but that leads to a nonterminating method if, for example, we try to add 1 to $(11101)_{i-1} = -1$.

The following solution does the job by providing four related algorithms (namely for adding or subtracting 1 or i). If α is a string of zeros and ones, let α^P be a string of zeros and ones such that $(\alpha^P)_{i-1} = (\alpha)_{i-1} + 1$; and let α^{-P}, α^Q, α^{-Q} be defined similarly, with -1, $+i$, and $-i$ respectively in place of $+1$. Then

$$\begin{array}{llll}
(\alpha 0)^P = \alpha 1; & (\alpha x 1)^P = \alpha^Q x 0. & (\alpha 0)^Q = \alpha^P 1; & (\alpha 1)^Q = \alpha^{-Q} 0. \\
(\alpha x 0)^{-P} = \alpha^{-Q} x 1; & (\alpha 1)^{-P} = \alpha 0. & (\alpha 0)^{-Q} = \alpha^Q 1; & (\alpha 1)^{-Q} = \alpha^{-P} 0.
\end{array}$$

Here x stands for either 0 or 1, and the strings are extended on the left with zeros if necessary. The processes will clearly always terminate. Hence every number of the form $a + bi$ with a and b integers is representable in the $i - 1$ system.

17. No (in spite of exercise 28); the number -1 cannot be so represented. This can be proved by constructing a set S as in Fig. 1. We do have the representations $-i = (0.1111\ldots)_{1+i}$, $i = (100.1111\ldots)_{1+i}$.

18. Let S_0 be the set of points $(a_7a_6a_5a_4a_3a_2a_1a_0)_{i-1}$, where each a_k is 0 or 1. (Thus, S_0 is given by the 256 interior dots shown in Fig. 1, if that picture is multiplied by 16.) We first show that S is closed: If y_1, y_2, ... is an infinite subset of S, we have $y_n = \sum_{k\geq 1} a_{nk}16^{-k}$, where each a_{nk} is in S_0. Construct a tree whose nodes are $(a_{n1}, \ldots, a_{nr})$, for $1 \leq r \leq n$, and let a node of this tree be an ancestor of another

node if it is an initial subsequence of that node. By the infinity lemma this tree has an infinite path $(a_1, a_2, a_3, \dots)$, and it follows that $\sum_{k\geq 1} a_k 16^{-k}$ is a limit point of $\{y_1, y_2, \dots\}$ in S.

By the answer to exercise 16, all numbers of the form $(a+bi)/16^k$ are representable, when a and b are integers. Therefore if x and y are arbitrary reals and $k \geq 1$, the number $z_k = (\lfloor 16^k x \rfloor + \lfloor 16^k y \rfloor i)/16^k$ is in $S + m + ni$ for some integers m and n. It can be shown that $S + m + ni$ is bounded away from the origin when $(m, n) \neq (0, 0)$. Consequently if $|x|$ and $|y|$ are fixed and k is sufficiently large, we have $z_k \in S$, and $\lim_{k\to\infty} z_k = x + yi$ is in S.

[B. Mandelbrot calls S the "twindragon," since he noticed that it is essentially obtained by joining two "dragon curves" belly-to-belly; see his book *Fractals: Form, Chance, and Dimension* (San Francisco: Freeman, 1977), 313–314. Other properties of the dragon curve are described in C. Davis and D. E. Knuth, *J. Recr. Math.* **3** (1970), 66–81, 133–149.]

19. If $m > u$ or $m < l$, find $a \in D$ such that $m \equiv a$ (modulo b); the desired representation will be a representation of $m' = (m - a)/b$ followed by a. Note that $m > u$ implies $l < m' < m$; $m < l$ implies $m < m' < u$; so the algorithm terminates.

[There are no solutions when $b = 2$. The representation will be unique iff $0 \in D$; nonunique representation occurs for example when $D = \{-3, -1, 7\}$, $b = 3$, since $(\alpha)_3 = (\overline{3}77\overline{3}\alpha)_3$. When $b \geq 3$ it is not difficult to show that there are exactly 2^{b-3} solution sets D in which $|a| < b$ for all $a \in D$. Furthermore the set $D = \{0, 1, 2 - \epsilon_2 b^n, 3 - \epsilon_3 b^n, \dots, b - 2 - \epsilon_{b-2} b^n, b - 1 - b^n\}$ gives unique representations, for all $b \geq 3$ and $n \geq 1$, when each ϵ_j is 0 or 1. Reference: *Proc. IEEE Symp. Comp. Arith.* **4** (1978), 1–9.]

20. (a) $0.\overline{111}\dots = \overline{1}.888\dots = \overline{1}8.^{111}_{777}\dots = \overline{1}8^{1\ 222}_{7\cdot 666}\dots = \cdots = \overline{1}8^{123456\ 777}_{765432\cdot 111}\dots$ has nine representations. (b) A "D-fraction" $.a_1a_2\dots$ always lies between $-1/9$ and $+71/9$. Suppose x has ten or more D-decimal representations. Then for sufficiently large k, $10^k x$ has ten representations that differ to the left of the decimal point: $10^k x = n_1 + f_1 = \cdots = n_{10} + f_{10}$ where each f_j is a D-fraction. By uniqueness of integer representations, the n_j are distinct, say $n_1 < \cdots < n_{10}$, hence $n_{10} - n_1 \geq 9$; but this implies $f_1 - f_{10} \geq 9 > 71/9 - (-1/9)$, a contradiction. (c) Any number of the form $0.a_1a_2\dots$, where each a_j is -1 or 8, equals $\overline{1}.a'_1a'_2\dots$ where $a'_j = a_j + 9$ (and it even has six *more* representations $\overline{1}8.a''_1a''_2\dots$, etc.).

21. We can convert to such a representation by using a method like that suggested in the test for converting to balanced ternary.

In contrast to the systems of exercise 20, zero can be represented in infinitely many ways, all obtained from $\frac{1}{2} + \sum_{k\geq 1}(-4\frac{1}{2}) \cdot 10^{-k}$ (or from the negative of this representation) by multiplying it by a power of ten. The representations of unity are $1\frac{1}{2} - \frac{1}{2}$, $\frac{1}{2} + \frac{1}{2}$, $5 - 3\frac{1}{2} - \frac{1}{2}$, $5 - 4\frac{1}{2} + \frac{1}{2}$, $50 - 45 - 3\frac{1}{2} - \frac{1}{2}$, $50 - 45 - 4\frac{1}{2} + \frac{1}{2}$, etc., where $\pm\frac{1}{2} = (\pm 4\frac{1}{2})(10^{-1} + 10^{-2} + \cdots)$. [*AMM* **57** (1950), 90–93.]

22. Given some approximation $b_n \dots b_1 b_0$ with error $\sum_{0\leq k\leq n} b_k 10^k - x > 10^{-t}$ for $t > 0$, we will show how to reduce the error by approximately 10^{-t}. (The process can be started by finding a suitable $\sum_{0\leq k\leq n} b_k 10^k > x$; then a finite number of reductions of this type will make the error less than ϵ.) Simply choose $m > n$ so large that the decimal representation of $-10^m\alpha$ has a one in position 10^{-t} and no ones in positions $10^{-t+1}, 10^{-t+2}, \dots, 10^n$. Then $10^m\alpha +$ (a suitable sum of powers of 10 between 10^m and 10^n) $+ \sum_{0\leq k\leq n} b_k 10^k \approx \sum_{0\leq k\leq n} b_k 10^k - 10^{-t}$.

23. The set $S = \{\sum_{k\geq 1} a_k b^{-k} \mid a_k \in D\}$ is closed as in exercise 18, hence it is measurable, and in fact it has positive measure. Since $bS = \bigcup_{a\in D}(a+S)$, we have $b\mu(S) = \mu(bS) \leq \sum_{a\in D}\mu(a+S) = \sum_{a\in D}\mu(S) = b\mu(S)$, and we must therefore have $\mu((a+S)\cap(a'+S)) = 0$ when $a \neq a' \in D$. Now T has measure zero since it is a union of countably many sets of the form $10^k(n+((a+S)\cap(a'+S)))$, $a \neq a'$, each of measure zero.

[The set T cannot be empty, since the real numbers cannot be written as a countable union of disjoint, closed, bounded sets; cf. *AMM* **84** (1977), 827–828. If D has less than b elements, the set of numbers representable with radix b and digits from D has measure zero. If D has more than b elements and represents all reals, T has infinite measure.]

24. $\{2a\cdot 10^k + a' \mid 0 \leq a < 5, 0 \leq a' < 2\}$ or $\{5a'\cdot 10^k + a \mid 0 \leq a < 5, 0 \leq a' < 2\}$, for $k \geq 0$. [R. L. Graham has shown that there are no more sets of integer digits with these properties. And Andrew Odlyzko has shown that the restriction to integers is superflous, in the sense that if the smallest two elements of D are 0 and 1, all the digits must be integers. *Proof:* Let $S = \{\sum_{k<0} a_k b^k \mid a_k \in D\}$ be the set of "fractions," and let $X = \{(a_n \ldots a_0)_b \mid a_k \in D\}$ be the set of "whole numbers"; then $[0,\infty) = \bigcup_{x\in X}(x+S)$, and $(x+S)\cap(x'+S)$ has measure zero for $x \neq x' \in X$. We have $(0,1) \subseteq S$, and by induction on m we will prove that $(m, m+1) \subseteq x_m + S$ for some $x_m \in X$. Let $x_m \in X$ be such that $(m, m+\epsilon)\cap(x_m+S)$ has positive measure for all $\epsilon > 0$. Then $x_m \leq m$, and x_m must be an integer lest $x_{\lfloor x_m\rfloor} + S$ overlap $x_m + S$ too much. If $x_m > 0$, the fact that $(m-x_m, m-x_m+1)\cap S$ has positive measure implies by induction that this measure is 1, and $(m, m+1) \subseteq x_m + S$ since S is closed. If $x_m = 0$ and $(m, m+1) \not\subseteq S$, we must have $m < x'_m < m+1$ for some $x'_m \in X$, where $(m, x'_m) \subseteq S$; but then $1+S$ overlaps $x'_m + S$. See *Proc. London Math. Soc.* (3) **18** (1978), 581–595.]

Note: If we drop the restriction $0 \in D$, there *are* many other cases, some of which are quite interesting, especially $\{1,2,3,4,5,6,7,8,9,10\}$, $\{1,2,3,4,5,51,52,53,54,55\}$, and $\{2,3,4,5,6,52,53,54,55,56\}$. Alternatively if we allow negative digits we obtain many other solutions by the method of exercise 19, plus further sets of unusual digits like $\{-1,0,1,2,3,4,5,6,7,18\}$ that don't meet the conditions stated there. It appears hopeless to find a nice characterization of all solutions with negative digits.]

25. A positive number whose base b representation has m consecutive $(b-1)$'s to the right of the decimal point must have the form $c/b^n + (b^m - \theta)/b^{n+m}$, where c and n are nonnegative integers and $0 < \theta \leq 1$. So if u/v has this form, we find that $b^{m+n}u = b^m cv + b^m v - \theta v$. Therefore θv is an integer that is a multiple of b^m. But $0 < \theta v \leq v < b^m$. [There can be arbitrarily long runs of other digits *aaaaa*, if $0 \leq a < b-1$, for example in the representation of $a/(b-1)$.]

26. The proof of "sufficiency" is a straightforward generalization of the usual proof for base b, by successively constructing the desired representation. The proof of "necessity" breaks into two parts: If β_{n+1} is greater than $\sum_{k\leq n} c_k\beta_k$ for some n, then $\beta_{n+1} - \epsilon$ has no representation for small ϵ. If $\beta_{n+1} \leq \sum_{k\leq n} c_k\beta_k$ for all n, but equality does not always hold, we can show that there are two representations for certain x. [See *Transactions of the Royal Society of Canada*, series III, **46** (1952), 45–55.]

27. Proof by induction on $|n|$: If n is even we must take $e_0 > 0$, and the result follows by induction, since $n/2$ has a unique such representation. If n is odd, we must take $e_0 = 0$, and the problem reduces to representing $-(n-1)/2$; if the latter quantity is

either zero or one, there is obviously only one way to proceed, otherwise it has a unique reversing representation by induction.

[It follows that every positive integer has exactly *two* such representations with *decreasing* exponents $e_0 > e_1 > \cdots > e_t$: one with t even and the other with t odd.]

28. A proof like that of exercise 27 may be given. Note that $a + bi$ is a multiple of $1+i$ by a complex integer if and only if $a+b$ is even. This representation is intimately related to the dragon curve discussed in the answer to exercise 18.

29. It suffices to prove that any collection $\{T_0, T_1, T_2, \dots\}$ satisfying Property B may be obtained by collapsing some collection $\{S_0, S_1, S_2, \dots\}$, where $S_0 = \{0, 1, \dots, b-1\}$ and all elements of S_1, S_2, ... are multiples of b.

To prove the latter statement, we may assume that $1 \in T_0$ and that there is a least element $b > 1$ such that $b \notin T_0$. We will prove, by induction on n, that if $nb \notin T_0$, then $nb+1$, $nb+2$, ..., $nb+b-1$ are not in any of the T_j's; but if $nb \in T_0$, then so are $nb+1$, ..., $nb+b-1$. The result then follows with $S_1 = \{\, nb \mid nb \in T_0 \,\}$, $S_2 = T_1$, $S_3 = T_2$, etc.

If $nb \notin T_0$, then $nb = t_0 + t_1 + \cdots$, where t_1, t_2, ... are multiples of b; hence $t_0 < nb$ is a multiple of b. By induction, $(t_0 + k) + t_1 + t_2 + \cdots$ is the representation of $nb+k$, for $0 < k < b$; hence $nb + k \notin T_j$ for any j.

If $nb \in T_0$ and $0 < k < b$, let the representation of $nb+k$ be $t_0 + t_1 + \cdots$. We cannot have $t_j = nb+k$ for $j \geq 1$, lest $nb+b$ have two representations $(b-k) + \cdots + (nb+k) + \cdots = (nb) + \cdots + b + \cdots$. By induction, $t_0 \bmod b = k$; and the representation $nb = (t_0 - k) + t_1 + \cdots$ implies that $t_0 = nb + k$.

[Reference: *Nieuw Archief voor Wiskunde* (3) **4** (1956), 15–17. A finite analog of this result was derived by P. A. MacMahon, *Combinatory Analysis* **1** (1915), 217–223.]

30. (a) Let A_j be the set of numbers n whose representation does not involve b_j; then by the uniqueness property, $n \in A_j$ iff $n + b_j \notin A_j$. Consequently we have $n \in A_j$ iff $n + 2b_j \in A_j$. It follows that, for $j \neq k$, $n \in A_j \cap A_k$ iff $n + 2b_jb_k \in A_j \cap A_k$. Let m be the number of integers $n \in A_j \cap A_k$ such that $0 \leq n < 2b_jb_k$. Then this interval contains exactly m integers that are in A_j but not A_k, exactly m in A_k but not A_j, and exactly m in neither A_j nor A_k; hence $4m = 2b_jb_k$. Therefore b_j and b_k cannot both be odd. But at least one b_j is odd, of course, since odd numbers can be represented.
(b) According to (a) we can renumber the b's so that b_0 is odd and b_1, b_2, ... are even; then $\frac{1}{2}b_1$, $\frac{1}{2}b_2$, ... must also be a binary basis, and the process can be iterated.

(c) If it is a binary basis, we must have positive and negative d_k's for arbitrarily large k, in order to represent $\pm 2^n$ when n is large. Conversely, the following algorithm may be used:

S1. [Initialize.] Set $k \leftarrow 0$.

S2. [Done?] If $n = 0$, terminate.

S3. [Choose.] If n is odd, include $2^k d_k$ in the representation, and set $n \leftarrow (n - d_k)/2$. Otherwise set $n \leftarrow n/2$.

S4. [Advance k.] Increase k by 1 and return to S2. ∎

At each step the choice is forced; furthermore step S3 always decreases $|n|$ unless $n = -d_k$, hence the algorithm must terminate.

(d) Two iterations of steps S2–S4 in the preceding algorithm will change $4m \to m$, $4m+1 \to m+5$, $4m+2 \to m+7$, $4m+3 \to m-1$. Arguing as in exercise 19, we need only show that the algorithm terminates for $-2 \leq n \leq 8$; all other values of n

are moved toward this interval. In this range $3 \to -1 \to -2 \to 6 \to 8 \to 2 \to 7 \to 0$ and $4 \to 1 \to 5 \to 6$. Thus $1 = 7\cdot 2^0 - 13\cdot 2^1 + 7\cdot 2^2 - 13\cdot 2^3 - 13\cdot 2^5 - 13\cdot 2^9 + 7\cdot 2^{10}$.

Note: The choice $d_0, d_1, d_2, \ldots = 5, -3, 3, 5, -3, 3, \ldots$ also yields a binary basis. For further details see *Math. Comp.* **18** (1964), 537–546; A. D. Sands, *Acta Mathematica*, Acad. Sci. Hung., **8** (1957), 65–86.

31. (See also the related exercises 3.2.2–11, 4.3.2–13, 4.6.2–22.)

(a) By multiplying numerator and denominator by suitable powers of 2, we may assume that $u = (\ldots u_2u_1u_0)_2$ and $v = (\ldots v_2v_1v_0)_2$ are 2-adic integers, where $v_0 = 1$. The following computational method now determines w, using the notation $u^{(n)}$ to stand for the integer $(u_{n-1}\ldots u_0)_2 = u \bmod 2^n$ when $n > 0$:

Let $w_0 = u_0$ and $w^{(1)} = w_0$. For $n = 1, 2, \ldots$, assume that we have found an integer $w^{(n)} = (w_{n-1}\ldots w_0)_2$ such that $u^{(n)} \equiv v^{(n)}w^{(n)}$ (modulo 2^n). Then we have $u^{(n+1)} \equiv v^{(n+1)}w^{(n)}$ (modulo 2^n), hence $w_n = 0$ or 1 according as the quantity $(u^{(n+1)} - v^{(n+1)}w^{(n)}) \bmod 2^{n+1}$ is 0 or 2^n.

(b) Find the smallest integer k such that $2^k \equiv 1$ (modulo $2n+1$). Then we have $1/(2n+1) = m/(2^k - 1)$ for some integer m, $1 \le m < 2^{k-1}$. Let α be the k-bit binary representation of m; then $(0.\alpha\alpha\alpha\ldots)_2$ times $2n+1$ is $(0.111\ldots)_2 = 1$ in the binary system, and $(\ldots\alpha\alpha\alpha)_2$ times $2n+1$ is $(\ldots 111)_2 = -1$ in the 2-adic system.

(c) If u is rational, say $u = m/(2^en)$ where n is odd and positive, the 2-adic representation of u is periodic, because the set of numbers with periodic expansions includes $-1/n$ and is closed under the operations of negation, division by 2, and addition. Conversely, if $u_{N+\lambda} = u_N$ for all $N \ge \mu$, the 2-adic number $(2^\lambda - 1)2^{-\mu}u$ is an integer.

(d) The square of any number of the form $(\ldots u_2u_11)_2$ has the form $(\ldots 001)_2$, hence the condition is necessary. To show the sufficiency, we can use the following procedure to compute $v = \sqrt{n}$ when $n \bmod 8 = 1$:

H1. [Initialize.] Set $m \leftarrow (n-1)/8$, $k \leftarrow 2$, $v_0 \leftarrow 1$, $v_1 \leftarrow 0$, $v \leftarrow 1$. (During this algorithm we will have $v = (v_{k-1}\ldots v_1v_0)_2$ and $v^2 = n - 2^{k+1}m$.)

H2. [Transform.] If m is even, set $v_k \leftarrow 0$, $m \leftarrow m/2$. Otherwise set $v_k \leftarrow 1$, $m \leftarrow (m - v - 2^{k-1})/2$, $v \leftarrow v + 2^k$.

H3. [Advance k.] Increase k by 1 and return to H2. ∎

32. A generalization appears in *Math. Comp.* **29** (1975), 84–86.

33. Let K_n be the set of all such n-digit numbers, so that $k_n = ||K_n||$. If S and T are any finite sets of integers, we shall say $S \sim T$ if $S = T + x$ for some integer x, and we shall write $k_n(S) = ||K_n(S)||$, where $K_n(S)$ is the family of all subsets of K_n that are $\sim S$. When $n = 0$, we have $k_n(S) = 0$ unless $||S|| \le 1$, since zero is the only "0-digit" number. When $n \ge 1$ and $S = \{s_1, \ldots, s_r\}$, we have

$$K_n(S) = \bigcup_{0\le j<b} \bigcup_{(a_1,\ldots,a_r)} \Big\{ \{t_1b + a_1, \ldots, t_rb + a_r\} \;\Big|\; \{t_1, \ldots, t_r\} \in K_{n-1}(\{(S_i + j - a_i)/b \mid 1 \le i \le r\}) \Big\},$$

where the inner union is over all sequences of digits $(a_1, \ldots, a_r)$ satisfying the condition $a_i \equiv S_i + j$ (modulo b) for $1 \le i \le r$. In this formula we require $t_i - t_{i'} = (s_i - a_i)/b - (s_{i'} - a_{i'})/b$ for $1 \le i < i' \le r$, so that the naming of subscripts is uniquely determined. By the principle of inclusion and exclusion, therefore, we have $k_n(S) = \sum_{0\le j<b}\sum_{m\ge 1}(-1)^{m-1}f(S, m, j)$, where $f(S, m, j)$ is the number of sets

of integers that can be expressed as $\{t_1 b + a_1, \ldots, t_r b + a_r\}$ in the above manner for m different sequences $(a_1, \ldots, a_r)$, summed over all choices of m different sequences $(a_1, \ldots, a_r)$. Given m different sequences $(a_1^{(l)}, \ldots, a_r^{(l)})$ for $1 \le l \le m$, the number of such sets is $k_{n-1}(\{(s_i + j - a_i^{(l)})/b \mid 1 \le i \le r, 1 \le l \le m\})$. Thus there is a collection of sets $\mathcal{T}(S)$ such that

$$k_n(S) = \sum_{T \in \mathcal{T}(S)} c_T \, k_{n-1}(T),$$

where each c_T is an integer. Furthermore if $T \in \mathcal{T}(S)$, its elements are near those of S; we have $\min T \ge (\min S - \max D)/b$ and $\max T \le (\max S + b - 1 - \min D)/b$. Thus we obtain simultaneous recurrence relations for the sequences $\langle k_n(S) \rangle$, where S runs through the nonempty integer subsets of $[l, u+1]$, in the notation of exercise 19. Since $k_n = k_n(S)$ for any one-element set S, the sequence $\langle k_n \rangle$ appears these recurrences. The coefficients c_T can be computed from the first few values of $k_n(S)$, so we can obtain a system of equations defining the generating functions $k_S(z) = \sum k_n(S) z^n = (\|S\| \le 1) + z \sum_{T \in \mathcal{T}(S)} k_T(z)$.

For example, when $D = \{-1, 0, 3\}$ and $b = 3$ we have $l = -\frac{3}{2}$ and $u = \frac{1}{2}$, so the relevant sets S are $\{0\}$, $\{0, 1\}$, $\{-1, 1\}$, and $\{-1, 0, 1\}$. The corresponding sequences for $n \le 3$ are $\langle 1, 3, 8, 21 \rangle$, $\langle 0, 1, 3, 8 \rangle$, $\langle 0, 0, 1, 4 \rangle$, and $\langle 0, 0, 0, 0 \rangle$; so we obtain

$$k_0(z) = 1 + z(3k_0(z) - k_{01}(z)), \qquad k_{02}(z) = z(k_{01}(z) + k_{02}(z)),$$
$$k_{01}(z) = zk_0(z), \qquad l_{012}(z) = 0,$$

and $k(z) = 1/(1 - 3z + z^2)$. In this case $k_n = F_{2n+2}$ and $k_n(\{0, 2\}) = F_{2n-1} - 1$.

SECTION 4.2.1

1. $N = (62, +.60\ 22\ 52\ 00)$; $\hbar = (37, +.10\ 54\ 50\ 00)$. Note that $10\hbar$ would be $(38, +.01\ 05\ 45\ 00)$.

2. $b^{E-q}(1 - b^{-p})$, b^{-q-p}; $b^{E-q}(1 - b^{-p})$, b^{-q-1}.

3. When e does not have its smallest value, the most significant "one" bit (which appears in all such normalized numbers) need not appear in the computer word.

4. $(51, +.10209877)$; $(50, +.12346000)$; $(53, +.99999999)$. The third answer would be $(54, +.10000000)$ if the first operand had been $(45, -.50000000)$.

5. If $x \sim y$ and m is an integer then $mb + x \sim mb + y$. Furthermore $x \sim y$ implies $x/b \sim y/b$, by considering all possible cases. Another crucial property is that x and y will round to the same integer, whenever $x \sim y$.

Now if $b^{-p-2} F_v \ne f_v$ we must have $(b^{p+2} f_v) \bmod b \ne 0$; hence the transformation leaves f_v unchanged unless $e_u - e_v \ge 2$. Since u was normalized, it is nonzero and $|f_u + f_v| > b^{-1} - b^{-2} \ge b^{-2}$: the leading nonzero digit of $f_u + f_v$ must be at most two places to the right of the radix point, and the rounding operation will convert $b^{p+j}(f_u + f_v)$ to an integer, where $j \le 1$. The proof will be complete if we can show that $b^{p+j+1}(f_u + f_v) \sim b^{p+j+1}(f_u + b^{-p-2} F_v)$. By the previous paragraph, we have $b^{p+2}(f_u + f_v) \sim b^{p+2} f_u + F_v = b^{p+2}(f_u + b^{-p-2} F_v)$, which implies the desired result for all $j \le 1$.

Note that, when $b > 2$ is even, such an integer F_v always exists; but when $b = 2$ we require $p + 3$ bits (let $2F_v$ be an integer). When b is odd, an integer F_v always exists except in the case of division, when a remainder of $\frac{1}{2}b$ is possible.

6. (Consider the case $e_u = e_v$, $f_u = -f_v$ in Program A.) Register A retains its previous sign, as in ADD.

7. Say that a number is normalized iff it is zero or its fraction part lies in the range $\frac{1}{6} < |f| < \frac{1}{2}$. A $(p+1)$-place accumulator suffices for addition and subtraction; rounding (except during division) is equivalent to truncation. A very pleasant system indeed! We might represent numbers with excess-zero exponent, inserted between the first and subsequent digits of the fraction, and complemented if the fraction is negative, so that fixed-point order is preserved.

8. (a) $(06, +.12345679) \oplus (06, -.12345678)$, $(01, +.10345678) \oplus (00, -.94000000)$; (b) $(99, +.87654321) \oplus$ itself, $(99, +.99999999) \oplus (91, +.50000000)$.

9. $a = c = (-50, +.10000000)$, $b = (-41, +.20000000)$, $d = (-41, +.80000000)$, $y = (11, +.10000000)$.

10. $(50, +.99999000) \oplus (55, +.99999000)$.

11. $(50, +.10000001) \otimes (50, +.99999990)$.

12. If $0 < |f_u| < |f_v|$, then $|f_u| \le |f_v| - b^{-p}$; hence $1/b < |f_u/f_v| \le 1 - b^{-p}/|f_v| < 1 - b^{-p}$. If $0 < |f_v| \le |f_u|$, we have $1/b < |f_u/f_v|/b \le ((1-b^{-p})/(1/b))/b = 1 - b^{-p}$.

16. If $|c| \geq |d|$, then set $r \leftarrow d \oslash c$, $s \leftarrow c \oplus (r \otimes d)$; $x \leftarrow (a \oplus (b \otimes r)) \oslash s$, $y \leftarrow (b \ominus (a \otimes r)) \oslash s$. Otherwise set $r \leftarrow c \oslash d$, $s \leftarrow d \oplus (r \otimes c)$; $x \leftarrow ((a \otimes r) \oplus b) \oslash s$, $y \leftarrow ((b \otimes r) \ominus a) \oslash s$. Then $x+iy$ is the desired approximation to $(a+bi)/(c+di)$. [*CACM* **5** (1963), 435. Other algorithms for complex arithmetic and function evaluation are given by P. Wynn, *BIT* **2** (1962), 232–255; see also Paul Friedland, *CACM* **10** (1967), 665.]

17. See Robert Morris, *IEEE Transactions* **C–20** (1971), 1578–1579. Error analysis is more difficult with such systems, so interval arithmetic is correspondingly more desirable.

18. For positive numbers: shift fraction left until $f_1 = 1$, then round, then if the fraction is zero (rounding overflow) shift it right again. For negative numbers: shift fraction left until $f_1 = 0$, then round, then if the fraction is zero (rounding underflow) shift it right again.

19. $(43+(1 \text{ if } e_v < e_u)-(1 \text{ if fraction overflow})-(10 \text{ if result zero})+(4 \text{ if magnitude is rounded up})+(1 \text{ if first rounding digit is } b/2)+(5 \text{ if rounding digits are } b/20\ldots0)+(7 \text{ if rounding overflow}) + 7N + A(-1 + (11 \text{ if } N > 0)))u$, where N is the number of left shifts during normalization and $A = 1$ if rX receives nonzero digits (otherwise $A = 0$). The maximum time of $73u$ occurs for example when

$$u = +50\ 01\ 00\ 00\ 00, \quad v = -46\ 49\ 99\ 99\ 99, \quad b = 100.$$

[The average time, considering the data in Section 4.2.4, will be about $45\frac{1}{2}u$.]

SECTION 4.2.2

1. $u \ominus v = u \oplus -v = -v \oplus u = -(v \oplus -u) = -(v \ominus u)$.

2. $u \oplus x \geq u \oplus 0 = u$, by (8), (2), (6); hence by (8) again, $(u \oplus x) \oplus v \geq u \oplus v$. Similarly, (8) and (6) together with (2) imply that $(u \oplus x) \oplus (v \oplus y) \geq (u \oplus x) \oplus v$.

3. $u = 8.0000001$, $v = 1.2500008$, $w = 8.0000008$; $(u \otimes v) \otimes w = 80.000064$, $u \otimes (v \otimes w) = 80.000057$.

4. Yes; let $1/u \approx v = w$, where v is large.

5. Not always; in decimal arithmetic take $u = v = 9$.

6. (a) Yes. (b) Only for $b+p \le 4$ (try $u = 1-b^{-p}$). [W. M. Kahan observes that the identity *does* hold whenever $b^{-1} \le f_u \le b^{-1/2}$. It follows that $1 \oslash (1 \oslash (1 \oslash u)) = 1 \oslash u$ for all u.]

7. If u and v are consecutive floating binary numbers, $u \oplus v = 2u$ or $2v$. When it is $2v$ we often have $u^{(2)} \oplus v^{(2)} < 2v^{(2)}$. For example, $u = (.10\ldots001)_2$, $v = (.10\ldots010)_2$, $u \oplus v = 2v$, and $u^{(2)} + v^{(2)} = (.10\ldots011)_2$.

8. (a) $\sim$, $\approx$; (b) $\sim$, $\approx$; (c) $\sim$, $\approx$; (d) $\sim$; (e) $\sim$.

9. $|u-w| \le |u-v| + |v-w| \le \epsilon_1 \min(b^{e_u-q}, b^{e_v-q}) + \epsilon_2 \min(b^{e_v-q}, b^{e_w-q}) \le \epsilon_1 b^{e_u-q} + \epsilon_2 b^{e_w-q} \le (\epsilon_1+\epsilon_2)\max(b^{e_u-q}, b^{e_w-q})$. The result cannot be strengthened in general, since for example we might have e_u very small compared to both e_v and e_w, and this means that $u - w$ might be fairly large under the hypotheses.

10. We have $(.a_1\ldots a_{p-1}a_p)_b \otimes (.9\ldots99)_b = (.a_1\ldots a_{p-1}(a_p-1))_b$ if $a_p \ge 1$; here "9" stands for $b-1$. Furthermore, $(.a_1\ldots a_{p-1}a_p)_b \otimes (1.0\ldots0)_b = (.a_1\ldots a_{p-1}0)_b$, so the multiplication is not monotone if $b > 2$ and $a_p \ge 2$. But when $b = 2$, this argument can be extended to show that multiplication *is* monotone; obviously the "certain computer" had $b > 2$.

11. Without loss of generality, let x be an integer, $|x| < b^p$. If $e \le 0$, then $t = 0$. If $0 < e \le p$, then $x - t$ has at most $p+1$ digits, the least significant being zero. If $e > p$, then $x - t = 0$. [The result holds also under the weaker hypothesis $|t| < 2b^e$.]

12. Assume that $e_u = p$, $e_v \le 0$, $u > 0$. Case 1, $u > b^{p-1}$. Case (1a), $w = u+1$, $v \ge \frac{1}{2}$, $e_v = 0$. Then $u' = u$ or $u+1$, $v' = 1$, $u'' = u$, $v'' = 1$ or 0. Case (1b), $w = u$, $|v| \le \frac{1}{2}$. Then $u' = u$, $v' = 0$, $u'' = u$, $v'' = 0$. If $|v| = \frac{1}{2}$ and more general rounding is permitted we might also have $u' = u \pm 1$, $v'' = \mp 1$. Case (1c), $w = u-1$, $v \le -\frac{1}{2}$, $e_v = 0$. Then $u' = u$ or $u-1$, $v' = -1$, $u'' = u$, $v'' = -1$ or 0. Case 2, $u = b^{p-1}$. Case (2a), $w = u+1$, $v \ge \frac{1}{2}$, $e_v = 0$. Like (1a). Case (2b), $w = u$, $|v| \le \frac{1}{2}$, $u' \ge u$. Like (1b). Case (2c), $w = u$, $|v| \le \frac{1}{2}$, $u' < u$. Then $u' = u - j/b$ where $v = j/b + v_1$ and $|v_1| \le \frac{1}{2}b^{-1}$ for some positive integer $j \le \frac{1}{2}b$; we have $v' = 0$, $u'' = u$, $v'' = j/b$. Case (2d), $w < u$. Then $w = u - j/b$ where $v = -j/b + v_1$ and $|v_1| \le \frac{1}{2}b^{-1}$ for some positive integer $j \le b$; we have $(v', u'') = (-j/b, u)$, and $(u', v'') = (u, -j/b)$ or $(u - 1/b, (1-j)/b)$, the latter case only when $v_1 = \frac{1}{2}b^{-1}$. In all cases $u \ominus u' = u - u'$, $v \ominus v' = v - v'$, $u \ominus u'' = u - u''$, $v \ominus v'' = v - v''$, $\text{round}(w - u - v) = w - u - v$.

13. Since $\text{round}(x) = 0$ iff $x = 0$, we want to find a large set of integer pairs (m, n) with the property that $m \oslash n$ is an integer iff m/n is. Assume that $|m|, |n| < b^p$. If m/n is an integer, then $m \oslash n = m/n$ is also. Conversely if m/n is not an integer, but $m \oslash n$ is, we have $1/|n| \le |m \oslash n - m/n| < \frac{1}{2}|m/n|b^{1-p}$, hence $|m| > 2b^{p-1}$. Our answer is therefore to require $|m| \le 2b^{p-1}$ and $0 < |n| < b^p$. (Slightly weaker hypotheses are also possible.)

14. $|(u \otimes v) \otimes w - uvw| \le |(u \otimes v) \otimes w - (u \otimes v)w| + |w|\,|u \otimes v - uv| \le \delta_{(u\otimes v)\otimes w} + b^{e_w-q-l_w}\delta_{u\otimes v} \le (1+b)\delta_{(u\otimes v)\otimes w}$. Now $|e_{(u\otimes v)\otimes w} - e_{u\otimes(v\otimes w)}| \le 2$, so we may take $\epsilon = \frac{1}{2}(1+b)b^{2-p}$.

15. $u \le v$ implies that $(u \oplus u) \oslash 2 \le (u \oplus v) \oslash 2 \le (v \oplus v) \oslash 2$, so the condition holds for all u and v iff it holds whenever $u = v$. For base $b = 2$, the condition is therefore always satisfied (barring overflow); but for $b > 2$ there are numbers $v \neq w$ such that $v \oplus v = w \oplus w$, hence the condition fails. [On the other hand, the formula $u \oplus ((v \ominus u) \oslash 2)$ does give a midpoint in the correct range. *Proof:* It suffices to show that $u + (v \ominus u) \oslash 2 \le v$, i.e., $(v \ominus u) \oslash 2 \le v - u$; and it is easy to verify that $\text{round}(\frac{1}{2}\text{round}(x)) \le x$ for all $x \ge 0$.]

16. (a) Exponent changes occur at $\sum_{10} = 11.111111$, $\sum_{91} = 101.11111$, $\sum_{901} = 1001.1102$, $\sum_{9001} = 10001.020$, $\sum_{90009} = 100000.91$, $\sum_{900819} = 1000000.0$; therefore $\sum_{1000000} = 1109099.1$.

(b) $\sum_{1 \le k \le n} 1.2345679 = 1224782.1$, and (14) tries to take the square root of $-.0053187053$. But (15) and (16) are exact in this case. [If $x_k = 1 + \lfloor (k-1)/2 \rfloor 10^{-7}$, (15) and (16) have errors of order n. See Chan and Lewis, *CACM* **22** (1979), 526–531, for further results on the accuracy of standard deviation calculations.]

(c) We need to show that $u \oplus ((v \ominus u) \oslash k)$ lies between u and v; see exercise 15.

19. Let $\gamma_k = \delta_k = \eta_k = \sigma_k = 0$ for $k > n$. It suffices to find the coefficient of x_1, since the coefficient of x_k will be just the same except with all subscripts increased by $k-1$. Let (f_k, g_k) denote the coefficient of x_1 in $(s_k - c_k, c_k)$ respectively. Then $f_1 = (1+\eta_1)(1-\gamma_1-\gamma_1\delta_1-\gamma_1\sigma_1-\delta_1\sigma_1-\gamma_1\delta_1\sigma_1)$, $g_1 = (1+\delta_1)(1+\eta_1)(\gamma_1+\sigma_1+\gamma_1\sigma_1)$, and $f_k = (1-\gamma_k\sigma_k-\delta_k\sigma_k-\gamma_k\delta_k\sigma_k)f_{k-1} + (\gamma_k-\eta_k+\gamma_k\delta_k+\gamma_k\eta_k+\gamma_k\delta_k\eta_k+\gamma_k\eta_k\sigma_k+\delta_k\eta_k\sigma_k+\gamma_k\delta_k\eta_k\sigma_k)g_{k-1}$, $g_k = \sigma_k(1+\gamma_k)(1+\delta_k)f_{k-1} - (1+\delta_k)(\gamma_k+$

$\gamma_k\eta_k + \eta_k\sigma_k + \gamma_k\eta_k\sigma_k)g_{k-1}$, for $1 < k \le n$. Thus $f_n = 1 + \eta_1 - \gamma_1 + (4n$ terms of 2nd order) + (higher order terms) $= 1 + \eta_1 - \gamma_1 + O(n\epsilon^2)$ is sufficiently small. [The Kahan summation formula was first published in *CACM* **8** (1965), 40; cf. *Proc. IFIP Congress* (1971), **2**, 1232. For another approach to accurate summation, see R. J. Hanson, *CACM* **18** (1975), 57–58. See also G. Bohlender, *IEEE Trans.* **C–26** (1977), 621–632, for algorithms that compute round$(x_1+\cdots+x_n)$ and round$(x_1 \ldots x_n)$ *exactly*, given $\{x_1, \ldots, x_n\}$.]

20. By the proof of Theorem C, (47) fails for $e_w = p$ only if $|v| + \frac{1}{2} \ge |w - u| \ge b^{p-1} + b^{-1}$; hence $|f_u| \ge |f_v| \ge 1 - (\frac{1}{2}b - 1)b^{-p}$. This rather rare case, in which $|f_w|$ before normalization takes its maximum value 2, is necessary and sufficient for failure.

21. (Solution by G. W. Veltkamp.) Let $c = 2^{\lceil p/2 \rceil} + 1$; we may assume that $p \ge 2$, so c is representable. First compute $u' = u \otimes c$, $u_1 = (u \ominus u') \oplus u'$, $u_2 = u \ominus u_1$; similarly, $v' = v \otimes c$, $v_1 = (v \ominus v') \oplus v'$, $v_2 = v \ominus v_1$. Then set $w \leftarrow u \otimes v$, $w' \leftarrow (((u_1 \otimes v_1 \ominus w) \oplus (u_1 \otimes v_2)) \oplus (u_2 \otimes v_1)) \oplus (u_2 \otimes v_2)$.

It suffices to prove this when $u, v > 0$ and $e_u = e_u = p$, so that u and v are integers $\in [2^{p-1}, 2^p)$. Then $u = u_1 + u_2$ where $2^{p-1} \le u_1 \le 2^p$, $u_1 \bmod 2^{\lceil p/2 \rceil} = 0$, and $|u_2| \le 2^{\lceil p/2 \rceil - 1}$; similarly $v = v_1 + v_2$. The operations during the calculation of w' are exact, because $w - u_1v_1$ is a multiple of 2^{p-1} such that $|w - u_1v_1| \le |w - uv| + |u_2v_1 + u_1v_2 + u_2v_2| \le 2^{p-1} + 2^{p+\lceil p/2 \rceil} + 2^{p-1}$; and similarly $|w - u_1v_1 - u_1v_2| \le |w - uv| + |u_2v| < 2^{p-1} + 2^{\lceil p/2 \rceil - 1 + p}$, where $w - u_1v_1 - u_1v_2$ is a multiple of $2^{\lceil p/2 \rceil}$.

22. We may assume that $b^{p-1} \le u, v < b^p$. If $uv \le b^{2p-1}$, then $x_1 = uv - r$ where $|r| \le \frac{1}{2}b^{p-1}$, hence $x_2 = \text{round}(u - r/v) = x_0$ (since $|r/v| \le \frac{1}{2}b^{p-1}/b^{p-1} \le \frac{1}{2}$, and equality implies $v = b^{p-1}$ hence $r = 0$). If $uv > b^{2p-1}$, then $x_1 = uv - r$ where $|r| \le \frac{1}{2}b^p$, hence $x_1/v \le u - r/v < b^p + \frac{1}{2}b$ and $x_2 \le b^p$. If $x_2 = b^p$, then $x_3 = x_1$ (for otherwise $(b^p - \frac{1}{2})v \le x_1 \le b^p(v - 1)$). If $x_2 < b^p$ and $x_1 > b^{2p-1}$, then let $x_2 = x_1/v + q$ where $|q| \le \frac{1}{2}$; we have $x_3 = \text{round}(x_1 + qv) = x_1$. Finally if $x_2 < b^p$ and $x_1 = b^{2p-1}$ and $x_3 < b^{2p-1}$, then $x_4 = x_2$ by the first case above. This situation arises, for example, when $b = 10$, $p = 2$, $u = 19$, $v = 55$, $x_1 = 1000$, $x_2 = 18$, $x_3 = 990$.

23. Let $\lfloor u \rfloor = n$, so that $u \bmod 1 = u \ominus n = u - n + r$ where $|r| \le \frac{1}{2}b^{-p}$; we wish to show that round$(n - r) = n$. The result is clear if $|n| > 1$; and $r = 0$ when $n = 0$ or 1, so the only subtle case is when $n = -1$, $r = -\frac{1}{2}b^{-p}$. The identity fails iff b is a multiple of 4 and $-b^{-1} < u < -b^{-2}$ and $u \bmod 2b^{-p} = \frac{3}{2}b^{-p}$ (e.g., $p = 3$, $b = 8$, $u = -(.0124)_8$).

24. Let $u = [u_l, u_r]$, $v = [v_l, v_r]$. Then $u \oplus v = [u_l \mathbin{\triangledown} v_l, u_r \mathbin{\triangle} v_r]$, where $x \mathbin{\triangle} y = y \mathbin{\triangle} x$, $x \mathbin{\triangle} +0 = x$ for all x, $x \mathbin{\triangle} -0 = x$ for all $x \ne +0$, $x \mathbin{\triangle} +\infty = +\infty$ for all $x \ne -\infty$, and $x \mathbin{\triangle} -\infty$ needn't be defined; $x \mathbin{\triangledown} y = -((-x) \mathbin{\triangle} (-y))$. If $x \oplus y$ would overflow in normal floating point arithmetic because $x + y$ is too large, then $x \mathbin{\triangle} y$ is $+\infty$ and $x \mathbin{\triangledown} y$ is the largest representable number.

For subtraction, let $u \ominus v = u \oplus (-v)$, where $-v = [-v_r, -v_l]$.

Multiplication is somewhat more complicated. The correct procedure is to let

$$u \otimes v = [\min(u_l \mathbin{\triangledown} v_l, u_l \mathbin{\triangledown} v_r, u_r \mathbin{\triangledown} v_l, u_r \mathbin{\triangledown} v_r),\ \max(u_l \mathbin{\triangle} v_l, u_l \mathbin{\triangle} v_r, u_r \mathbin{\triangle} v_l, u_r \mathbin{\triangle} v_r)],$$

where $x \mathbin{\triangle} y = y \mathbin{\triangle} x$, $x \mathbin{\triangle} (-y) = -(x \mathbin{\triangledown} y) = (-x) \mathbin{\triangle} y$; $x \mathbin{\triangle} +0 = (+0$ for $x > 0$, -0 for $x < 0)$; $x \mathbin{\triangle} -0 = -(x \mathbin{\triangle} +0)$; $x \mathbin{\triangle} +\infty = (+\infty$ for $x > +0$, $-\infty$ for $x < -0)$. (It is possible to determine the min and max simply by looking at the signs of u_l, u_r, v_l, and v_r, thereby computing only two of the eight products, except when

$u_l < 0 < u_r$ and $v_l < 0 < v_r$; in the latter case we compute four products, and the answer is $[\min(u_l \mathbin{\triangledown} v_r, u_r \mathbin{\triangledown} v_l), \max(u_l \mathbin{\triangle} v_l, u_r \mathbin{\triangle} v_r)]$.)

Finally, $u \oslash v$ is undefined if $v_l < 0 < v_r$; otherwise we use the formulas for multiplication with v_l and v_r replaced respectively by v_r^{-1} and v_l^{-1}, where $x \mathbin{\triangle} y^{-1} = x \mathbin{\triangle} y$, $x \mathbin{\triangledown} y^{-1} = x \mathbin{\triangledown} y$, $(\pm 0)^{-1} = \pm\infty$, $(\pm\infty)^{-1} = \pm 0$.

[Cf. E. R. Hansen, *Math. Comp.* **22** (1968), 374–384. An alternative scheme, in which division by 0 gives no error messages and intervals may be neighborhoods of ∞, has been proposed by W. M. Kahan. In Kahan's scheme, for example, the reciprocal of $[-1, +1]$ is $[+1, -1]$, and an attempt to multiply an interval containing 0 by an interval containing ∞ yields $[-\infty, +\infty]$, the set of all numbers. See *Numerical Analysis*, Univ. Michigan Engineering Summer Conf. Notes No. 6818 (1968).]

25. Cancellation reveals *previous* errors in the computation of u and v. For example, if ϵ is small, we often get poor accuracy when computing $f(x + \epsilon) \ominus f(x)$, because the rounded calculation of $f(x + \epsilon)$ destroys much of the information about ϵ. It is desirable to rewrite such formulas as $\epsilon \otimes g(x, \epsilon)$, where $g(x, \epsilon) = (f(x + \epsilon) - f(x))/\epsilon$ is first computed symbolically. Thus, if $f(x) = x^2$ then $g(x, \epsilon) = 2x + \epsilon$; if $f(x) = \sqrt{x}$ then $g(x, \epsilon) = 1/(\sqrt{x + \epsilon} + \sqrt{x})$.

26. See *Math. Comp.* **32** (1978), 227–232.

SECTION 4.2.3

1. First, $(w_m, w_l) = (.573, .248)$; then $w_m v_l / v_m = .290$; so the answer is $(.572, .958)$. This in fact is the correct result to six decimals.

2. The answer is not affected, since the normalization routine truncates to eight places and can never look at this particular byte position. (Scaling to the left occurs at most once during normalization, since the inputs are normalized.)

3. Overflow obviously cannot occur at line 09, since we are adding two-byte quantities, or at line 22, since we are adding four-byte quantities. In line 30 we are computing the sum of three four-byte quantities, so this cannot overflow. Finally, in line 32, overflow is impossible because the product $f_u f_v$ must be less than unity.

4. Insert "`JOV OFLO; ENT1 0`" between lines 03 and 04. Replace lines 21–22 by "`ADD TEMP(ABS); JNOV *+2; INC1 1`", and change lines 28–31 to "`SLAX 5; ADD TEMP; JNOV *+2; INC1 1; ENTX 0,1; SRC 5`". This adds five lines of code and only 1, 2, or 3 units of execution time.

5. Insert "`JOV OFLO`" after line 06. Change lines 22, 31, 39 respectively to "`SRAX 0,1`", "`SLAX 5`", "`ADD ACC`". Between lines 40 and 41, insert "`DEC2 1; JNOV DNORM; INC2 1; INCX 1; SRC 1`". (It's tempting to remove the "`DEC2 1`" in favor of "`STZ EXPO`", but then "`INC2 1`" might overflow rI2!) This adds six lines of code; the running time *decreases* by $3u$, unless there is fraction overflow, when it increases by $7u$.

6.
```
DOUBLE STJ  EXITDF      Convert to double precision:
       ENTX 0           Clear rX.
       STA  TEMP
       LD2  TEMP(EXP)   rI2 ← e.
       INC2 QQ-Q        Correct for difference in excess.
```

```
        STZ   EXPO          EXPO ← 0.
        SLAX  1             Remove exponent.
        JMP   DNORM         Normalize and exit.
SINGLE  STJ   EXITF         Convert to single precision:
        JOV   OFLO          Ensure overflow is off.
        STA   TEMP
        LD2   TEMP(EXPD)    rI2 ← e.
        DEC2  QQ-Q          Correct for difference in excess.
        SLAX  2             Remove exponent.
        JMP   NORM          Normalize, round, and exit. ∎
```

7. All three routines give zero as the answer if and only if the exact result would be zero, so we need not worry about zero denominators in the expressions for relative error. The worst case of the addition routine is pretty bad: Visualized in decimal notation, if the inputs are 1.0000000 and .99999999, the answer is b^{-7} instead of b^{-8}; thus the maximum relative error δ_1 is $b-1$, where b is the byte size.

For multiplication and division, we may assume that both operands are positive and have the same exponent QQ. The maximum error in multiplication is readily bounded by considering Fig. 4: When $uv \geq 1/b$, we have $0 \leq uv - u \otimes v < 3b^{-9} + (b-1)b^{-9}$, so the relative error is bounded by $(b+2)b^{-8}$. When $1/b^2 \leq uv < 1/b$, we have $0 \leq uv - u \otimes v < 3b^{-9}$, so the relative error in this case is bounded by $3b^{-9}/uv \leq 3b^{-7}$. We take δ_2 to be the larger of the two estimates, namely $3b^{-7}$.

Division requires a more careful analysis of Program D. The quantity actually computed by the subroutine is $\alpha - \delta - b\epsilon((\alpha-\delta'')(\beta-\delta') - \delta''') - \delta_n$ where $\alpha = (u_m + \epsilon u_l)/bv_m$, $\beta = v_l/bv_m$, and the nonnegative truncation errors $(\delta, \delta', \delta'', \delta''')$ are respectively less than $(b^{-10}, b^{-5}, b^{-5}, b^{-6})$; finally δ_n (the truncation during normalization) is nonnegative and less than either b^{-9} or b^{-8}, depending on whether scaling occurs or not. The actual value of the quotient is $\alpha/(1+b\epsilon\beta) = \alpha - b\epsilon\alpha\beta + b^2\alpha\beta^2\delta''''$, where δ'''' is the nonnegative error due to truncation of the infinite series (2); here $\delta'''' < \epsilon^2 = b^{-10}$, since it is an alternating series. The relative error is therefore the absolute value of $(b\epsilon\delta' + b\epsilon\delta''\beta/\alpha + b\epsilon\delta'''/\alpha) - (\delta/\alpha + b\epsilon\delta'\delta''/\alpha + b^2\beta^2\delta'''' + \delta_n/\alpha)$, times $(1+b\epsilon\beta)$. The positive terms in this expression are bounded by $b^{-9}+b^{-8}+b^{-8}$, and the negative terms are bounded by $b^{-8}+b^{-12}+b^{-8}$ plus the contribution by the normalizing phase, which can be about b^{-7} in magnitude. It is therefore clear that the potentially greatest part of the relative error comes during the normalization phase, and that $\delta_3 = (b+2)b^{-8}$ is a safe upper bound for the relative error.

8. Addition: If $e_u \leq e_v + 1$, the entire relative error occurs during the normalization phase, so it is bounded above by b^{-7}. If $e_u \geq e_v + 2$, and if the signs are the same, again the entire error may be ascribed to normalization; if the signs are opposite, the error due to shifting digits out of the register is in the opposite direction from the subsequent error introduced during normalization. Both of these errors are bounded by b^{-7}, hence $\delta_1 = b^{-7}$. (This is substantially better then the result in exercise 7.)

Multiplication: An analysis as in exercise 7 gives $\delta_2 = (b+2)b^{-8}$.

SECTION 4.2.4

1. Since fraction overflow can occur only when the operands have the same sign, this is the probability that fraction overflow occurs divided by the probability that the operands have the same sign, namely, $7\%/(\frac{1}{2}(91\%)) \approx 15\%$.

3. $\log_{10} 2.4 - \log_{10} 2.3 \approx 1.84834\%$.

4. The pages would be uniformly gray (same as "random point on a slide rule").

5. The probability that $10f_U \le r$ is $(r-1)/10 + (r-1)/100 + \cdots = (r-1)/9$. So in this case the leading digits are *uniformly* distributed; e.g., leading digit 1 occurs with probability $\frac{1}{9}$.

6. The probability that there are three leading zero bits is $\log_{16} 2 = \frac{1}{4}$; the probability that there are two leading zero bits is $\log_{16} 4 - \log_{16} 2 = \frac{1}{4}$; and similarly for the other two cases. The "average" number of leading zero bits is $1\frac{1}{2}$, so the "average" number of "significant bits" is $p + \frac{1}{2}$. The worst case, $p-1$ bits, occurs however with rather high probability. In practice, it is usually necessary to base error estimates on the worst case, since a chain of calculations is only as strong as its weakest link. In the error analysis of Section 4.2.2, the upper bound on relative rounding error for floating hex is 2^{1-p}. In the binary case we can have $p+1$ significant bits at all times (cf. exercise 4.2.1–3), with relative rounding errors bounded by 2^{-1-p}. Extensive computational experience confirms that floating binary (even with p-bit precision instead of $p+1$) produces significantly more accurate results than $(p+2)$-bit floating hex.

Tables 1 and 2 show that hexadecimal arithmetic can be done a little faster, since fewer cycles are needed when scaling to the right or normalizing to the left. But this fact is insignificant compared to the substantial advantages of $b = 2$ over other radices (cf. also Theorem 4.2.2C and exercises 4.2.2–13, 15, 21), especially since floating binary can be made as fast as floating hex with only a tiny increase in total processor cost.

7. For example, suppose that $\sum_m (F(10^{km} \cdot 5^k) - F(10^{km})) = \log 5^k / \log 10^k$ and also that $\sum_m (F(10^{km} \cdot 4^k) - F(10^{km})) = \log 4^k / \log 10^k$; then

$$\sum_m (F(10^{km} \cdot 5^k) - F(10^{km} \cdot 4^k)) = \log_{10} \frac{5}{4}$$

for all k. But now let ϵ be a small positive number, and choose $\delta > 0$ so that $F(x) < \epsilon$ for $0 < x < \delta$, and choose $M > 0$ so that $F(x) > 1 - \epsilon$ for $x > M$. We can take k so large that $10^{-k} \cdot 5^k < \delta$ and $4^k > M$; hence by the monotonicity of F,

$$\begin{aligned}\sum_m (F(10^{km} \cdot 5^k) - F(10^{km} \cdot 4^k)) &\le \sum_{m \le 0} (F(10^{km} \cdot 5^k) - F(10^{k(m-1)} \cdot 5^k)) \\ &\quad + \sum_{m \ge 0} (F(10^{k(m+1)} \cdot 4^k) - F(10^{km} \cdot 4^k)) \\ &= F(10^{-k}5^k) + 1 - F(10^k 4^k) < 2\epsilon.\end{aligned}$$

8. When $s > r$, $P_0(10^n s)$ is 1 for small n, and 0 when $\lfloor 10^n s \rfloor > \lfloor 10^n r \rfloor$. The least n for which this happens may be arbitrarily large, so no uniform bound can be given for $N_0(\epsilon)$ independent of s. (In general, calculus textbooks prove that such a uniform bound would imply that the limit function $S_0(s)$ would be continuous, and it isn't.)

9. Let $q_1, q_2, \ldots$ be such that $P_0(n) = q_1\binom{n-1}{0} + q_2\binom{n-1}{1} + \cdots$ for all n. It follows that $P_m(n) = 1^{-m} q_1\binom{n-1}{0} + 2^{-m} q_2\binom{n-1}{1} + \cdots$ for all m and n.

10. When $1 < r < 10$ the generating function $C(z)$ has simple poles at the points $1 + w_n$, where $w_n = 2\pi ni/\ln 10$, hence

$$C(z) = \frac{\log_{10} r - 1}{1 - z} + \sum_{n\neq 0} \frac{1 + w_n}{w_n} \frac{e^{-w_n \ln r} - 1}{(\ln 10)(z - 1 - w_n)} + E(z)$$

where $E(z)$ is analytic in the entire plane. Thus if $\theta = \arctan(2\pi/\ln 10)$,

$$\begin{aligned} c_m &= \log_{10} r - 1 - \frac{2}{\ln 10} \sum_{n>0} \Re\left(\frac{e^{-w_n \ln r} - 1}{w_n(1 + w_n)^m}\right) + e_m \\ &= \log_{10} r - 1 + \frac{\sin(m\theta + 2\pi \log_{10} r) - \sin(m\theta)}{\pi(1 + 4\pi^2/(\ln 10)^2)^{m/2}} + O\left(\frac{1}{(1 + 16\pi^2/(\ln 10)^2)^{m/2}}\right). \end{aligned}$$

11. When $(\log_b U) \bmod 1$ is uniformly distributed in $[0, 1)$, so is $(\log_b 1/U) \bmod 1 = (1 - \log_b U) \bmod 1$.

12. We have $h(z) = \int_{1/b}^{z} f(x)\,dx\, g(z/bx)/bx + \int_{z}^{1} f(x)\,dx\, g(z/x)/x$, and the same holds for $l(z) = \int_{1/b}^{z} f(x)\,dx\, l(z/bx)/bx + \int_{z}^{1} f(x)\,dx\, l(z/x)/x$, hence

$$\frac{h(z) - l(z)}{l(z)} = \int_{1/b}^{z} f(x)\,dx \frac{g(z/bx) - l(z/bx)}{l(z/bx)} + \int_{z}^{1} f(x)\,dx \frac{g(z/x) - l(z/x)}{l(z/x)}.$$

Since $f(x) \geq 0$, $|(h(z) - l(z))/l(z)| \leq \int_{1/b}^{z} f(x)\,dx\, A(g) + \int_{z}^{1} f(x)\,dx\, A(g)$ for all z, hence $A(h) \leq A(g)$. By symmetry, $A(h) \leq A(f)$. [*Bell System Tech. J.* **49** (1970), 1609–1625.]

13. Let $X = (\log_b U) \bmod 1$ and $Y = (\log_b V) \bmod 1$, so that X and Y are independently and uniformly distributed in $[0, 1)$. No left shift is needed if and only if $X + Y \geq 1$, and this occurs with probability $\frac{1}{2}$.

(Similarly, the probability is $\frac{1}{2}$ that floating point division by Algorithm 4.2.1M needs no normalization shifts; this needs only the weaker assumption that both of the operands independently have the *same* distribution.)

14. For convenience, the calculations are shown here for $b = 10$. If $k = 0$, the probability of a carry is

$$\left(\frac{1}{\ln 10}\right)^2 \int_{\substack{1\leq x,y\leq 10 \\ x+y\geq 10}} \frac{dx}{x} \frac{dy}{y}.$$

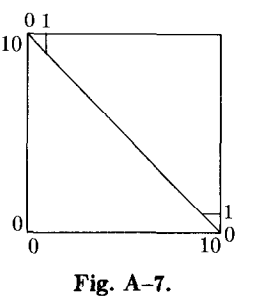

Fig. A–7.

(See Fig. A–7.) The value of the integral is

$$\int_0^{10} \frac{dy}{y} \int_{10-y}^{10} \frac{dx}{x} - 2\int_0^{1} \frac{dy}{y} \int_{10-y}^{10} \frac{dx}{x},$$

and

$$\int_0^t \frac{dy}{y} \ln\left(\frac{1}{1 - y/10}\right) = \int_0^t \left(\frac{1}{10} + \frac{y}{200} + \frac{y^2}{3000} + \cdots\right) dy = \frac{t}{10} + \frac{t^2}{400} + \frac{t^3}{9000} + \cdots.$$

(The latter integral is essentially a "dilogarithm.") Hence the probability of a carry when $k = 0$ is $(1/\ln 10)^2(\pi^2/6 - 2\sum_{n\geq 1} 1/n^2 10^n) = .27154$. [*Note:* When $b = 2$ and $k = 0$, fraction overflow *always* occurs, so this derivation proves that $\sum_{n\geq 1} 1/n^2 2^n = \pi^2/12 - \frac{1}{2}(\ln 2)^2$.]

When $k > 0$, the probability is

$$\Big(\frac{1}{\ln 10}\Big)^2 \int_{10^{1-k}}^{10^{1-k}} \frac{dy}{y} \int_{10-y}^{10} \frac{dx}{x} = \Big(\frac{1}{\ln 10}\Big)^2 \Big(\sum_{n\geq 1} \frac{1}{n^2 10^{nk}} - \sum_{n\geq 1} \frac{1}{n^2 10^{n(k+1)}}\Big).$$

Thus when $b = 10$, fraction overflow should occur with probability $.272p_0 + .017p_1 + .002p_2 + \cdots$. When $b = 2$ the corresponding figures are $p_0 + .655p_1 + .288p_2 + .137p_3 + .067p_4 + \cdots$.

Now if we use the probabilities from Table 1, dividing by .91 to eliminate zero operands and assuming that the probabilities are independent of the operand signs, we predict a probability of about 14 percent when $b = 10$, instead of the 15 percent in exercise 1. For $b = 2$, we predict about 48 percent, while the table yields 44 percent. These results are certainly in agreement within the limits of experimental error.

15. When $k = 0$, the leading digit is 1 if and only if there is a carry. (It is possible for fraction overflow and subsequent rounding to yield a leading digit of 2, when $b \geq 4$, but we are ignoring rounding in this exercise.) The probability of fraction overflow is $.272 < \log_{10} 2$, as shown in the previous exercise.

When $k > 0$, the leading digit is 1 with probability

$$\Big(\frac{1}{\ln 10}\Big)^2 \Big(\int_{10^{1-k}}^{10^{1-k}} \frac{dy}{y} \int_{\substack{1\leq x<2-y \\ \text{or } 10-y\leq x<10}} \frac{dx}{x}\Big) < \Big(\frac{1}{\ln 10}\Big)^2 \Big(\int_{10^{1-k}}^{10^{1-k}} \frac{dy}{y} \int_{1\leq x\leq 2} \frac{dx}{x}\Big) = \log_{10} 2.$$

16. To prove the hint [which is due to Landau, *Prace matematyczno-fizyczne* **21** (1910), 103–113], assume first that $\limsup a_n = \lambda > 0$. Let $\epsilon = \lambda/(\lambda + 4M)$ and choose N so that $|a_1 + \cdots + a_n| < \frac{1}{10}\epsilon\lambda n$ for all $n > N$. Let $n > N/(1-\epsilon)$, $n > 5/\epsilon$ be such that $a_n > \frac{1}{2}\lambda$. Then, by induction, $a_{n-k} \geq a_n - kM/(n-\epsilon n) > \frac{1}{4}\lambda$ for $0 \leq k < \epsilon n$, and $\sum_{n-\epsilon n<k\leq n} a_k \geq \frac{1}{4}\lambda(\epsilon n - 1) > \frac{1}{5}\lambda\epsilon n$. But

$$\Big|\sum_{n-\epsilon n<k\leq n} a_k\Big| = \Big|\sum_{1\leq k\leq n} a_k - \sum_{1\leq k\leq n-\epsilon n} a_k\Big| \leq \tfrac{1}{5}\epsilon\lambda n$$

since $n - \epsilon n > N$. A similar contradiction applies if $\liminf a_n < 0$.

Assuming that $P_{m+1}(n) \to \lambda$ as $n \to \infty$, let $a_k = P_m(k) - \lambda$. If $m > 0$, the a_k satisfy the hypotheses of the hint (cf. Eq. 4.2.2–15), since $0 \leq P_m(k) \leq 1$; hence $P_m(n) \to \lambda$.

17. See *Fibonacci Quarterly* **7** (1969), 474–475. (Persi Diaconis [Ph.D. thesis, Harvard University, 1974] has shown among other things that the definition of probability by repeated averaging is weaker than harmonic probability, in the following precise sense: If $\lim_{m\to\infty} \liminf_{n\to\infty} P_m(n) = \lim_{m\to\infty} \limsup_{n\to\infty} P_m(n) = \lambda$ then the harmonic probability is λ. On the other hand the statement "$10^{k^2} \leq n < 10^{k^2+k}$ for some integer $k > 0$" has logarithmic probability $\frac{1}{2}$, while repeated averaging never settles down to give it any particular probability.)

18. Let $p(a) = P(L_a)$ and $p(a,b) = \sum_{a \le k < b} p(k)$ for $1 \le a < b$. Since $L_a = L_{10a} \cup L_{10a+1} \cup \cdots \cup L_{10a+9}$ for all a, we have $p(a) = p(10a, 10(a+1))$ by (i). Furthermore since $P(S) = P(2S) + P(2S+1)$ by (i), (ii), (iii), we have $p(a) = p(2a, 2(a+1))$. It follows that $p(a,b) = p(2^m 10^n a, 2^m 10^n b)$ for all $m, n \ge 0$.

If $1 < b/a < b'/a'$, then $p(a,b) \le p(a',b')$. The reason is that there exist integers m, n, m', n' such that $2^{m'}10^{n'}a' \le 2^m 10^n a < 2^m 10^n b \le 2^{m'}10^{n'}b'$ as a consequence of the fact that $\log 2/\log 10$ is irrational, hence we can apply (v). (Cf. exercise 3.5–22 with $k = 1$ and $U_n = n \log 2/\log 10$.) In particular, $p(a) \ge p(a+1)$, and it follows that $p(a,b)/p(a,b+1) \ge (b-a)/(b+1-a)$. (Cf. Eq. 4.2.2–15.)

Now we can prove that $p(a,b) = p(a',b')$ whenever $b/a = b'/a'$; for $p(a,b) = p(10^n a, 10^n b) \le c_n p(10^n a, 10^n b - 1) \le c_n p(a',b')$, for arbitrarily large values of n, where $c_n = 10^n(b-a)/(10^n(b-a)-1) = 1 + O(10^{-n})$.

For any positive integer n we have $p(a^n, b^n) = p(a^n, ba^{n-1}) + p(ba^{n-1}, b^2a^{n-2}) + \cdots + p(b^{n-1}a, b^n) = np(a,b)$. If $10^m \le a^n \le 10^{m+1}$ and $10^{m'} \le b^n \le 10^{m'+1}$, then $p(10^{m+1}, 10^{m'}) \le p(a^n, b^n) \le p(10^m, 10^{m'+1})$ by (v). But $p(1,10) = 1$ by (iv), hence $p(10^m, 10^{m'}) = m' - m$ for all $m' \ge m$. We conclude that $\lfloor \log_{10} b^n \rfloor - \lfloor \log_{10} a^n \rfloor - 1 \le np(a,b) \le \lfloor \log_{10} b^n \rfloor + \lfloor \log_{10} a^n \rfloor + 1$ for all n, and $p(a,b) = \log_{10}(b/a)$.

[This exercise was inspired by D. I. A. Cohen, who proved a slightly weaker result in *J. Combinatorial Theory* (A) **20** (1976), 367–370.]

SECTION 4.3.1

2. If the ith number to be added is $u_i = (u_{i1}u_{i2}\ldots u_{in})_b$, use Algorithm A with step A2 changed to the following:

A2′. [Add digits.] Set

$$w_j \leftarrow (u_{1j} + \cdots + u_{mj} + k) \bmod b, \quad \text{and} \quad k \leftarrow \lfloor (u_{1j} + \cdots + u_{mj} + k)/b \rfloor.$$

(The maximum value of k is $m-1$, so step A3 would have to be altered if $m > b$.)

3.

```
    ENT1 N          1
    JOV  OFLO       1       Ensure overflow is off.
    ENTA 0          1       k ← 0.
2H  ENT2 0          N       (rI2 ≡ next value of k)
    ENT3 M*N-N,1    N       (LOC(u_ij) ≡ U + n(i-1) + j)
3H  ADD  U,3        MN      rA ← rA + u_ij.
    JNOV *+2        MN
    INC2 1          K       Carry one.
    DEC3 N          MN      Repeat for m ≥ i ≥ 0.
    J3P  3B         MN      (rI3 ≡ n(i-1) + j)
    STA  W,1        N       w_j ← rA.
    ENTA 0,2        N       k ← rI2.
    DEC1 1          N
    J1P  2B         N       Repeat for n ≥ j ≥ 0.
    STA  W          1       Store final carry in w_0.  ∎
```

Running time, assuming that $K = \frac{1}{2}MN$, is $5.5MN + 7N + 4$ cycles.

4. We may make the following assertion before A1: "$n \geq 1$; and $0 \leq u_i, v_i < b$ for $1 \leq i \leq n$." Before A2, we assert: "$1 \leq j \leq n$; $0 \leq u_i, v_i < b$ for $1 \leq i \leq n$; $0 \leq w_i < b$ for $j < i \leq n$; $0 \leq k \leq 1$; and

$$(u_{j+1} \ldots u_n)_b + (v_{j+1} \ldots v_n)_b = (kw_{j+1} \ldots w_n)_b.$$"

The latter statement means more precisely that

$$\sum_{j<t\leq n} u_t b^{n-t} + \sum_{j<t\leq n} v_t b^{n-t} = kb^{n-j} + \sum_{j<t\leq n} w_t b^{n-t}.$$

Before A3, we assert: "$1 \leq j \leq n$; $0 \leq u_i, v_i < b$ for $1 \leq i \leq n$; $0 \leq w_i < b$ for $j \leq i \leq n$; $0 \leq k \leq 1$; and $(u_j \ldots u_n)_b + (v_j \ldots v_n)_b = (kw_j \ldots w_n)_b$." After A3, we assert that $0 \leq w_i < b$ for $1 \leq i \leq n$; $0 \leq w_0 \leq 1$; and $(u_1 \ldots u_n)_b + (v_1 \ldots v_n)_b = (w_0 \ldots w_n)_b$.

It is a simple matter to complete the proof by verifying the necessary implications between the assertions and by showing that the algorithm always terminates.

5. **B1.** Set $j \leftarrow 1$, $w_0 \leftarrow 0$.

B2. Set $t \leftarrow u_j + v_j$, $w_j \leftarrow t \bmod b$, $i \leftarrow j$.

B3. If $t \geq b$, set $i \leftarrow i - 1$, $t \leftarrow w_i + 1$, $w_i \leftarrow t \bmod b$, and repeat this step until $t < b$.

B4. Increase j by one, and if $j \leq n$ go back to B2. ∎

6. **C1.** Set $j \leftarrow 1$, $i \leftarrow 0$, $r \leftarrow 0$.

C2. Set $t \leftarrow u_j + v_j$. If $t \geq b$, set $w_i \leftarrow r + 1$, $w_k \leftarrow 0$ for $i < k < j$; then set $i \leftarrow j$ and $r \leftarrow t \bmod b$. Otherwise if $t < b - 1$, set $w_i \leftarrow r$, $w_k \leftarrow b - 1$ for $i < k < j$; then set $i \leftarrow j$ and $r \leftarrow t$.

C3. Increase j by one. If $j \leq n$, go back to C2; otherwise set $w_i \leftarrow r$, and $w_k \leftarrow b - 1$ for $i < k \leq n$. ∎

7. When $j = 3$, for example, we have $k = 0$ with probability $(b+1)/2b$; $k = 1$ with probability $((b-1)/2b)(1 - 1/b)$, namely the probability that a carry occurs and that the preceding digit wasn't $b - 1$; $k = 2$ with probability $((b-1)/2b)(1/b)(1 - 1/b)$; and $k = 3$ with probability $((b-1)/2b)(1/b)(1/b)(1)$. For fixed k we may add the probabilities as j varies from 1 to n; this gives the mean number of times the carry propagates back k places,

$$m_k = \frac{b-1}{2b^k}\Big((n+1-k)\Big(1-\frac{1}{b}\Big)+\frac{1}{b}\Big).$$

As a check, we find that the average number of carries is

$$m_1 + 2m_2 + \cdots + nm_n = \frac{1}{2}\left(n - \frac{1}{b-1}\left(1 - \left(\frac{1}{b}\right)^n\right)\right),$$

in agreement with (6).

```

The running time depends on L, the number of positions in which $u_j + v_j \geq b$; and on K, the total number of carries. It is not difficult to see that K is the same quantity that appears in Program A. The analysis in the text shows that L has the average value $N((b-1)/2b)$, and K has the average value $\frac{1}{2}(N - b^{-1} - b^{-2} - \cdots - b^{-n})$. So if we ignore terms of order $1/b$, the running time is $9N + L + 7K + 3 \approx 13N + 3$ cycles.

Note: Since a carry occurs almost half of the time, it would be more efficient to delay storing the result by one step. This leads to a somewhat longer program whose running time is approximately $12N + 5$ cycles, based on the somewhat more detailed information calculated in exercise 7.

9. Replace "b" by "b_{n-j}" everywhere in step A2.

10. If lines 06 and 07 were interchanged, we would almost always have overflow, but register A might have a negative value at line 08, so this would not work. If the instructions on lines 05 and 06 were interchanged, the sequence of overflows occurring in the program would be slightly different in some cases, but the program would still be right.

11. (a) Set $j \leftarrow 1$; (b) if $u_j < v_j$, terminate $[u < v]$; if $u_j = v_j$ and $j = n$, terminate $[u = v]$; if $u_j = v_j$ and $j < n$, set $j \leftarrow j + 1$ and repeat (b); if $u_j > v_j$, terminate $[u > v]$. This algorithm tends to be quite fast, since there is usually low probability that j will have to get very high before we encounter a case with $u_j \neq v_j$.

12. Use Algorithm S with $u_j = 0$ and $v_j = w_j$. Another "borrow" will occur at the end of the algorithm; this time it should be ignored.

```
13.    ENTX N      1          ADD  CARRY N
       JOV  OFLO   1          JNOV *+2   N
       ENTX 0      1          INCX 1     K
     2H STX  CARRY N          STA  W,1   N
       LDA  U,1    N          DEC1 1     N
       MUL  V      N          J1P  2B    N
       SLC  5      N          STX  W     1   ∎
```

The running time is $23N + K + 5$ cycles, and K is roughly $\frac{1}{2}N$.

14. The key inductive assertion is the one that should be valid at the beginning of step M4; all others are readily filled in from this one, which is as follows: "$1 \leq i \leq n$; $1 \leq j \leq m$; $0 \leq u_r < b$ for $1 \leq r \leq n$; $0 \leq v_r < b$ for $1 \leq r \leq m$; $0 \leq w_r < b$ for $j < r \leq m + n$; $0 \leq k < b$; and

$$(w_{j+1} \ldots w_{m+n})_b + kb^{m+n-i-j} = u \times (v_{j+1} \ldots v_m)_b + (u_{i+1} \ldots u_n)_b \times v_j b^{m-j}.$$"

(For the precise meaning of this notation, see the answer to exercise 4.)

15. The error is nonnegative and less than $(n-2)b^{-n-1}$. [Similarly, if we ignore the products with $i+j > n+3$, the error is bounded by $(n-3)b^{-n-2}$, etc.; but, in some cases, we must compute all of the products if we want to get the true rounded result.]

16. **S1.** Set $r \leftarrow 0$, $j \leftarrow 1$.

S2. Set $w_j \leftarrow \lfloor (rb+u_j)/v \rfloor$, $r \leftarrow (rb+u_j) \bmod v$.

S3. Increase j by 1, and return to S2 if $j \le n$. ∎

17. $u/v > u_0 b^n/(v_1+1)b^{n-1} = b(1-1/(v_1+1)) > b(1-1/(b/2)) = b-2$.

18. $(u_0 b + u_1)/(v_1+1) \le u/(v_1+1)b^{n-1} < u/v$.

19. $u - \hat{q}v \le u - \hat{q}v_1 b^{n-1} - \hat{q}v_2 b^{n-2} = u_2 b^{n-2} + \cdots + u_n + \hat{r}b^{n-1} - \hat{q}v_2 b^{n-2} < b^{n-2}(u_2 + 1 + \hat{r}b - \hat{q}v_2) \le 0$. Since $u - \hat{q}v < 0$, $q < \hat{q}$.

20. If $q \le \hat{q} - 2$, then $u < (\hat{q}-1)v < \hat{q}(v_1 b^{n-1} + (v_2+1)b^{n-2}) - v < \hat{q}v_1 b^{n-1} + \hat{q}v_2 b^{n-2} + b^{n-1} - v \le \hat{q}v_1 b^{n-1} + (b\hat{r} + u_2)b^{n-2} + b^{n-1} - v = u_0 b^n + u_1 b^{n-1} + u_2 b^{n-2} + b^{n-1} - v \le u_0 b^n + u_1 b^{n-1} + u_2 b^{n-2} \le u$. In other words, $u < u$, and this is a contradiction.

21. (Solution by G. K. Goyal.) The inequality $v_2\hat{q} \le b\hat{r} + u_2$ implies that we have $\hat{q} \le (u_0 b^2 + u_1 b + u_2)/(v_1 b + v_2) \le u/((v_1 b + v_2)b^{n-2})$. Now $u \bmod v = u - qv = v(1-\alpha)$ where $0 \le \alpha = q - u/v \le \hat{q} - u/v \le u(1/((v_1 b + v_2)b^{n-2}) - 1/v) = u(v_3 b^{n-3} + \cdots)/((v_1 b + v_2)b^{n-2}v) < u/(v_1 b v) \le \hat{q}/(v_1 b) \le (b-1)/(v_1 b)$, and this is at most $2/b$ since $v_1 \ge \frac{1}{2}(b-1)$.

22. Let $u = 4100$, $v = 588$. We first try $\hat{q} = \lfloor \frac{41}{5} \rfloor = 8$, but $8 \cdot 8 > 10(41-40) + 0$. Then we set $\hat{q} = 7$, and now we find $7 \cdot 8 < 10(41-35) + 0$. But 7 times 588 equals 4116, so the true quotient is $q = 6$. (Incidentally, this example shows that Theorem B cannot be improved under the given hypotheses, when $b = 10$.)

23. Obviously $v\lfloor b/(v+1) \rfloor < (v+1)\lfloor b/(v+1) \rfloor \le (v+1)b/(v+1) = b$; also if $v \ge \lfloor b/2 \rfloor$ we obviously have $v\lfloor b/(v+1) \rfloor \ge v \ge \lfloor b/2 \rfloor$. Finally, assume that we have $1 \le v < \lfloor b/2 \rfloor$. Then $v\lfloor b/(v+1) \rfloor > v(b/(v+1) - 1) \ge b/2 - 1 \ge \lfloor b/2 \rfloor - 1$, because $v(b/(v+1) - 1) - (b/2 - 1) = (b/2 - v - 1)(v-1)/(v+1) \ge 0$. Since $v\lfloor b/(v+1) \rfloor > \lfloor b/2 \rfloor - 1$, we must have $v\lfloor b/(v+1) \rfloor \ge \lfloor b/2 \rfloor$.

24. The approximate probability is only $\log_b 2$, not $\frac{1}{2}$. (For example, if $b = 2^{35}$, the probability is approximately $\frac{1}{35}$; this is still high enough to warrant the special test for $d = 1$ in steps D1 and D8.)

```

At this point, the division routine is complete; and by the next exercise, register AX is zero.

27. It is $du \bmod dv = d(u \bmod v)$.

28. For convenience, let us assume that v has a decimal point at the left, i.e., $v = (v_0.v_1v_2\ldots)_b$. After step N1 we have $\frac{1}{2} \le v < 1 + 1/b$: for

$$v\left\lfloor\frac{b+1}{v_1+1}\right\rfloor \le \frac{v(b+1)}{v_1+1} = \frac{v(1+1/b)}{(1/b)(v_1+1)} < 1+\frac{1}{b},$$

and

$$v\left\lfloor\frac{b+1}{v_1+1}\right\rfloor \ge \frac{v(b+1-v_1)}{v_1+1} \ge \frac{1}{b}\frac{v_1(b+1-v_1)}{v_1+1}.$$

The latter quantity takes its smallest value when $v_1 = 1$, since it is a convex function and the other extreme value is greater.

The formula in step N2 may be written

$$v \leftarrow \left\lfloor\frac{b(b+1)}{v_1+1}\right\rfloor\frac{v}{b},$$

so we see as above that v will never become $\ge 1 + 1/b$.

The minimum value of v after one iteration of step N2 is $\geq$

$$\left(\frac{b(b+1)-v_1}{v_1+1}\right)\frac{v}{b} \geq \left(\frac{b(b+1)-v_1}{v_1+1}\right)\frac{v_1}{b^2} = \left(\frac{b(b+1)+1-t}{t}\right)\left(\frac{t-1}{b^2}\right)$$
$$= 1+\frac{1}{b}+\frac{2}{b^2}-\frac{1}{b^2}\left(t+\frac{b(b+1)+1}{t}\right),$$

if $t = v_1 + 1$. The minimum of this quantity occurs for $t = b/2 + 1$; a lower bound is $1 - 3/2b$. Hence $v_1 \geq b - 2$, after one iteration of step N2. Finally, we have $(1-3/2b)(1+1/b)^2 > 1$, when $b \geq 5$, so at most two more iterations are needed. The assertion is easily verified when $b < 5$.

29. True, since $(u_j \ldots u_{j+n})_b < v$.

30. In Algorithms A and S, such overlap is possible if the algorithms are rewritten slightly; e.g., in Algorithm A, we could rewrite step A2 thus: "Set $t \leftarrow u_j + v_j + k$, $w_j \leftarrow t \bmod b$, $k \leftarrow \lfloor t/b \rfloor$."

In Algorithm M, v_j may be in the same location as w_j. In Algorithm D, it is most convenient (as in Program D, exercise 26) to let $r_1 \ldots r_n$ be the same as $u_{m+1} \ldots u_{m+n}$; and we can also have $q_0 \ldots q_m$ the same as $u_0 \ldots u_m$, provided that no alteration of u_j is made in step D6. (Line 098 of Program D can safely be changed to "J1P 2B", since u_j isn't used in the subsequent calculation.)

31. Consider the situation of Fig. 6 with $u = (u_j u_{j+1} \ldots u_{j+n})_3$ as in Algorithm D. If the leading nonzero digits of u and v have the same sign, set $r \leftarrow u - v$, $q \leftarrow 1$; otherwise set $r \leftarrow u + v$, $q \leftarrow -1$. Now if $|r| > |u|$, or if $|r| = |u|$ and the first nonzero digit of $u_{j+n+1} \ldots u_{m+n}$ has the same sign as the first nonzero digit of r, set $q \leftarrow 0$; otherwise set $u_j \ldots u_{j+n}$ equal to the digits of r.

36. Values to 1000 decimal and 1100 octal places have been computed by R. P. Brent, Comp. Centre Tech. Rep. 47 (Canberra: Australian Nat. Univ., 1975).

37. Let $d = 2^e$ so that $b > dv_1 \geq b/2$. Instead of normalizing u and v in step D1, simply compute the two leading digits $v'_1 v'_2$ of $2^e(v_1 v_2 v_3)_b$ by shifting left e bits. In step D3, use (v'_1, v'_2) instead of (v_1, v_2) and $(u'_j, u'_{j+1}, u'_{j+2})$ instead of (u_j, u_{j+1}, u_{j+2}), where the digits $u'_j u'_{j+1} u'_{j+2}$ are obtained from $(u_j u_{j+1} u_{j+2} u_{j+3})_b$ by shifting left e bits. Omit division by d in step D8. (In essence, u and v are being "virtually" shifted. This method saves computation when m is small compared to n.)

SECTION 4.3.2

1. The solution is unique since $7 \cdot 11 \cdot 13 = 1001$. The "constructive" proof of Theorem C tells us that the answer is $((11 \cdot 13)^6 + 6 \cdot (7 \cdot 13)^{10} + 5 \cdot (7 \cdot 11)^{12}) \bmod 1001$. But this answer is perhaps not explicit enough! By (23) we have $v_1 = 1$, $v_2 = (6-1) \cdot 8 \bmod 11 = 7$, $v_3 = ((5-1) \cdot 2 - 7) \cdot 6 \bmod 13 = 6$, so $u = 6 \cdot 7 \cdot 11 + 7 \cdot 7 + 1 = 512$.

2. No. There is at most one such u; the additional condition $u_1 \equiv \cdots \equiv u_r$ (modulo 1) is necessary and sufficient, and it follows that such a generalization is not very interesting.

3. $u \equiv u_i$ (modulo m_i) implies that $u \equiv u_i$ (modulo $\gcd(m_i, m_j)$), so the condition $u_i \equiv u_j$ (modulo $\gcd(m_i, m_j)$) must surely hold if there is a solution. Furthermore if $u \equiv v$ (modulo m_j) for all j, then $u - v$ is a multiple of $\operatorname{lcm}(m_1, \ldots, m_r) = m$; hence there is at most one solution.

The proof can now be completed in a nonconstructive manner by counting the number of different r-tuples $(u_1, \ldots, u_r)$ satisfying the conditions $0 \le u_j < m_j$ and $u_i \equiv u_j$ (modulo $\gcd(m_i, m_j)$). If this number is m, there must be a solution since $(u \bmod m_1, \ldots, u \bmod m_r)$ takes on m distinct values as u goes from a to $a + m$. Assume that $u_1, \ldots, u_{r-1}$ have been chosen satisfying the given conditions; we must now pick $u_r \equiv u_j$ (modulo $\gcd(m_j, m_r)$) for $1 \le j < r$, and by the generalized Chinese remainder theorem for $r - 1$ elements there are

$$\begin{aligned} m_r/\operatorname{lcm}(\gcd(m_1, m_r), \ldots, \gcd(m_{r-1}, m_r)) &= m_r/\gcd(\operatorname{lcm}(m_1, \ldots, m_{r-1}), m_r) \\ &= \operatorname{lcm}(m_1, \ldots, m_r)/\operatorname{lcm}(m_1, \ldots, m_{r-1}) \end{aligned}$$

ways to do this. [This proof is based on identities (10), (11), (12), and (14) of Section 4.5.2.]

A constructive proof [A. S. Fraenkel, *Proc. Amer. Math. Soc.* **14** (1963), 790–791] generalizing (24) can be given as follows. Let $M_j = \operatorname{lcm}(m_1, \ldots, m_j)$; we wish to find $u = v_r M_{r-1} + \cdots + v_2 M_1 + v_1$, where $0 \le v_j < M_j/M_{j-1}$. Assume that $v_1, \ldots, v_{j-1}$ have already been determined; then we must solve the congruence

$$v_j M_{j-1} + v_{j-1} M_{j-2} + \cdots + v_1 \equiv u_j \text{ (modulo } m_j).$$

Here $v_{j-1} M_{j-2} + \cdots + v_1 \equiv u_i \equiv u_j$ (modulo $\gcd(m_i, m_j)$) for $i < j$ by hypothesis, so $c = u_j - (v_{j-1} M_{j-2} + \cdots + v_1)$ is a multiple of

$$\operatorname{lcm}(\gcd(m_1, m_j), \ldots, \gcd(m_{j-1}, m_j)) = \gcd(M_{j-1}, m_j) = d_j.$$

We therefore must solve $v_j M_{j-1} \equiv c$ (modulo m_j). By Euclid's algorithm there is a number c_j such that $c_j M_{j-1} \equiv d_j$ (modulo m_j); hence we may take

$$v_j = (c_j\, c)/d_j \bmod (m_j/d_j).$$

Note that, as in the nonconstructive proof, we have $m_j/d_j = M_j/M_{j-1}$.

4. (After $m_4 = 91 = 7 \cdot 13$, we have used up all products of two or more odd primes that can be less than 100, so $m_5, \ldots$ must all be prime.)

$$\begin{array}{lllll} m_7 = 79, & m_8 = 73, & m_9 = 71, & m_{10} = 67, & m_{11} = 61, \\ m_{12} = 59, & m_{13} = 53, & m_{14} = 47, & m_{15} = 43, & m_{16} = 41, \\ m_{17} = 37, & m_{18} = 31, & m_{19} = 29, & m_{20} = 23, & m_{21} = 17, \end{array}$$

and then we are stuck ($m_{22} = 1$ does no good).

5. No. The obvious upper bound,

$$3^4 5^2 7^2 11^1 \cdots = \prod_{\substack{p \text{ odd} \\ p \text{ prime}}} p^{\lfloor \log_p 100 \rfloor},$$

is attained if we choose $m_1 = 3^4$, $m_2 = 5^2$, etc. (It is more difficult, however, to maximize $m_1 \ldots m_r$ when r is fixed, or to maximize $m_1 + \cdots + m_r$ as we would attempt to do when using moduli $2^{m_j} - 1$.)

6. (a) If $e = f + kg$, then $2^e = 2^f(2^g)^k \equiv 2^f \cdot 1^k$ (modulo $2^g - 1$). So if $2^e \equiv 2^f$ (modulo $2^g - 1$), we have $2^{e \bmod g} \equiv 2^{f \bmod g}$ (modulo $2^g - 1$); and since the latter quantities lie between zero and $2^g - 1$ we must have $e \bmod g = f \bmod g$. (b) By part (a), $(1 + 2^d + \cdots + 2^{(c-1)d}) \cdot (2^e - 1) \equiv (1 + 2^d + \cdots + 2^{(c-1)d}) \cdot (2^d - 1) = 2^{cd} - 1 \equiv 2^{ce} - 1 \equiv 2^1 - 1 = 1$ (modulo $2^f - 1$).

7.
$$\begin{aligned}(u_j - (v_1 + m_1(v_2 + m_2(v_3 + \cdots + m_{j-2}v_{j-1})\ldots)))\,c_{1j}\ldots c_{(j-1)j} &= (u_j - v_1)\,c_{1j}\ldots c_{(j-1)j} - m_1v_2c_{1j}\ldots c_{(j-1)j} - \cdots \\ &\qquad - m_1\ldots m_{j-2}v_{j-1}c_{1j}\ldots c_{(j-1)j} \\ &\equiv (u_j - v_1)\,c_{1j}\ldots c_{(j-1)j} - v_2c_{2j}\ldots c_{(j-1)j} - \cdots - v_{j-1}c_{(j-1)j} \\ &= (\ldots((u_j - v_1)\,c_{1j} - v_2)\,c_{2j} - \cdots - v_{j-1})\,c_{(j-1)j} \text{ (modulo } m_j).\end{aligned}$$

This method of rewriting the formulas uses the same number of arithmetic operations and fewer constants; but the number of constants is fewer only if we order the moduli so that $m_1 < m_2 < \cdots < m_r$, otherwise we would need a table of $m_i \bmod m_j$. This ordering of the moduli might seem to require more computation than if we made m_1 the largest, m_2 the next largest, etc., since there are many more operations to be done modulo m_r than modulo m_1; but since v_j can be as large as $m_j - 1$, we are better off with $m_1 < m_2 < \cdots < m_r$ in (23) also. So this idea appears to be preferable to the formulas in the text, although the formulas in the text are advantageous when the moduli have the form (14), as shown in Section 4.3.3.

8. $m_{j-1}\ldots m_1v_j \equiv m_{j-1}\ldots m_1\,(\ldots((u_j - v_1)\,c_{1j} - v_2)\,c_{2j} - \cdots - v_{j-1})\,c_{(j-1)j} \equiv m_{j-2}\ldots m_1\,(\ldots(u_j - v_1)\,c_{1j} - \cdots - v_{j-2})\,c_{(j-2)j} - v_{j-1}m_{j-2}\ldots m_1 \equiv \cdots \equiv u_j - v_1 - v_2m_1 - \cdots - v_{j-1}m_{j-2}\ldots m_1$ (modulo m_j).

9. $u_r \leftarrow ((\ldots(v_rm_{r-1} + v_{r-1})\,m_{r-2} + \cdots)\,m_1 + v_1) \bmod m_r,\ \ldots,$
$u_2 \leftarrow (v_2m_1 + v_1) \bmod m_2,\ u_1 \leftarrow v_1 \bmod m_1.$

(The computation should be done in this order, if we want to let u_j and v_j share the same memory locations, as they can in (23).)

10. If we redefine the "mod" operator so that it produces residues in the symmetrical range, the basic formulas (2), (3), (4) for arithmetic and (23), (24) for conversion remain the same, and the number u in (24) lies in the desired range (10). (Here (24) is a *balanced mixed-radix* notation, generalizing "balanced ternary" notation.) The comparison of two numbers may still be done from left to right, in the simple manner described in the text. Furthermore, it is possible to retain the value u_j in a single computer word, if we have signed magnitude representation within the computer, even if m_j is almost twice the word size. But the arithmetic operations analogous to (11) and (12) are more difficult, so it appears that on most computers this idea would result in slightly slower operation.

11. Multiply by

$$\frac{m+1}{2} = \left(\frac{m_1+1}{2}, \ldots, \frac{m_r+1}{2}\right).$$

Note that $2t \cdot \frac{m+1}{2} \equiv t$ (modulo m). In general if v is relatively prime to m, then we can find (by Euclid's algorithm) a number $v' = (v'_1, \ldots, v'_r)$ such that $vv' \equiv 1$ (modulo m); and then if u is known to be a multiple of v we have $u/v = uv'$, where the latter is computed with modular multiplication. When v is not relatively prime to m, division is much more difficult.

12. Obvious from (11), if we replace m_j by m. [Another way to test for overflow, if m is odd, is to maintain extra bits $u_0 = u \bmod 2$ and $v_0 = v \bmod 2$. Then overflow has occurred iff $u_0 + v_0 \not\equiv w_1 + \cdots + w_r$ (modulo 2), where $(w_1, \ldots, w_r)$ are the mixed-radix digits corresponding to $u + v$.]

13. (a) $x^2 - x = (x-1)x \equiv 0$ (modulo 10^n) is equivalent to $(x-1)x \equiv 0$ (modulo p^n) for $p = 2$ and 5. Either x or $x-1$ must be a multiple of p, and then the other is relatively prime to p^n; so either x or $x-1$ must be a multiple of p^n. If $x \bmod 2^n = x \bmod 5^n = 0$ or 1, we must have $x \bmod 10^n = 0$ or 1; hence automorphs have $x \bmod 2^n \neq x \bmod 5^n$. (b) If $x = qp^n + r$, where $r = 0$ or 1, then $r \equiv r^2 \equiv r^3$, so $3x^2 - 2x^3 \equiv (6qp^n r + 3r) - (6qp^n r + 2r) \equiv r$ (modulo p^{2n}). (c) Let c' be the magic constant $(3(cx)^2 - 2(cx)^3)/x^2 = 3c^2 - 2c^3 x$.

Note: Since the last k digits of an n-digit automorph form a k-digit automorph, it makes sense to speak of the two ∞-digit automorphs, x and $1 - x$, which are 10-adic numbers (cf. exercise 4.1–31). The set of 10-adic numbers is equivalent under modular arithmetic to the set of ordered pairs (u_1, u_2), where u_1 is a 2-adic number and u_2 is a 5-adic number.

SECTION 4.3.3

1.

27×47:	18×42:	09×05:	2718×4742:
08	04	00	1269
08	04	00	1269
−15	+14	−45	−0045
49	16	45	0756
49	16	45	0756
1269	0756	0045	12888756

2. $\sqrt{Q + \lfloor\sqrt{Q}\rfloor} \leq \sqrt{Q + \sqrt{Q}} < \sqrt{Q + 2\sqrt{Q} + 1} = \sqrt{Q} + 1$, so $\lfloor\sqrt{Q+R}\rfloor \leq \lfloor\sqrt{Q}\rfloor + 1$.

3. When $k \leq 2$, the result is true, so assume that $k > 2$. Let $q_k = 2^{Q_k}$, $r_k = 2^{R_k}$, so that $R_k = \lfloor\sqrt{Q_k}\rfloor$ and $Q_k = Q_{k-1} + R_{k-1}$. We must show that $1 + (R_k + 1)2^{R_k} \leq 2^{Q_k - 1}$; this inequality isn't close at all, one way is to observe that $1 + (R_k + 1)2^{R_k} \leq 1 + 2^{2R_k}$ and $2R_k < Q_{k-1}$ when $k > 2$. (The fact that $2R_k < Q_{k-1}$ is readily proved by induction since $R_{k+1} - R_k \leq 1$ and $Q_k - Q_{k-1} \geq 2$.)

4. For $j = 1, \ldots, r$, calculate $U_e(j^2)$, $jU_o(j^2)$, $V_e(j^2)$, $jV_o(j^2)$; and by recursively calling the multiplication algorithm, calculate

$$W(j) = (U_e(j^2) + jU_o(j^2))(V_e(j^2) + jV_o(j^2)),$$
$$W(-j) = (U_e(j^2) - jU_o(j^2))(V_e(j^2) - jV_o(j^2)).$$

Then we have $W_e(j^2) = \frac{1}{2}(W(j) + W(-j))$, $W_o(j^2) = \frac{1}{2}(W(j) - W(-j))$. Also calculate $W_e(0) = U(0)V(0)$. Now construct difference tables for W_e and W_o, which are polynomials whose respective degrees are r and $r - 1$.

This method reduces the size of the numbers being handled, and reduces the number of additions and multiplications. Its only disadvantage is a longer program (since the control is somewhat more complex, and some of the calculations must be done with signed numbers).

Another possibility would perhaps be to evaluate W_e and W_o at 1^2, 2^2, 4^2, ..., $(2^r)^2$; although the numbers involved are larger, the calculations are faster, since all multiplications are replaced by shifting and all divisions are by binary numbers of the form $2^j(2^k - 1)$. (Simple procedures are available for dividing by such numbers.)

5. Start the q and r sequences out with q_0 and q_1 large enough so that the inequality in exercise 3 is valid. Then we will find in the formulas like those preceding Theorem C that we have $\eta_1 \to 0$ and $\eta_2 = (1+1/(2r_k))2^{1+\sqrt{2Q_k}-\sqrt{2Q_{k+1}}}(Q_k/Q_{k+1})$. The factor $Q_k/Q_{k+1} \to 1$ as $k \to \infty$, so we can ignore it if we want to show that $\eta_2 < 1-\epsilon$ for all large k. Now $\sqrt{2Q_{k+1}} = \sqrt{2Q_k + 2\lceil\sqrt{2Q_k}\rceil + 2} \geq \sqrt{(2Q_k + 2\sqrt{2Q_k} + 1) + 1} \geq \sqrt{2Q_k} + 1 + 1/(3R_k)$. Hence $\eta_2 \leq (1 + 1/(2r_k))2^{-1/(3R_k)}$, and $\lg \eta_2 < 0$ for large enough k.

Note: Algorithm C can also be modified to define a sequence $q_0, q_1, \ldots$ of a similar type that is based on n, so that $n \approx q_k + q_{k+1}$ after step C1. This modification leads to the estimate (19).

6. Any common divisor of $6q + d_1$ and $6q + d_2$ must also divide their difference $d_2 - d_1$. The $\binom{6}{2}$ differences are 2, 3, 4, 6, 8, 1, 2, 4, 6, 1, 3, 5, 2, 4, 2, so we must only show that at most one of the given numbers is divisible by each of the primes 2, 3, 5. Clearly only $6q + 2$ is even, and only $6q + 3$ is a multiple of 3; and there is at most one multiple of 5, since $q_k \not\equiv 3$ (modulo 5).

7. Let $p_{k-1} < N \leq p_k$. We have $t_k \leq 6t_{k-1} + ck3^k$ for some constant c; so $t_k/6^k \leq t_{k-1}/6^{k-1} + ck/2^k \leq t_0 + c\sum_{j\geq 1}(j/2^j) = M$. Thus $t_k \leq M \cdot 6^k = O(p_k^{\log_3 6})$.

8. Let 2^k be the smallest power of 2 that exceeds $2K$. Set $a_t \leftarrow \omega^{-t^2/2}u_t$ and $b_t \leftarrow \omega^{(2K-2-t)^2/2}$, where $u_t = 0$ for $t \geq K$. We want to calculate the convolutions $c_r = \sum_{0\leq j\leq r} a_j b_{r-j}$ for $r = 2K - 2 - s$, when $0 \leq s < K$. The convolutions can be found by using three fast Fourier transformations of order 2^k, as in the text's multiplication procedure. [Note that this device works for any complex number ω, not necessarily a root of unity. See L. I. Bluestein, *Northeast Electronics Res. and Eng. Meeting Record* **10** (1968), 218–219.]

9. $\tilde{u}_s = \hat{u}_{(qs) \bmod K}$. In particular, if $q = -1$ we get $\hat{u}_{(-r) \bmod K}$, which avoids shuffling when computing inverse transforms.

10. $A^{[j]}(s_{k-1}, \ldots, s_{k-j}, t_{k-j-1}, \ldots, t_0)$ can be written

$$\sum_{0\leq t_{k-1},\ldots,t_{k-j}\leq 1} \omega^{(s_0\ldots s_{k-1})_2\cdot(t_{k-1}\ldots t_{k-j}0\ldots0)_2} \Big(\sum_{0\leq p<K} \omega^{tp}u_p\Big)\Big(\sum_{0\leq q<K} \omega^{tq}v_q\Big),$$

and this is $\sum_{p,q} u_p v_q S(p,q)$, where $S(p,q) = 0$ or 2^j. We have $S(p,q) = 2^j$ for exactly $2^{2k}/2^j$ values of p and q.

11. An automaton cannot have $z_2 = 1$ until it has $c \geq 2$, and this occurs first for M_j at time $3j - 1$. It follows that M_j cannot have $z_2 z_1 z_0 \neq 000$ until time $3(j-1)$. Furthermore, if M_j has $z_0 \neq 0$ at time t, we cannot change this to $z_0 = 0$ without affecting the output; but the output cannot be affected by this value of z_0 until at least time $t + j - 1$, so we must have $t + j - 1 \leq 2n$. Since the first argument we gave proves that $3(j-1) \leq t$, we must have $4(j-1) \leq 2n$, that is, $j - 1 \leq n/2$, i.e., $j \leq \lfloor n/2 \rfloor + 1$. This is the best possible bound, since the inputs $u = v = 2^n - 1$ require the use of M_j for all $j \leq \lfloor n/2 \rfloor + 1$. (For example, note from Table 1 that M_2 is needed to multiply two-bit numbers, at time 3.)

12. We can "sweep through" K lists of MIX-like instructions, executing the first instruction on each list, in $O(K + (N \log N)^2)$ steps as follows: (1) A radix list sort (Section 5.2.5) will group together all identical instructions, in time $O(K + N)$. (2) Each set of j identical instructions can be performed in $O(\log N)^2 + O(j)$ steps, and there are $O(N^2)$ sets. A bounded number of sweeps will finish all the lists. The remaining details are straightforward; for example, arithmetic operations can be simulated by converting p and q to binary. [*SIAM J. Computing*, to appear.]

13. If it takes $T(n)$ steps to multiply n-bit numbers, we can accomplish m-bit times n-bit multiplication by breaking the n-bit number into $\lceil n/m \rceil$ m-bit groups, using $\lceil n/m \rceil T(m) + O(n + m)$ operations. The results of this section therefore give an estimated running time of $O(n \log m \log\log m)$ on Turing machines, or $O(n \log m)$ on machines with random access to words of bounded size, or $O(n)$ on pointer machines.

SECTION 4.4

1. We compute $(\ldots(a_m b_{m-1} + a_{m-2})b_{m-2} + \cdots + a_1)b_1 + a_0$ by adding and multiplying in the B_j system.

	T.	= 20(cwt.	= 8(st.	= 14(lb.	= 16 oz.)))
Start with zero	0	0	0	0	0
Add 3	0	0	0	0	3
Multiply by 24	0	0	0	4	8
Add 9	0	0	0	5	1
Multiply by 60	0	2	5	9	12
Add 12	0	2	5	10	8
Multiply by 60	8	3	1	0	0
Add 37	8	3	1	2	5

(Addition and multiplication by a constant in a mixed-radix system are readily done using a simple generalization of the usual carry rule; cf. exercise 4.3.1–9.)

2. We compute $\lfloor u/B_0 \rfloor$, $\lfloor \lfloor u/B_0 \rfloor / B_1 \rfloor$, etc., and the remainders are A_0, A_1, etc. The division is done in the b_j system.

	d.	= 24(h.	= 60(m.	= 60 s.))	
Start with u	3	9	12	37	
Divide by 16	0	5	4	32	Remainder = 5
Divide by 14	0	0	21	45	Remainder = 2
Divide by 8	0	0	2	43	Remainder = 1
Divide by 20	0	0	0	8	Remainder = 3
Divide by ∞	0	0	0	0	Remainder = 8

Answer: 8 T. 3 cwt. 1 st. 2 lb. 5 oz.

3. The following procedure due to G. L. Steele Jr. and Jon L. White generalizes Taranto's algorithm for $B = 2$ originally published in *CACM* **2**, 7 (July 1959), 27.

A1. [Initialize.] Set $M \leftarrow 0$, $U_0 \leftarrow 0$.

A2. [Done?] If $u < \epsilon$ or $u > 1 - \epsilon$, go to step A4. (Otherwise no M-place fraction will satisfy the given conditions.)

A3. [Transform.] Set $M \leftarrow M+1$, $U_{-M} \leftarrow \lfloor Bu \rfloor$, $u \leftarrow Bu \bmod 1$, $\epsilon \leftarrow B\epsilon$, and return to A2. (This transformation returns us to essentially the same state we were in before; the remaining problem is to convert u to U with fewest radix-B places so that $|U-u| < \epsilon$. Note, however, that ϵ may now be ≥ 1; in this case we could go immediately to step A4 instead of storing the new value of ϵ.)

A4. [Round.] If $u \geq \frac{1}{2}$, increase U_{-M} by 1. (If $u = \frac{1}{2}$ exactly, another rounding rule such as "increase U_{-M} by 1 only when it is odd" might be preferred.) ∎

Step A4 will never increase U_{-M} from $B-1$ to B; for if $U_{-M} = B-1$ we must have $M > 0$, but no $(M-1)$-place fraction was sufficiently accurate. Steele and White go on to consider floating-point conversions in their paper [to appear].

4. (a) $1/2^k = 5^k/10^k$. (b) Every prime divisor of b divides B.

5. Iff $10^n - 1 \leq c < w$, cf. (3).

7. $\alpha u \leq ux \leq \alpha u + u/w \leq \alpha u + 1$, hence $\lfloor \alpha u \rfloor \leq \lfloor ux \rfloor \leq \lfloor \alpha u + 1 \rfloor$. Furthermore, in the special case cited we have $ux < \alpha u + \alpha$ and $\lfloor \alpha u \rfloor = \lfloor \alpha u + \alpha - \epsilon \rfloor$.

```

9. If x' is an integer, $x - \epsilon \leq x' \leq x$, then $(1+1/n)x - ((1+1/n)\epsilon + 1 - 1/n) \leq x' + \lfloor x'/n \rfloor \leq (1+1/n)x$. Hence if α is the binary fraction satisfying

$$1/10 - 2^{-35} < \alpha = (.00011001100110011001100110011001)_2 < 1/10,$$

we find that $\alpha u - \epsilon \leq v \leq \alpha u$ at the end of the computation, where

$$\epsilon = \tfrac{7}{8} + (.10001000101010001100100010101001)_2 < \tfrac{3}{2}.$$

Hence $u/10 - 2 < u/10 - (\epsilon + (1/10 - \alpha)u) \leq v \leq \alpha u < u/10$. Since v is an integer, the proof is complete.

10. (a) Shift right one; (b) Extract left bit of each group; (c) Shift result of (b) right two; (d) Shift result of (c) right one, and add to result of (c); (e) Subtract result of (d) from result of (a).

14. Let $K(n)$ be the number of steps required to convert an n-digit decimal number to binary and at the same time to compute the binary representation of 10^n. Then we have $K(2n) \le 2K(n) + O(M(n))$. *Proof:* Given the number $U = (u_{2n-1} \dots u_0)_{10}$, compute $U_1 = (u_{2n-1} \dots u_n)_{10}$ and $U_0 = (u_{n-1} \dots u_0)_{10}$ and 10^n, in $2K(n)$ steps, then compute $U = 10^n U_1 + U_0$ and $10^{2n} = 10^n \cdot 10^n$ in $O(M(n))$ steps. It follows that $K(2^n) = O(M(2^n) + 2M(2^{n-1}) + 4M(2^{n-2}) + \cdots) = O(nM(2^n))$.

[Similarly, Schönhage has observed that we can convert a $(2^n \lg 10)$-bit number U from binary to decimal, in $O(nM(2^n))$ steps. First form $V = 10^{2^{n-1}}$ in $O(M(2^{n-1}) + M(2^{n-2}) + \cdots) = O(M(2^n))$ steps, then compute $U_0 = (U \bmod V)$ and $U_1 = \lfloor U/V \rfloor$ in $O(M(2^n))$ further steps, then convert U_0 and U_1.]

18. Let $U = \text{round}_B(u, P)$ and $v = \text{round}_b(U, p)$. We may assume that $u \neq 0$, so that $U \neq 0$ and $v \neq 0$. *Case 1, $v < u$:* Determine e and E such that $b^{e-1} < u \le b^e$, $B^{E-1} \le U < B^E$. Then $u \le U + \frac{1}{2}B^{E-P}$ and $U \le u - \frac{1}{2}b^{e-p}$; hence $B^{P-1} \le B^{P-E}U < B^{P-E}u \le b^{p-e}u \le b^p$. *Case 2, $v > u$:* Determine e and E such that $b^{e-1} \le u < b^e$, $B^{E-1} < U \le B^E$. Then $u \ge U - \frac{1}{2}B^{E-P}$ and $U \ge u + \frac{1}{2}b^{e-p}$; hence $B^{P-1} \le B^{P-E}(U - B^{E-P}) < B^{P-E}u \le b^{p-e}u < b^p$. Thus we have proved that $B^{P-1} < b^p$ whenever $v \neq u$.

Conversely, if $B^{P-1} < b^p$, the above proof suggests that the most likely example for which $u \neq v$ will occur when u is a power of b and at the same time it is close to a power of B. We have $B^{P-1}b^p < B^{P-1}b^p + \frac{1}{2}b^p - \frac{1}{2}B^{P-1} - \frac{1}{4} = (B^{P-1} + \frac{1}{2})(b^p - \frac{1}{2})$; hence $1 < \alpha = 1/(1 - \frac{1}{2}b^{-p}) < 1 + \frac{1}{2}B^{1-P} = \beta$. There are integers e and E such that $\log_B \alpha < e \log_B b - E < \log_B \beta$, since Weyl's theorem (exercise 3.5–22) implies that there is an integer e with $0 < \log_B \alpha < (e \log_B b) \bmod 1 < \log_B \beta < 1$ when $\log_B b$ is irrational. Hence $\alpha < b^e/B^E < \beta$, for some e and E. (Such e and E may also be found by applying the theory of continued fractions, see Section 4.5.3.) Now we have $\text{round}_B(b^e, P) = B^E$, and $\text{round}_b(B^E, p) < b^e$. [*CACM* **11** (1968), 47–50; *Proc. Amer. Math. Soc.* **19** (1968), 716–723.]

19. $m_1 = (\texttt{F0F0F0F0})_{16}$, $c_1 = 1 - 10/16$ makes $U = ((u_7u_6)_{10} \dots (u_1u_0)_{10})_{256}$; then $m_2 = (\texttt{FF00FF00})_{16}$, $c_2 = 1 - 10^2/16^2$ makes $U = ((u_7u_6u_5u_4)_{10}(u_3u_2u_1u_0)_{10})_{65536}$; and $m_3 = (\texttt{FFFF0000})_{16}$, $c_3 = 1 - 10^4/16^4$ finishes the job. (Cf. exercise 14. This technique is due to Roy A. Keir, circa 1958.)

SECTION 4.5.1

1. Test whether or not $uv' < u'v$, since the denominators are positive.

2. If $c > 1$ divides both u/d and v/d, then cd divides both u and v.

3. Let p be prime. If p^e is a divisor of uv and $u'v'$ for $e \ge 1$, then either $p^e \setminus u$ and $p^e \setminus v'$ or $p^e \setminus u'$ and $p^e \setminus v$; hence $p^e \setminus \gcd(u, v')\gcd(u', v)$. The converse follows by reversing the argument.

4. Let $d_1 = gcd(u, v)$, $d_2 = \gcd(u', v')$; the answer is $w = (u/d_1)(v'/d_2)\text{sign}(v)$, $w' = |(u'/d_2)(v/d_1)|$, with a "divide by zero" error message if $v = 0$.

5. $d_1 = 10$, $t = 17 \cdot 7 - 27 \cdot 12 = -205$, $d_2 = 5$, $w = -41$, $w' = 168$.

6. Let $u'' = u'/d_1$, $v'' = v'/d_1$; our goal is to show that $\gcd(uv'' + u''v, d_1) = \gcd(uv'' + u''v, d_1u''v'')$. If p is a prime that divides u'', then p does not divide u or v'', so p does not divide $uv'' + u''v$. A similar argument holds for prime divisors of v'', so no prime divisors of $u''v''$ affect the given gcd.

7. $(N-1)^2+(N-2)^2 = 2N^2-(6N-5)$. If the inputs are n-bit binary numbers, $2n+1$ bits may be necessary to represent t.

8. For multiplication and division these quantities obey the rules $x/0 = \text{sign}(x)\infty$, $(\pm\infty)\times x = x\times(\pm\infty) = (\pm\infty)/x = \pm\text{sign}(x)\infty$, $x/(\pm\infty) = 0$, provided that x is finite and nonzero, without change to the algorithms described. Furthermore, the algorithms can readily be modified so that $0/0 = 0\times(\pm\infty) = (\pm\infty)\times 0 =$ "(0/0)", where the latter is a representation of "undefined"; and so that if either operand is "undefined" the result will be "undefined" also.

Since the multiplication and division subroutines can yield these fairly natural rules of "extended arithmetic," it is sometimes worthwhile to modify the addition and subtraction operations so that they satisfy the rules $x\pm\infty = \pm\infty$, $x\pm(-\infty) = \mp\infty$, for x finite; $(\pm\infty)+(\pm\infty) = \pm\infty-(\mp\infty) = \pm\infty$; furthermore $(\pm\infty)+(\mp\infty) = (\pm\infty)-(\pm\infty) = (0/0)$; and if either or both operands are (0/0), the result should also be (0/0). Equality tests and comparisons may be treated in a similar manner.

The above remarks are independent of "overflow" indications. If ∞ is being used to suggest overflow, it is incorrect to let $1/\infty$ be equal to zero, lest inaccurate results be regarded as true answers. It is far better to represent overflow by (0/0), and to adhere to the convention that the result of any operation is undefined if at least one of the inputs is undefined. This type of overflow indication has the advantage that final results of an extended calculation reveal exactly which answers are defined and which are not.

9. If $u/u' \neq v/v'$, then

$$1 \le |uv'-u'v| = u'v'|(u/u')-(v/v')| < |2^{2n}(u/u')-2^{2n}(v/v')|;$$

two quantities differing by more than unity cannot have the same "floor." (In other words, the first $2n$ bits to the right of the binary point are enough to characterize the value of the fraction, when there are n-bit denominators. We cannot improve this to $2n-1$ bits, for if $n=4$ we have $\frac{1}{13} = (.00010011\ldots)_2$, $\frac{1}{14} = (.00010010\ldots)_2$.)

11. To divide by $(v+v'\sqrt{5})/v''$, when v and v' are not both zero, multiply by the reciprocal, $(v-v'\sqrt{5})v''/(v^2-5v'^2)$, and reduce to lowest terms.

12. One idea is to limit numerator and denominator to a total of 27 bits, where we need only store 26 of these bits (since the leading bit of the denominator can be assumed 1). This leaves room for a sign and five bits to indicate the denominator size. Another idea is to use 28 bits for numerator and denominator, which are to have a total of at most seven hexadecimal digits, together with a sign and a 3-bit field to indicate the number of hexadecimal digits in the denominator.

[Using the formulas in the next exercise, the first alternative leads to exactly 2140040119 finite representable numbers, while the second leads to 1830986459. The first alternative is preferable because it represents more values, and because it is 'cleaner' and makes smoother transitions between ranges.]

13. The number of multiples of n in the interval $(a,b]$ is $\lfloor n/a\rfloor - \lfloor a/n\rfloor$. Hence, by inclusion and exclusion, the answer to this problem is $S_0 - S_1 + S_2 - \cdots$, where S_k is $\sum\lfloor M/P\rfloor(\lfloor N_2/P\rfloor - \lfloor N_1/P\rfloor)$, summed over all products P of k distinct primes.

SECTION 4.5.2

1. Substitute min, max, $+$ consistently for gcd, lcm, $\times$, respectively.

2. For prime p, let $u_p, v_{1p}, \ldots, v_{np}$ be the exponents of p in the canonical factorizations of $u, v_1, \ldots, v_n$. By hypothesis, $u_p \le v_{1p} + \cdots + v_{np}$. We must show that $u_p \le \min(u_p, v_{1p}) + \cdots + \min(u_p, v_{np})$, and this is certainly true if u_p is greater than or equal to each v_{jp}, or if u_p is less than some v_{jp}.

3. *Solution 1:* A one-to-one correspondence is obtained if we set $u = \gcd(d, n)$ and $v = n^2/\operatorname{lcm}(d, n)$ for each divisor d of n^2. *Solution 2:* If $n = p_1^{e_1} \ldots p_r^{e_r}$, the number in each case is $(2e_1 + 1) \ldots (2e_r + 1)$.

4. See exercise 3.2.1.2–15(a).

5. Shift u and v right until neither is a multiple of 3, remembering the proper power of 3 that will appear in the gcd. Each subsequent iteration sets $t \leftarrow u + v$ or $t \leftarrow u - v$ (whichever is a multiple of 3), shifts t right until it is not a multiple of 3, then replaces $\max(u, v)$ by the result.

u	v	t
13634	24140	10506, 3502;
13634	3502	17136, 5712, 1904;
1904	3502	5406, 1802;
1904	1802	102, 34;
34	1802	1836, 612, 204, 68;
34	68	102, 34;
34	34	0.

The evidence that $\gcd(40902, 24140) = 34$ is now overwhelming.

6. The probability that both u and v are even is $\frac{1}{4}$; the probability that both are multiples of four is $\frac{1}{16}$; etc. Thus A has the distribution given by the generating function

$$\frac{3}{4} + \frac{3}{16}z + \frac{3}{64}z^2 + \cdots = \frac{3/4}{1 - z/4}.$$

The mean is $\frac{1}{3}$, and the standard deviation is $\sqrt{\frac{2}{9} + \frac{1}{3} - \frac{1}{9}} = \frac{2}{3}$. If u and v are independently and uniformly distributed with $1 \le u, v < 2^N$, then some small correction terms are needed; the mean is then actually

$$(2^N - 1)^{-2} \sum_{1 \le k \le N} (2^{N-k} - 1)^2 = \tfrac{1}{3} - \tfrac{4}{3}(2^N - 1)^{-1} + N(2^N - 1)^{-2}.$$

7. When u, v are not both even, each of the cases (even, odd), (odd, even), (odd, odd) is equally probable, and $B = 1, 0, 0$ in these cases. Hence $B = \frac{1}{3}$ on the average. Actually, as in exercise 6, a small correction could be given to be strictly accurate when $1 \le u, v < 2^N$; the probability that $B = 1$ is actually

$$(2^N - 1)^{-2} \sum_{1 \le k \le N} (2^{N-k} - 1)2^{N-k} = \tfrac{1}{3} - \tfrac{1}{3}(2^N - 1)^{-1}.$$

8. The quantity E is the number of subtraction cycles in which $u > v$, plus one if u is odd after step B1. If we change the inputs from (u, v) to (v, u), the value of C stays unchanged, while E becomes $C - E$ or $C - E - 1$; the latter case occurs iff u and v are both odd after step B1, and this has probability $\frac{1}{3} + \frac{2}{3}/(2^N - 1)$. Hence

$$E_{\text{ave}} = C_{\text{ave}} - E_{\text{ave}} - \tfrac{1}{3} - \tfrac{2}{3}/(2^N - 1).$$

9. The binary algorithm first gets to B6 with $u = 1963$, $v = 1359$; then $t \leftarrow 604, 302, 151$, etc. The gcd is 302. Using Algorithm X we find that $2 \cdot 31408 - 23 \cdot 2718 = 302$.

10. (a) Two integers are relatively prime iff they are not both divisible by any prime number. (b) Rearrangement of the sum in (a), in terms of the denominators $k = p_1 \ldots p_r$. (Note that each of the sums in (a) and (b) is actually finite.) (c) Since $(n/k)^2 - \lfloor n/k \rfloor^2 = O(n/k)$, we have $q_n - \sum_{1 \le k \le n} \mu(k)(n/k)^2 = \sum_{1 \le k \le n} O(n/k) = O(nH_n)$. Furthermore $\sum_{k>n} (n/k)^2 = O(n)$. (d) $\sum_{d \backslash n} \mu(d) = \delta_{1n}$. [In fact, we have the more general result

$$\sum_{d \backslash n} \mu(d) \Big(\frac{n}{d}\Big)^s = n^s - \sum \Big(\frac{n}{p}\Big)^s + \sum \Big(\frac{n}{pq}\Big)^s - \cdots,$$

as in part (b), where the sums on the right are over the prime divisors of n, and this is equal to $n^s(1 - 1/p_1^s) \ldots (1 - 1/p_r^s)$ if $n = p_1^{e_1} \ldots p_r^{e_r}$.]

Notes: Similarly, we find that a set of k integers is relatively prime with probability $1/(\sum_{n \ge 1} 1/n^k)$. This proof of Theorem D is due to F. Mertens, *J. für die reine und angew. Math.* **77** (1874), 289–291. The technique actually gives a much stronger result, namely that $6\pi^{-2}mn + O(n \log m)$ pairs of integers $u \in [f(m), f(m) + m)$, $v \in [g(n), g(n) + n)$ are relatively prime, for arbitrary f and g, when $m \le n$.

11. (a) $6/\pi^2$ times $1 + \frac{1}{4} + \frac{1}{9}$, namely $49/(6\pi^2) \approx .82746$. (b) $6/\pi^2$ times $1/1 + 2/4 + 3/9 + \cdots$, namely ∞. (This is true in spite of the result of exercise 12, and in spite of the fact that the average value of $\ln \gcd(u, v)$ is a small, finite number.)

12. Let $\sigma(n)$ be the number of positive divisors of n. The answer is

$$\sum_{k \ge 1} \sigma(k) \cdot \frac{6}{\pi^2 k^2} = \frac{6}{\pi^2} \Big(\sum_{k \ge 1} \frac{1}{k^2} \Big)^2 = \frac{\pi^2}{6}.$$

[Thus, the average is *less* than 2, although there are always at least two common divisors when u and v are not relatively prime.]

13. $1 + \frac{1}{9} + \frac{1}{25} + \cdots = 1 + \frac{1}{4} + \frac{1}{9} + \cdots - \frac{1}{4}(1 + \frac{1}{4} + \frac{1}{9} + \cdots)$.

14. $v_1 = \pm v/u_3$, $v_2 = \mp u/u_3$ (the sign depends on whether the number of iterations is even or odd). This follows from the fact that v_1 and v_2 are relatively prime to each other (throughout the algorithm), and that $v_1 u = -v_2 v$. [Hence $v_1 u = \operatorname{lcm}(u, v)$ at the close of the algorithm, but this is not an especially efficient way to compute the least common multiple. For a generalization, see exercise 4.6.1–18.]

G. E. Collins has observed that $|u_1| \le \frac{1}{2} v/u_3$, $|u_2| \le \frac{1}{2} u/u_3$, at the termination of Algorithm X, except in certain trivial cases, since the final value of q is usually ≥ 2. This bounds the size of $|u_1|$ and $|u_2|$ throughout the execution of the algorithm.

15. Apply Algorithm X to v and m, thus obtaining a value x such that $xv \equiv 1$ (modulo m). (This can be done by simplifying Algorithm X so that u_2, v_2, and t_2 are not computed, since they are never used in the answer.) Then set $w \leftarrow ux \bmod m$. [It follows, as in exercise 30, that this process requires $O(n^2)$ units of time, when it is applied to large n-bit numbers. An alternative to Algorithm X appears in exercise 35.]

16. (a) Set $t_1 = x + 2y + 3z$; then $3t_1 + y + 2z = 1$, $5t_1 - 3y - 20z = 3$. Eliminate y, then $14t_1 - 14z = 6$: No solution. (b) This time $14t_1 - 14z = 0$. Divide by 14, eliminate t_1; the general solution is $x = 8z - 2$, $y = 1 - 5z$, z arbitrary.

17. Let u_1, u_2, u_3, v_1, v_2, v_3 be multiprecision variables, in addition to u and v. The extended algorithm will act the same on u_3 and v_3 as Algorithm L does on u and v. New multiprecision operations are to set $t \leftarrow Au_j$, $t \leftarrow t + Bv_j$, $w \leftarrow Cu_j$, $w \leftarrow w + Dv_j$, $u_j \leftarrow t$, $v_j \leftarrow w$ for all j, in step L4; also if $B = 0$ in that step to set $t \leftarrow u_j - qv_j$, $u_j \leftarrow v_j$, $v_j \leftarrow t$ for all j and for $q = \lfloor u_3/v_3 \rfloor$. A similar modification is made to step L1 if v_3 is small. The inner loop (steps L2 and L3) is unchanged.

18. If $mn = 0$, the probabilities of the lattice-point model in the test are exact, so we may assume that $m \geq n > 0$. *Valida vi*, the following values have been obtained:

Case 1, $m = n$. From (n, n) we go to $(n-t, n)$ with probability $t/2^t - 5/2^{t+1} + 3/2^{2t}$, for $2 \leq t < n$. (These values are $\frac{1}{16}$, $\frac{7}{64}$, $\frac{27}{256}$, ...) To $(0, n)$ the probability is $n/2^{n-1} - 1/2^n + 1/2^{2n-2}$. To (n, k) the probability is the same as to (k, n). The algorithm terminates with probability $1/2^{n-1}$.

Case 2, $m = n+1$. From $(n+1, n)$ we get to (n, n) with probability $\frac{1}{8}$ when $n > 1$, or 0 when $n = 1$; to $(n-t, n)$ with probability $11/2^{t+3} - 3/2^{2t+1}$, for $1 \leq t < n-1$. (These values are $\frac{5}{16}$, $\frac{1}{4}$, ...) We get to $(1, n)$ with probability $5/2^{n+1} - 3/2^{2n-1}$, for $n > 1$; to $(0, n)$ with probability $3/2^n - 1/2^{2n-1}$.

Case 3, $m \geq n + 2$. The probabilities are given by the following table:

$(m-1, n)$:	$1/2 - 3/2^{m-n+2} - \delta_{n1}/2^{m+1}$;
$(m-t, n)$:	$1/2^t + 3/2^{m-n+t+1}$, $\quad 1 < t < n$;
$(m-n, n)$:	$1/2^n + 1/2^m$, $\quad n > 1$;
$(m-n-1, n)$:	$1/2^{n+1} + 1/2^{m-1}$;
$(m-n-t, n)$:	$1/2^{n+t}$, $\quad 1 < t < m-n$;
$(0, n)$:	$1/2^{m-1}$.

Note: Although these exact probabilities will certainly improve on the lattice-point model considered in the text, they lead to recurrence relations of much greater complexity; and they will not provide the true behavior of Algorithm B, since for example the probability that $\gcd(u, v) = 5$ is different from the probability that $\gcd(u, v) = 7$.

19. $A_{n+1} = a + \sum_{1 \leq k \leq n} 2^{-k} A_{(n+1)(n-k)} + 2^{-n} b = a + \sum_{1 \leq k \leq n} 2^{-k} A_{n(n-k)} + \frac{1}{2}c(1 - 2^{-n}) + 2^{-n} b = a + \frac{1}{2}A_{n(n-1)} + \frac{1}{2}(A_n - a) + \frac{1}{2}c(1 - 2^{-n})$; now substitute for $A_{n(n-1)}$ from (36).

20. The paths described in the hint have the same probability, but the subsequent termination of the algorithm has a different probability; thus $\lambda = k+1$ with probability 2^{-k} times the probability that $\lambda = 1$. Let the latter probability be p. We know from the text that $\lambda = 0$ with probability $\approx \frac{3}{5}$; hence $\frac{2}{5} \approx p(1 + \frac{1}{2} + \frac{1}{4} + \cdots) = 2p$. The average is $p(1 + \frac{2}{2} + \frac{3}{4} + \frac{4}{8} + \cdots) = p(1 + \frac{1}{2} + \frac{1}{4} + \frac{1}{8} + \cdots)^2 = 4p$. [The exact probability that $\lambda = 1$ is $\frac{1}{5} - \frac{6}{5}(-\frac{1}{4})^n$ if $m > n \geq 1$, $\frac{1}{5} - \frac{16}{5}(-\frac{1}{4})^n$ if $m = n \geq 2$.]

21. Show that for fixed v and for $2^m < u < 2^{m+1}$, when m is large, each subtraction-shift cycle of the algorithm reduces $\lfloor \lg u \rfloor$ by two, on the average.

22. Exactly $(N-m)2^{m-1+\delta_{m0}}$ integers u in the range $1 \leq u < 2^N$ have $\lfloor \lg u \rfloor = m$, after u has been shifted right until it is odd.

23. The first sum is $2^{2N-2}\sum_{0\le m<n<N} mn2^{-m-n}((\alpha+\beta)N+\gamma-\alpha m-\beta n)$. Since

$$\sum_{0\le m<n} m2^{-m} = 2-(n+1)2^{1-n}$$

and

$$\sum_{0\le m<n} m(m-1)2^{-m} = 4-(n^2+n+2)2^{1-n},$$

the sum on m is

$$2^{2N-2}\sum_{0\le n<N} n2^{-n}((\gamma-\alpha+(\alpha+\beta)N)(2-(n+1)2^{1-n}) \\ -\alpha(4-(n^2+n+2)2^{1-n})-\beta n)$$

$$= 2^{2N-2}((\alpha+\beta)N\sum_{0\le n<N} n2^{-n}(2-(n+1)2^{1-n})+O(1)).$$

Thus the coefficient of $(\alpha+\beta)N$ in the answer is found to be $2^{-2}(4-(\frac{4}{3})^3)=\frac{11}{27}$. A similar argument applies to the other sum.

Note: The exact value of the sums may be obtained after some tedious calculation by means of the general formula

$$\sum_{0\le k<n} k^{\underline{m}} z^k = \frac{m!\,z^m}{(1-z)^{m+1}} - \sum_{0\le k\le m} \frac{m^{\underline{k}} n^{\underline{m-k}} z^{n+k}}{(1-z)^{k+1}},$$

which follows from summation by parts.

24. Solving a recurrence similar to (34), we find that the number of times is A_{mn}, where $A_{00}=1$, $A_{0n}=(n+3)/2$, $A_{nn}=\frac{8}{5}-(3n+13)/(9\cdot 2^n)+\frac{128}{45}(-\frac{1}{4})^n$ if $n\ge 1$, $A_{mn}=\frac{8}{5}-2/(3\cdot 2^n)+\frac{16}{15}(-\frac{1}{4})^n$ if $m>n\ge 1$. Since the condition $u=1$ or $v=1$ is therefore satisfied only about 1.6 times in an average run, it is not worth making the suggested test each time step B5 is performed. (Of course the lattice model is not completely accurate, but it seems reasonable to believe that it is not too inaccurate for this application.)

25. (a) $F_{n+1}(x)=\sum_{d\ge 1}2^{-d}$ probability that ($X_n<1$ and $2^d/(X_n^{-1}-1)<x$ or $X_n>1$ and $(X_n-1)/2^d<x$) $=\sum_{d\ge 1}2^{-d}(F_n(1/(1+2^dx^{-1}))+F_n(1+2^dx)-F_n(1))$. (b) $G_{n+1}(x)=1-\sum_{d\ge 1}2^{-d}(G_n(1/(1+2^dx))-G_n(1/(1+2^dx^{-1})))$. (c) $H_n(x)=\sum_{d\ge 1}2^{-d}$ probability that ($Y_n\le x$ and $(1-Y_n)/2^d\le x$) can be transformed into $\sum_{d\ge 1}2^{-d}\max(0,G_n(x)-G_n(1-2^dx))$.

Starting with $G_0(x)=x$ we get rapid convergence to a limiting distribution where

$$(G(.1),\ldots,G(.9))=(.2750,.4346,.5544,.6507,.7310,.7995,.8590,.9114,.9581).$$

The expected value of $\ln(\max(u_n,v_n)/\max(u_{n+1},v_{n+1}))$ is $\int_0^1 H_n(t)\,dt/t$, and Brent has shown that this can be written

$$\int_{1/3}^1 \frac{G_n(t)}{t}\,dt-\int_0^{1/3}\frac{G_n(t)}{1-t}\,dt+\sum_{k\ge 1}2^{-k}\int_{1/(1+2^{k+1})}^{1/(1+2^k)}\frac{G_n(t)}{t(1-t)}\,dt.$$

26. By induction, the length is $m+\lfloor n/2\rfloor$ when $m \geq n$, except that when $m = n = 1$ there is *no* path to $(0,0)$.

27. Let $a_n = (2^n - (-1)^n)/3$; then $a_0, a_1, a_2, \ldots = 0, 1, 1, 3, 5, 11, 21, \ldots$. (This sequence of numbers has an interesting pattern of zeros and ones in its binary representation. Note that $a_n = a_{n-1} + 2a_{n-2}$, and $a_n + a_{n+1} = 2^n$.) For $m > n$, let $u = 2^{m+1} - a_{n+2}$, $v = a_{n+2}$. For $m = n > 0$, let $u = a_{n+2}$ and $v = 2a_{n+1}$, or $u = 2a_{n+1}$ and $v = a_{n+2}$ (depending on which is larger). Another example for the case $m = n > 0$ is $u = 2^{n+1} - 1$, $v = 2^{n+1} - 2$; this choice takes more shifts, and gives $C = n + 1$, $D = 2n$, $E = 1$.

28. This is a problem where it appears to be necessary to prove *more* than was asked just to prove what was asked. Let us prove the following: *If u and v are positive integers, Algorithm B does $\leq 1 + \lfloor \lg \max(u,v) \rfloor$ subtraction steps; and if equality holds, then $\lfloor \lg(u+v) \rfloor > \lfloor \lg \max(u,v) \rfloor$.*

For convenience, let us assume that $u \geq v$; let $m = \lfloor \lg u \rfloor$, $n = \lfloor \lg v \rfloor$; and let us use the "lattice-point" terminology, saying that we are "at point (m,n)." The proof is by induction on $m + n$.

Case 1, $m = n$. Clearly, $\lfloor \lg(u+v) \rfloor > \lfloor \lg u \rfloor$ in this case. If $u = v$ the result is trivial; otherwise the next subtraction-shift cycle takes us to a point $(m-k, m)$. By induction, at most $m+1$ further subtraction steps will be required; but if $m+1$ more *are* needed, we have $\lfloor \lg((u-v)2^{-r} + v) \rfloor > \lfloor \lg v \rfloor$, where $r \geq 1$ is the number of right shifts that were made. This is impossible, since $(u-v)2^{-r} + v < (u-v) + v = u$. So at most m further steps are needed.

Case 2, $m > n$. The next subtraction step takes us to $(m-k, n)$, and at most $1 + \max(m-k, n) \leq m$ further steps will be required. Now if m further steps *are* required, then u has been replaced by $u' = (u-v)2^{-r}$ for some $r \geq 1$. By induction, $\lfloor \lg(u'+v) \rfloor \geq m$; hence

$$\lfloor \lg(u+v) \rfloor = \lfloor \lg 2((u-v)/2 + v) \rfloor \geq \lfloor \lg 2(u'+v) \rfloor \geq m + 1 > \lfloor \lg u \rfloor.$$

29. Subtract the kth column from the $2k$th, $3k$th, $4k$th, etc., for $k = 1, 2, 3, \ldots$. The result is a triangular matrix with x_k on the diagonal in column k, where $m = \sum_{d \backslash m} x_d$. It follows that $x_m = \varphi(m)$, so the determinant is $\varphi(1)\varphi(2)\ldots\varphi(n)$.

[In general, "Smith's determinant," in which the (i,j) element is $f(\gcd(i,j))$ for an arbitrary function f, is equal to $\prod_{1 \leq m \leq n} \sum_{d \backslash m} \mu(m/d) f(d)$, by the same argument. See L. E. Dickson, *History of the Theory of Numbers* **1** (New York: Chelsea, 1952), 122–123.]

30. To determine A and r such that $u = Av + r$, $0 \leq r < v$, using ordinary long division, takes $O((1 + \log A)(\log u))$ units of time. If the quotients during the algorithm are $A_1, A_2, \ldots, A_m$, then $A_1 A_2 \ldots A_m \leq u$, so $\log A_1 + \cdots + \log A_m \leq \log u$. Also $m = O(\log u)$.

31. In general, since $(a^u - 1) \bmod (a^v - 1) = a^{u \bmod v} - 1$ (cf. Eq. 4.3.2–19), we find that $\gcd(a^m - 1, a^n - 1) = a^{\gcd(m,n)} - 1$ for all positive integers a.

32. Yes, to $O(n(\log n)^2(\log\log n))$, even if we also need to compute the sequence of partial quotients that would be computed by Euclid's algorithm; see A. Schönhage, *Acta Informatica* **1** (1971), 139–144. [But Algorithm L is better in practice unless n is extremely large.]

34. Keep track of the most significant and least significant words of the operands (the most significant is used to guess the sign of t and the least significant is to determine the amount of right shift), while building a 2×2 matrix A of single-precision integers such that $A\binom{u}{v} = \binom{u'w}{v'w}$, where w is the computer word size and where u' and v' are smaller than u and v. (Instead of dividing the simulated odd operand by 2, multiply the other one by 2, until obtaining multiples of w after exactly $\lg w$ shifts.) Experiments show this algorithm running four times as fast as Algorithm L, on at least one computer.

35. (Solution by Michael Penk.)

Y1. [Find power of 2.] Same as step B1.

Y2. [Initialize.] Set $(u_1, u_2, u_3) \leftarrow (1, 0, u)$ and $(v_1, v_2, v_3) \leftarrow (v, 1 - u, v)$. If u is odd, set $(t_1, t_2, t_3) \leftarrow (0, -1, -v)$ and go to Y4. Otherwise set $(t_1, t_2, t_3) \leftarrow (1, 0, u)$.

Y3. [Halve t_3.] If t_1 and t_2 are both even, set $(t_1, t_2, t_3) \leftarrow (t_1, t_2, t_3)/2$; otherwise set $(t_1, t_2, t_3) \leftarrow (t_1 + v, t_2 - u, t_3)/2$. (In the latter case, $t_1 + v$ and $t_2 - u$ will both be even.)

Y4. [Is t_3 even?] If t_3 is even, go back to Y3.

Y5. [Reset $\max(u_3, v_3)$.] If t_3 is positive, set $(u_1, u_2, u_3) \leftarrow (t_1, t_2, t_3)$; otherwise set $(v_1, v_2, v_3) \leftarrow (v - t_1, -u - t_2, -t_3)$.

Y6. [Subtract.] Set $(t_1, t_2, t_3) \leftarrow (u_1, u_2, u_3) - (v_1, v_2, v_3)$. Then if $t_1 < 0$, set $(t_1, t_2) \leftarrow (t_1 + v, t_2 - u)$. If $t_3 \neq 0$, go back to B3. Otherwise the algorithm terminates with $(u_1, u_2, u_3 \cdot 2^k)$ as the output. ∎

It is clear that the relations in (16) are preserved, and that $0 \le u_1, v_1, t_1 \le v$, $0 \ge u_2, v_2, t_2 \ge -u$ after each of steps Y2–Y6. If u is odd after step Y2, then step Y3 can be simplified, since t_1 and t_2 are both even iff t_2 is even; similarly, if v is odd, then t_1 and t_2 are both even iff t_1 is even. Thus, as in Algorithm X, it is possible to suppress all calculations involving u_2, v_2, and t_2, provided that v is odd after step Y2. This condition is often known in advance (e.g., when v is prime and we are trying to compute u^{-1} modulo v).

SECTION 4.5.3

1. The running time is about $19.02T + 6$, just a trifle slower than Program 4.5.2A.

2. $\begin{pmatrix} Q_n(x_1, x_2, \ldots, x_{n-1}, x_n) & Q_{n-1}(x_1, x_2, \ldots, x_{n-1}) \\ Q_{n-1}(x_2, \ldots, x_{n-1}, x_n) & Q_{n-2}(x_2, \ldots, x_{n-1}) \end{pmatrix}$.

3. $Q_n(x_1, \ldots, x_n)$.

4. By induction, or by taking the determinant of the matrix product in exercise 2.

5. When the x's are positive, the q's of (9) are positive, and $q_{n+1} > q_{n-1}$; hence (9) is an alternating series of decreasing terms, and it converges iff $q_n q_{n+1} \to \infty$. By induction, if the x's are greater than ϵ, we have $q_n \ge c(1 + \epsilon/2)^n$, where c is chosen small enough to make this inequality valid for $n = 1$ and 2. But if $x_n = 1/2^n$, we have $q_n \le 2 - 1/2^n$.

6. It suffices to prove that $A_1 = B_1$; and from the fact that $0 \le /x_1, \ldots, x_n/ < 1$ whenever $x_1, \ldots, x_n$ are positive integers, we have $B_1 = \lfloor 1/X \rfloor = A_1$.

7. Only $1\,2\ldots n$ and $n\ldots 2\,1$. (The variable x_k appears in exactly $F_k F_{n-k}$ terms; hence x_1 and x_n can only be permuted into x_1 and x_n. If x_1 and x_n are fixed by the permutation, it follows by induction that $x_2, \ldots, x_{n-1}$ are also fixed.)

8. This is equivalent to

$$\frac{Q_{n-2}(A_{n-1},\ldots,A_2) - XQ_{n-1}(A_{n-1},\ldots,A_1)}{Q_{n-1}(A_n,\ldots,A_2) - XQ_n(A_n,\ldots,A_1)} = -\frac{1}{X_n},$$

and by (6) this is equivalent to

$$X = \frac{Q_{n-1}(A_2,\ldots,A_n) + X_n Q_{n-2}(A_2,\ldots,A_{n-1})}{Q_n(A_1,\ldots,A_n) + X_n Q_{n-1}(A_1,\ldots,A_{n-1})}.$$

9. (a) By definition. (b), (d) Prove this when $n = 1$, then apply (a) to get the result for general n. (c) Prove when $n = k + 1$, then apply (a).

10. If $A_0 > 0$, then $B_0 = 0$, $B_1 = A_0$, $B_2 = A_1$, $B_3 = A_2$, $B_4 = A_3$, $B_5 = A_4$, $m = 5$. If $A_0 = 0$, then $B_0 = A_1$, $B_1 = A_2$, $B_2 = A_3$, $B_3 = A_4$, $m = 3$. If $A_0 = -1$ and $A_1 = 1$, then $B_0 = -(A_2 + 2)$, $B_1 = 1$, $B_2 = A_3 - 1$, $B_3 = A_4$, $m = 3$. If $A_0 = -1$ and $A_1 > 1$, then $B_0 = -2$, $B_2 = A_1 - 2$, $B_3 = A_2$, $B_4 = A_3$, $B_5 = A_4$, $m = 5$. If $A_0 < -1$, then $B_0 = -1$, $B_1 = 1$, $B_2 = -A_0 - 2$, $B_3 = 1$, $B_4 = A_1 - 1$, $B_5 = A_2$, $B_6 = A_3$, $B_7 = A_4$. [Actually, the last three cases involve eight subcases; if any of the B's is set to zero, the values should be "collapsed together" by using the rule of exercise 9(c). For example, if $A_0 = -1$, $A_1 = A_3 = 1$, we actually have $B_0 = -(A_2 + 2)$, $B_1 = A_4 + 1$, $m = 1$. Double collapsing occurs when $A_0 = -2$, $A_1 = 1$.]

11. Let $q_n = Q_n(A_1,\ldots,A_n)$, $q'_n = Q_n(B_1,\ldots,B_n)$, $p_n = Q_{n+1}(A_0,\ldots,A_n)$, $p'_n = Q_{n+1}(B_0,\ldots,B_n)$. By (5) and (11) we have $X = (p_m + p_{m-1}X_m)/(q_m + q_{m-1}X_m)$, $Y = (p'_n + p'_{n-1}Y_n)/(q'_n + q'_{n-1}Y_n)$; therefore if $X_m = Y_n$, the stated relation between X and Y holds by (8). Conversely, if $X = (qY + r)/(sY + t)$, $|qt - rs| = 1$, we may assume that $s \geq 0$, and we can show that the partial quotients of X and Y eventually agree, by induction on s. The result is clear when $s = 0$, by exercise 9(d). If $s > 0$, let $q = as + s'$, where $0 \leq s' < s$. Then $X = a + 1/((sY + t)/(s'Y + r - at))$; since $s(r - at) - ts' = sr - tq$, and $s' < s$, we know by induction and exercise 10 that the partial quotients of X and Y eventually agree. [*Note:* The fact that m is always odd in exercise 10 shows, by a close inspection of this proof, that $X_m = Y_n$ if and only if $X = (qY + r)/(sY + t)$, where $qt - rs = (-1)^{m-n}$.]

12. (a) Since $V_n V_{n+1} = D - U_n^2$, we know that $D - U_{n+1}^2$ is a multiple of V_{n+1}; hence by induction $X_n = (\sqrt{D} - U_n)/V_n$, where U_n and V_n are integers. [Note that the identity $V_{n+1} = A_n(U_{n-1} - U_n) + V_{n-1}$ makes it unnecessary to divide when V_{n+1} is being determined.]

(b) Let $Y = (-\sqrt{D} - U)/V$, $Y_n = (-\sqrt{D} - U_n)/V_n$. The stated identity obviously holds by replacing $\sqrt{D}$ by $-\sqrt{D}$ in the proof of (a). We have

$$Y = (p_n/Y_n + p_{n-1})/(q_n/Y_n + q_{n-1}),$$

where p_n and q_n are defined in part (c) of this exercise; hence

$$Y_n = (-q_n/q_{n-1})(Y - p_n/q_n)/(Y - p_{n-1}/q_{n-1}).$$

But by (12), p_{n-1}/q_{n-1} and p_n/q_n are extremely close to X; since $X \neq Y$, $Y - p_n/q_n$ and $Y - p_{n-1}/q_{n-1}$ will have the same sign as $Y - X$ for all large n. This proves that $Y_n < 0$ for all large n; hence $0 < X_n < X_n - Y_n = 2\sqrt{D}/V_n$; V_n must be positive. Also $U_n < \sqrt{D}$, since $X_n > 0$. Hence $V_n < 2\sqrt{D}$, since $V_n \le A_n V_n < \sqrt{D} + U_{n-1}$.

Finally, we want to show that $U_n > 0$. Since $X_n < 1$, we have $U_n > \sqrt{D} - V_n$, so we need only consider the case $V_n > \sqrt{D}$; then $U_n = A_n V_n - U_{n-1} \ge V_n - U_{n-1} > \sqrt{D} - U_{n-1}$, and this is positive as we have already observed.

Note: In the repeating cycle, $\sqrt{D} + U_n = A_n V_n + (\sqrt{D} - U_{n-1}) > V_n$; hence $\lfloor(\sqrt{D} + U_{n+1})/V_{n+1}\rfloor = \lfloor A_{n+1} + V_n/(\sqrt{D} + U_n)\rfloor = A_{n+1} = \lfloor(\sqrt{D} + U_n)/V_{n+1}\rfloor$. In other words A_{n+1} is determined by U_{n+1} and V_{n+1}; we can determine (U_n, V_n) from its successor (U_{n+1}, V_{n+1}) in the period. In fact, when $0 < V_n < \sqrt{D} + U_n$ and $0 < U_n < \sqrt{D}$, the arguments above prove that $0 < V_{n+1} < \sqrt{D} + U_{n+1}$ and $0 < U_{n+1} < \sqrt{D}$; moreover, if the pair (U_{n+1}, V_{n+1}) follows (U', V') with $0 < V' < \sqrt{D} + U'$ and $0 < U' < \sqrt{D}$, then $U' = U_n$ and $V' = V_n$. Hence (U_n, V_n) *is part of the cycle if and only if* $0 < V_n < \sqrt{D} + U_n$ *and* $0 < U_n < \sqrt{D}$.

(c) $$\frac{-V_{n+1}}{V_n} = X_n Y_n = \frac{(q_n X - p_n)(q_n Y - p_n)}{(q_{n-1} X - p_{n-1})(q_{n-1} Y - p_{n-1})}.$$

There is also a companion identity, namely

$$V p_n p_{n-1} + U(p_n q_{n-1} + p_{n-1} q_n) + ((U^2 - D)/V) q_n q_{n-1} = (-1)^n U_n.$$

(d) If $X_n = X_m$ for some $n \neq m$, then X is an irrational number that satisfies the quadratic equation $(q_n X - p_n)/(q_{n-1} X - p_{n-1}) = (q_m X - p_m)/(q_{m-1} X - p_{m-1})$.

14. As in exercise 9, we need only verify the stated identities when c is the last partial quotient, and this verification is trivial. Now Hurwitz's rule gives $2/e = /1, 2, 1, 2, 0, 1, 1, 1, 1, 1, 0, 2, 3, 2, 0, 1, 1, 3, 1, 1, 0, 2, 5, \ldots/$. Taking the reciprocal, collapsing out the zeros as in exercise 9, and taking note of the pattern that appears, we find (cf. exercise 16) that $e/2 = 1 + /2, \overline{2m+1, 3, 1, 2m+1, 1, 3}/$, $m \ge 0$. [*Schriften der phys.-ökon. Gesellschaft zu Königsberg* **32** (1891), 59–62.]

15. (This procedure maintains four integers (A, B, C, D) with the invariant meaning that "our remaining job is to output the continued fraction for $(Ay + B)/(Cy + D)$, where y is the input yet to come.") Initially set $j \leftarrow k \leftarrow 0$, $(A, B, C, D) \leftarrow (a, b, c, d)$; then input x_j and set $(A, B, C, D) \leftarrow (Ax_j + B, A, Cx_j + D, C)$, $j \leftarrow j + 1$, one or more times until $C + D$ has the same sign as C. (When $j \ge 1$ and the input has not terminated, we know that $1 < y < \infty$; and when $C + D$ has the same sign as C we know therefore that $(Ay + B)/(Cy + D)$ lies between $(A + B)/(C + D)$ and A/C.) Now comes the general step: If no integer lies strictly between $(A + B)/(C + D)$ and A/C, output $X_k \leftarrow \lfloor A/C\rfloor$, and set $(A, B, C, D) \leftarrow (C, D, A - X_k C, B - X_k D)$, $k \leftarrow k + 1$; otherwise input x_j and set $(A, B, C, D) \leftarrow (Ax_j + B, A, Cx_j + D, C)$, $j \leftarrow j + 1$. The general step is repeated ad infinitum. However, if at any time the *final* x_j is input, the algorithm immediately switches gears: It outputs the continued fraction for $(Ax_j + B)/(Cx_j + D)$, using Euclid's algorithm, and terminates.

The following tableau shows the working for the requested example, where the matrix $\left(\begin{smallmatrix} B & A \\ D & C \end{smallmatrix}\right)$ begins at the upper left corner, then shifts right one on input, down one

on output:

	x_j	-1	5	1	1	1	2	1	2	∞
X_k	39	97	-58	-193						
-2	-25	-62	37	123						
2			16	53						
3			5	17	22					
7			1	2	3	5				
1				3	1	4	5	14		
1					2	1	3	7		
1							2	7	9	25
12							1	0	1	2
2										1
∞										0

M. Mendès France has shown that the number of quotients output per quotient input is asymptotically bounded between $1/r$ and r, where $r = 2\lfloor K(|ad-bc|)/2\rfloor + 1$ and K is the function defined in exercise 38; this bound is best possible. [*Topics in Number Theory*, ed. by P. Turán, *Colloquia Math. Soc. János Bolyai* **13** (1976), 183–194.]

Gosper has also shown that the above algorithm can be generalized to compute the continued fraction for $(axy+bx+cy+d)/(Axy+Bx+Cy+D)$ from those of x and y (in particular, to compute sums and products). [MIT AI Laboratory Memo 239 (Feb. 29, 1972), Hack 101.]

16. It is not difficult to prove by induction that $f_n(z) = z/(2n+1) + O(z^3)$ is an odd function with a convergent power series in a neighborhood of the origin, and that it satisfies the given differential equation. Hence

$$f_0(z) = \mathop{/}z^{-1} + f_1(z)\mathop{/} = \cdots = \mathop{/}z^{-1}, 3z^{-1}, \ldots, (2n+1)z^{-1} + f_{n+1}(z)\mathop{/}.$$

It remains to prove that $\lim_{n\to\infty} \mathop{/}z^{-1}, 3z^{-1}, \ldots, (2n+1)z^{-1}\mathop{/} = f_0(z)$. [Actually Euler, age 24, obtained continued fraction expansions for the considerably more general differential equation $f_n'(z) = az^m + bf_n(z)z^{m-1} + cf_n(z)^2$; but he did not bother to prove convergence, since formal manipulation and intuition were good enough in the eighteenth century.]

There are several ways to prove the desired limiting equation. First, letting $f_n(z) = \sum_k a_{nk} z^k$, we can argue from the equation

$$(2n+1)a_{n1} + (2n+3)a_{n3}z^2 + (2n+5)a_{n5}z^4 + \cdots = 1 - (a_{n1}z + a_{n3}z^3 + a_{n5}z^5 + \cdots)^2$$

that $(-1)^k a_{n(2k+1)}$ is a sum of terms of the form $c_k/(2n+1)^{k+1}(2n+b_{k1})\ldots(2n+b_{kk})$, where the c_k and b_{km} are positive integers independent of n. For example, we have $-a_{n7} = 4/(2n+1)^4(2n+3)(2n+5)(2n+7) + 1/(2n+1)^4(2n+3)^2(2n+7)$. Thus $|a_{(n+1)k}| \le |a_{nk}|$, and $|f_n(z)| \le \tan|z|$ for $|z| < \pi/2$. This uniform bound on $f_n(z)$ makes the convergence proof very simple. Careful study of this argument reveals that the power series for $f_n(z)$ actually converges for $|z| < \pi\sqrt{2n+1}/2$; this is interesting, since it shows that the singularities of $f_n(z)$ get farther and farther away from the

origin as n grows, so the continued fraction actually represents $\tanh z$ *throughout* the complex plane.

Another proof gives further information of a different kind: If we let

$$A_n(z) = n! \sum_{0\le k\le n} \binom{2n-k}{n} z^k/k! = \sum_{k\ge 0} \frac{(n+k)!\, z^{n-k}}{k!\,(n-k)!},$$

then

$$\begin{aligned} A_{n+1}(z) &= \sum_{k\ge 0} \frac{(n+k-1)!\,\big((4n+2)k + (n+1-k)(n-k)\big)}{k!\,(n+1-k)!}\, z^{n+1-k} \\ &= (4n+2)A_n(z) + z^2 A_{n-1}(z). \end{aligned}$$

It follows, by induction, that

$$\begin{aligned} Q_n\Big(\frac{1}{z}, \frac{3}{z}, \ldots, \frac{2n-1}{z}\Big) &= \frac{A_n(2z) + A_n(-2z)}{2^{n+1} z^n}, \\ Q_{n-1}\Big(\frac{3}{z}, \ldots, \frac{2n-1}{z}\Big) &= \frac{A_n(2z) - A_n(-2z)}{2^{n+1} z^n}. \end{aligned}$$

Hence

$$\big/ z^{-1}, 3z^{-1}, \ldots, (2n-1)z^{-1} \big/ = \frac{A_n(2z) - A_n(-2z)}{A_n(2z) + A_n(-2z)},$$

and we want to show that this ratio approaches $\tanh z$. By Eqs. 1.2.9–11 and 1.2.6–24,

$$e^z A_n(-z) = n! \sum_{m\ge 0} z^m \left(\sum_{0\le k\le n} \binom{m}{k}\binom{2n-k}{n}(-1)^k \right) = \sum_{m\ge 0} \binom{2n-m}{n} z^m \frac{n!}{m!}.$$

Hence

$$e^z A_n(-z) - A_n(z) = R_n(z) = (-1)^n x^{2n+1} \sum_{k\ge 0} \frac{(n+k)!\, x^k}{(2n+k+1)!\, k!}.$$

We now have $(e^{2z}-1)(A_n(2z)+A_n(-2z)) - (e^{2z}+1)(A_n(2z)-A_n(-2z)) = 2R_n(2z)$; hence

$$\tanh z - \big/ z^{-1}, 3z^{-1}, \ldots, (2n-1)z^{-1} \big/ = \frac{2R_n(2z)}{(A_n(2z) + A_n(-2z))(e^{2z}+1)}.$$

Thus we have an exact formula for the difference. When $|z| \le 1$, the factor $e^{2z}+1$ is bounded away from zero, $|R_n(2z)| \le e\, n!/(2n+1)!$, and

$$\begin{aligned} \tfrac{1}{2}|A_n(2z) + A_n(-2z)| &\ge n! \left(\binom{2n}{n} - \binom{2n-2}{n} - \binom{2n-4}{n} - \cdots \right) \\ &\ge \frac{(2n)!}{n!}(1 - \tfrac{1}{4} - \tfrac{1}{16} - \cdots) = \frac{2}{3}\,\frac{(2n)!}{n!}. \end{aligned}$$

Thus convergence is very rapid, even for complex values of z.

To go from this continued fraction to the continued fraction for e^z, we have $\tanh z = 1 - 2/(e^{2z}+1)$; hence we get the continued-fraction representation for $(e^{2z}+1)/2$ by simple manipulations. Hurwitz's rule gives the expansion of $e^{2z}+1$, from which we may subtract unity. For n odd,

$$e^{-2/n} = \big/ \overline{1, 3mn + \lfloor n/2 \rfloor, (12m+6)n, (3m+2)n + \lfloor n/2 \rfloor, 1} \big/, \qquad m \ge 0.$$

Another derivation has been given by C. S. Davis, *J. London Math. Soc.* **20** (1945), 194–198.

17. (b) $/x_1 - 1, 1, x_2 - 2, 1, x_3 - 2, 1, \ldots, 1, x_{2n-1} - 2, 1, x_{2n} - 1/$. [*Note:* One can remove negative parameters from continuants by using the identity

$$Q_{m+n+1}(x_1, \ldots, x_n, -x, y_m, \ldots, y_1) = (-1)^{m-1} Q_{m+n+2}(x_1, \ldots, x_{n-1}, x_n - 1, 1, x - 1, -y_m, \ldots, -y_1),$$

from which we obtain

$$Q_{m+n+1}(x_1, \ldots, x_n, -x, y_m, \ldots, y_1) = -Q_{m+n+3}(x_1, \ldots, x_{n-1}, x_n - 1, 1, x - 2, 1, y_m - 1, y_{m-1}, \ldots, y_1)$$

after a second application.]

(c) $1 + /1, 1, 3, 1, 5, 1, \ldots/ = 1 + /\overline{2m+1, 1}/, \quad m \geq 0.$

19. The sum for $1 \leq k \leq N$ is $\log_b((1+x)(N+1)/(N+1+x))$.

20. Let $H = SG$, $g(x) = (1+x)G'(x)$, $h(x) = (1+x)H'(x)$. Then (35) implies that $h(x+1)/(x+2) - h(x)/(x+1) = -(1+x)^{-2} g(1/(1+x))/(1+1/(1+x))$.

21. $\varphi(x) = c/(cx+1)^2 + (2-c)/((c-1)x+1)^2$, $U\varphi(x) = 1/(x+c)^2$. When $c \leq 1$, the minimum of $\varphi(x)/U\varphi(x)$ occurs at $x = 0$ and is $2c^2 \leq 2$. When $c \geq \phi = \frac{1}{2}(\sqrt{5}+1)$, the minimum occurs at $x = 1$ and is $\leq \phi^2$. When $c \approx 1.31266$ the values at $x = 0$ and $x = 1$ are nearly equal and the minimum is > 3.2; the bounds $(0.29)^n \varphi \leq U^n \varphi \leq (0.31)^n \varphi$ are obtained. Still better bounds come from well-chosen linear combinations $Tg(x) = \sum a_j/(x + c_j)$.

23. By the interpolation formula of exercise 4.6.4–15 with $x_0 = 0$, $x_1 = x$, $x_2 = x + \epsilon$, letting $\epsilon \to 0$, we have the general identity $R_n'(x) = (R_n(x) - R_n(0))/x + \frac{1}{2} x R_n''(\theta(x))$ for some $\theta(x)$ between 0 and x, whenever R_n is a function with continuous second derivative. Hence in this case $R_n'(x) = O(2^{-n})$.

24. ∞. [A. Khinchin, in *Compos. Math.* **1** (1935), 361–382, proved that the sum $A_1 + \cdots + A_n$ of the first n partial quotients of a real number X will be asymptotically $n \lg n$, for almost all X. Exercise 35 shows that the behavior is different for rational X.]

25. Any union of intervals can be written as a union of disjoint intervals, since we have $\bigcup_{k \geq 1} I_k = \bigcup_{k \geq 1} (I_k \setminus \bigcup_{1 \leq j < k} I_j)$, and this is a disjoint union in which $I_k \setminus \bigcup_{1 \leq j < k} I_j$ can be expressed as a finite union of disjoint intervals. Therefore we may take $\mathcal{I} = \bigcup I_k$, where I_k is an interval of length $\epsilon/2^k$ containing the kth rational number in $[0, 1]$, using some enumeration of the rationals. In this case $\mu(\mathcal{I}) \leq \epsilon$, but $\|\mathcal{I} \cap P_n\| = n$ for all n.

26. The continued fractions $/A_1, \ldots, A_t/$ that appear are precisely those for which $A_1 > 1$, $A_t > 1$, and $Q_t(A_1, A_2, \ldots, A_t)$ is a divisor of n. Therefore (6) completes the proof. [*Note:* If $m_1/n = /A_1, \ldots, A_t/$ and $m_2/n = /A_t, \ldots, A_1/$, where m_1 and m_2 are relatively prime to n, then $m_1 m_2 \equiv \pm 1$ (modulo n); this rule defines the correspondence. When $A_1 = 1$ an analogous symmetry is valid, according to (44).]

27. First prove the result for $n = p^e$, then for $n = rs$, where r and s are relatively prime. Alternatively, use the formulas in the next exercise.

28. (a) The left-hand side is multiplicative (see exercise 1.2.4–31), and it is easily evaluated when n is a power of a prime. (c) From (a), we have *Möbius's inversion formula*: If $f(n) = \sum_{d \backslash n} g(d)$, then $g(n) = \sum_{d \backslash n} \mu(n/d) f(d)$.

29. The sum is approximately $(((12\ln 2)/\pi^2)\ln N!)/N - \sum_{d\geq 1}\Lambda(d)/d^2 + 1.47$; here $\sum_{d\geq 1}\Lambda(d)/d^2$ converges to the constant value $-\zeta'(2)/\zeta(2)$, and we know that $\ln N! = N\ln N - N + O(\log N)$ by Stirling's approximation.

30. The modified algorithm affects the calculation if and only if the following division step in the unmodified algorithm would have the quotient 1, and in this case it avoids the following division step. The probability that a given division step is avoided is the probability that $A_k = 1$ and that this quotient is preceded by an even number of quotients equal to 1. By the symmetry condition, this is the probability that $A_k = 1$ and is *followed* by an even number of quotients equal to 1. The latter happens if and only if $X_{k-1} > \phi - 1 = 0.618\ldots$, where ϕ is the golden ratio: For $A_k = 1$ and $A_{k+1} > 1$ iff $\frac{2}{3} \leq X_{k-1} < 1$; $A_k = A_{k+1} = A_{k+2} = 1$ and $A_{k+3} > 1$ iff $\frac{5}{8} \leq X_{k-1} < \frac{2}{3}$; etc. Thus we save approximately $F'_{k-1}(1) - F_{k-1}(\phi - 1) \approx 1 - \lg\phi \approx 0.306$ of the division steps. The average number of steps is approximately $((12\ln\phi)/\pi^2)\ln n$, when $v = n$ and u is relatively prime to n. Kronecker [*Vorlesungen über Zahlentheorie* **1** (Leipzig: Teubner, 1901), 118] observed that this choice of least remainder in absolute value always gives the shortest possible number of iterations, over all algorithms that replace u by $(\pm u) \bmod v$ at each iteration. For further results see N. G. de Bruijn and W. M. Zaring, *Nieuw Archief voor Wiskunde* (3) **1** (1953), 105–112; G. J. Rieger, *Math. Nachr.* **82** (1978), 157–180.

On many computers, the modified algorithm makes each division step longer; the idea of exercise 1, which saves *all* division steps when the quotient is unity, would be preferable in such cases.

31. Let $a_0 = 0$, $a_1 = 1$, $a_{n+1} = 2a_n + a_{n-1}$; then $a_n = ((1+\sqrt{2})^n - (1-\sqrt{2})^n)/2\sqrt{2}$, and the worst case (in the sense of Theorem F) occurs when $u = a_n + a_{n-1}$, $v = a_n$, $n \geq 2$.

This result is due to A. Dupré [*J. de Math.* **11** (1846), 41–64], who also investigated more general "look-ahead" procedures suggested by J. Binet. See P. Bachmann, *Niedere Zahlentheorie* **1** (Leipzig: Teubner, 1902), 99–118, for a discussion of early analyses of Euclid's algorithm.

32. (b) $Q_{m-1}(x_1,\ldots,x_{m-1})Q_{n-1}(x_{m+2},\ldots,x_{m+n})$ corresponds to Morse code sequences of length $(m+n)$ in which a dash occupies positions m and $(m+1)$; the other term corresponds to the opposite case. (Alternatively, use exercise 2. The more general identity

$$\begin{aligned} Q_{m+n}(x_1,\ldots,x_{m+n})Q_k(x_{m+1},\ldots,x_{m+k}) = \\ Q_{m+k}(x_1,\ldots,x_{m+k})Q_n(x_{m+1},\ldots,x_{m+n}) \\ + (-1)^k Q_{m-1}(x_1,\ldots,x_{m-1})Q_{n-k-1}(x_{m+k+2},\ldots,x_{m+n}) \end{aligned}$$

also appeared in Euler's paper.)

33. (a) The new representations are $x = m/d$, $y = (n-m)/d$, $x' = y' = d = \gcd(m, n-m)$, for $\frac{1}{2}n < m < n$. (b) The relation $(n/x') - y \leq x < n/x'$ defines x. (c) Count the x' satisfying (b). (d) A pair of integers $x > y > 0$ with $\gcd(x,y) = 1$ can be uniquely written in the form $x = Q_m(x_1,\ldots,x_m)$, $y = Q_{m-1}(x_1,\ldots,x_{m-1})$, where $x_1 \geq 2$ and $m \geq 1$; here $y/x = /x_m,\ldots,x_1/$. (e) It suffices to show that $\sum_{1\leq k\leq n/2} T(k,n) = 2\lfloor n/2\rfloor + h(n)$. For $1 \leq k \leq n/2$ the continued fractions $k/n = /x_1,\ldots,x_m/$ run through all sequences $(x_1,\ldots,x_m)$ such that $m \geq 1$, $x_1 \geq 2$, $x_m \geq 2$, $Q_m(x_1,\ldots,x_m) \setminus n$; and $T(k,n) = 2 + (m-1)$.

34. (a) Dividing x and y by $\gcd(x,y)$ yields $g(n) = \sum_{d\backslash n} h(n/d)$; apply exercise 28(c), and use the symmetry between primed and unprimed variables. (b) For fixed y and t, the representations with $xd \geq x'$ have $x' < \sqrt{nd}$; hence there are $O(\sqrt{nd}/y)$ such representations. Now sum for $0 < t \leq y < \sqrt{n/d}$. (c) If $s(y)$ is the given sum, then $\sum_{d\backslash y} s(d) = y(H_{2y} - H_y) = k(y)$, say; hence $s(y) = \sum_{d\backslash y} k(y/d)$. Now $k(y) = y\ln 2 - \frac{1}{4} + O(1/y)$. (d) $\sum_{1\leq y\leq n} \varphi(y)/y^2 = \sum_{1\leq y\leq n,\, d\backslash y} \mu(d)/yd = \sum_{cd\leq n} \mu(d)/cd^2$. (Similarly, $\sum_{1\leq y\leq n} \sigma_{-1}(y)/y^2 = O(1)$.) (e) $\sum_{1\leq k\leq n} \mu(k)/k^2 = 6/\pi^2 + O(1/n)$ (see exercise 4.5.2–10(d)); and $\sum_{1\leq k\leq n} \mu(k)\log k/k^2 = O(1)$. Hence we have $h_d(n) = n((3\ln 2)/\pi^2)\ln(n/d) + O(n)$ for $d \geq 1$. Finally $h(n) = 2\sum_{cd\backslash n} \mu(d)h_c(n/cd) = ((6\ln 2)/\pi^2)n(\ln n - \sum - \sum') + O(n\sigma_{-1}(n)^2)$, where the remaining sums are $\sum = \sum_{cd\backslash n} \mu(d)\ln(cd)/cd = 0$ and $\sum' = \sum_{cd\backslash n} \mu(d)\ln c/cd = \sum_{d\backslash n} \Lambda(d)/d$. [It is well known that $\sigma_{-1}(n) = O(\log\log n)$; cf. Hardy and Wright, *Theory of Numbers*, §22.9.]

35. See *Proc. Nat. Acad. Sci.* **72** (1975), 4720–4722.

36. Working the algorithm backwards, we want to choose $k_1, \ldots, k_{n-1}$ so that $u_k \equiv F_{k_1}\ldots F_{k_i-1}F_{k_i} - 1$ (modulo $\gcd(u_{i+1},\ldots,u_n)$) for $1 \leq i < n$, with $u_n = F_{k_1}\ldots F_{k_{n-1}}$ a minimum, where the k's are positive, $k_1 \geq 3$, and $k_1 + \cdots + k_{n-1} = N + n - 1$. The solution is $k_2 = \cdots = k_{n-1} = 2$, $u_n = F_{N-n+3}$. [See *CACM* **13** (1970), 433–436, 447–448.]

37. See *Proc. Amer. Math. Soc.* **7** (1956), 1014–1021; cf. also exercise 6.1–18.

38. Let $m = \lceil n/\phi \rceil$, so that $m/n = \phi^{-1} + \epsilon = /x_1, x_2, \ldots/$ where $0 < \epsilon < 1/n$. Let k be minimal such that $x_k \geq 2$; then $(\phi^{1-k} + (-1)^k F_{k-1}\epsilon)/(\phi^{-k} - (-1)^k F_k\epsilon) \geq 2$, hence k is even and $\phi^{-2} = 2 - \phi \leq \phi^k F_{k+2}\epsilon = (\phi^{2k+2} - \phi^{-2})\epsilon/\sqrt{5}$. [*Ann. Polon. Math.* **1** (1954), 203–206.]

39. At least 287 at bats; $/2,1,95/ = 96/287 = .33449477\ldots$, and no fraction with denominator < 287 lies in the interval $[.3335, .3345] = [/2,1,666/, /2,1,94,1,1,3/]$.

To solve the general question of the fraction in $[a,b]$ with smallest denominator, where $0 < a < b < 1$, note that in terms of regular continued-fraction representations we have $/x_1,x_2,\ldots/ < /y_1,y_2,\ldots/$ iff $(-1)^j x_j < (-1)^j y_j$ for the smallest j with $x_j \neq y_j$, where we place "∞" after the last partial quotient of a rational number. Thus if $a = /x_1,x_2,\ldots/$ and $b = /y_1,y_2,\ldots/$, and if j is minimal with $x_j \neq y_j$, the fractions in $[a,b]$ have the form $c = /x_1,\ldots,x_{j-1},z_j,\ldots,z_m/$ where $/z_j,\ldots,z_m/$ lies between $/x_j,x_{j+1},\ldots/$ and $/y_j,y_{j+1},\ldots/$ inclusive. Let $Q_{-1} = 0$. The denominator

$$Q_{j-1}(x_1,\ldots,x_{j-1})Q_{m-j+1}(z_j,\ldots,z_m) + Q_{j-2}(x_1,\ldots,x_{j-2})Q_{m-j}(z_{j+1},\ldots,z_m)$$

of c is minimized when $m = j$ and $z_j = (j \text{ odd} \Rightarrow y_j + 1 - \delta_{y_{j+1}\infty};\ x_j + 1 - \delta_{x_{j+1}\infty})$. [Another way to derive this method comes from the theory in the following exercise.]

40. One can prove by induction that $p_r q_l - p_l q_r = 1$ at each node, hence p_l and q_l are relatively prime. Since $p/q < p'/q'$ implies that $p/q < (p+p')/(q+q') < p'/q'$, it is also clear that the labels on all left descendants of p/q are less than p/q, while the labels on all its right descendants are greater. Therefore each rational number occurs at most once as a label.

It remains to show that each rational does appear. If $p/q = /a_1,\ldots,a_r,1/$, where each a_i is a positive integer, one can show by induction that the node labeled p/q is found by going left a_1 times, then right a_2 times, then left a_3 times, etc.

[The sequence of labels on successive levels of this tree was first studied by M. A. Stern, *J. für die reine und Angew. Math.* **55** (1858), 193–220, although the relation to binary trees is not explicit in his paper. Peirce independently communicated this construction in a letter dated July 17, 1903, but he never published it; and during the next few years he occasionally amused himself by making rather cryptic remarks about it without revealing the underlying mechanism. See C. S. Peirce, *The New Elements of Mathematics* **3** (The Hague: Mouton, 1976), 781–784, 826–829; also **1**, 207–211; and his *Collected Papers* **4** (1933), 276–280. See also D. H. Lehmer, *AMM* **36** (1929), 59–67.]

41. In fact, the regular continued fractions for numbers of the general form

$$\frac{1}{l_1}+\frac{(-1)^{e_1}}{l_1^2 l_2}+\frac{(-1)^{e_2}}{l_1^4 l_2^2 l_3}+\cdots$$

have an interesting pattern, based on the continuant identity

$$\begin{aligned}Q_{m+n+1}(x_1,\ldots,x_{n-1},x_n-1,1,y_m-1,y_{m-1},\ldots,y_1)=\\ x_nQ_{n-1}(x_1,\ldots,x_{n-1})Q_m(y_m,\ldots,y_1)\\ +(-1)^mQ_{m+n}(x_1,\ldots,x_{n-1},0,-y_m,-y_{m-1},\ldots,-y_1).\end{aligned}$$

This identity is most interesting when $y_m = x_{n-1}$, $y_{m-1} = x_{n-2}$, etc., since

$$Q_{n+1}(z_1,\ldots,z_k,0,z_{k+1},\ldots,z_n)=Q_{n-1}(z_1,\ldots,z_{k-1},z_k+z_{k+1},z_{k+2},\ldots,z_n).$$

In particular we find that if $p_n/q_n = Q_{n-1}(x_2,\ldots,x_n)/Q_n(x_1,\ldots,x_n) = /x_1,\ldots,x_n/$, then $p_n/q_n+(-1)^n/q_n^2 r = /x_1,\ldots,x_n,r-1,1,x_n-1,x_{n-1},\ldots,x_1/$. By changing $/x_1,\ldots,x_n/$ to $/x_1,\ldots,x_{n-1},x_n-1,1/$, we can control the sign $(-1)^n$ as desired.

For example, the partial sums of the first series have the following continued fractions of even length: $/1,1/$; $/1,1,1,1,0,1/ = /1,1,1,2/$; $/1,1,1,2,1,1,1,1,1,1/$; $/1,1,1,2,1,1,1,1,1,1,1,1,0,1,1,1,1,1,2,1,1,1/ = /1,1,1,2,1,1,1,1,1,1,1,2,1,1,1,1,2,1,1,1/$; and from this point on the sequence settles down and obeys a simple reflecting pattern. We find that the nth partial quotient a_n can be computed rapidly as follows, if $n-1 = 20q+r$ where $0\le r<20$:

$$a_n=\begin{cases}1, & \text{if } r=0,2,4,5,6,7,9,10,12,13,14,15,17 \text{ or } 19;\\ 2, & \text{if } r=3 \text{ or } 16;\\ 1+(q+r)\bmod 2, & \text{if } r=8 \text{ or } 11;\\ 2-d_q, & \text{if } r=1;\\ 1+d_{q+1}, & \text{if } r=18.\end{cases}$$

Here d_n is the "dragon sequence" defined by the rules $d_0=1$, $d_{2n}=d_n$, $d_{4n+1}=0$, $d_{4n+3}=1$; the dragon curve discussed in exercise 4.1–18 turns right at its nth step iff $d_n=1$.

Liouville's numbers with $l\ge 3$ are equal to $/l-1,l+1,l^2-1,1,l,l-1,l^{12}-1,1,l-2,l,1,l^2-1,l+1,l-1,l^{72}-1,\ldots/$. The nth partial quotient a_n depends on the dragon sequence on $m \bmod 4$ as follows: If $n \bmod 4 = 1$ it is $l-2+d_{n-1}+(\lfloor n/2\rfloor \bmod 4)$ and if $n \bmod 4 = 2$ it is $l+2-d_{n+2}-(\lfloor n/2\rfloor \bmod 4)$; if $n \bmod 4 = 0$ it is 1 or $l^{k!(k-1)}-1$, depending on whether or not $d_n=0$ or 1, where k is the largest power of 2 dividing n; and if $n \bmod 4 = 3$ it is $l^{k!(k-1)}-1$ or 1, depending on whether $d_{n+1}=0$ or 1, where k is the largest power of 2 dividing $n+1$. When $l=2$ the same rules apply, except that 0's must be removed, so there is a more complicated pattern depending on $n \bmod 24$.

[Cf. *J. Number Theory* **11** (1979), 209–217.]

42. Suppose that $\|qX\| = |qX - p|$. We can always find integers u and v such that $q = uq_{n-1} + vq_n$ and $p = up_{n-1} + vp_n$, where $p_n = Q_{n-1}(A_2, \ldots, A_n)$, since $q_np_{n-1} - q_{n-1}p_n = \pm 1$. We must have $uv < 0$, hence $u(q_{n-1}X - p_{n-1})$ has the same sign as $v(q_nX - p_n)$, and $|qX - p| = |u|\,|q_{n-1}X - p_{n-1}| + |v|\,|q_nX - p_n|$. This completes the proof, since $u \neq 0$. See Theorem 6.4S for a generalization.

43. If x is representable, so is the father of x in the Stern–Peirce tree of exercise 40; thus the representable numbers form a subtree of that binary tree. Let (u/u') and (v/v') be adjacent representable numbers. Then one is an ancestor of the other; say (u/u') is an ancestor of (v/v'), since the other case is similar. Then (u/u') is the nearest left ancestor of (v/v'), so all numbers between u/u' and v/v' are left descendants of (v/v') and the mediant $((u + v)/(u' + v'))$ is its left son. According to the relation between regular continued fractions and the binary tree, the mediant and all of its left descendants will have (u/u') as their last representable p_i/q_i, while all of the mediant's right descendants will have (v/v') as one of the p_i/q_i. (The numbers p_i/q_i label the *fathers* of the 'turning-point' nodes on the path to x.)

44. A counterexample for $M = N = 100$ is $(u/u') = \frac{1}{3}$, $(v/v') = \frac{67}{99}$. However, the identity is almost always true, because of (12); it fails only when $u/u' + v/v'$ is very nearly equal to a fraction that is simpler than (u/u').

45. See M. S. Waterman, *BIT* **17** (1977), 465–478.

SECTION 4.5.4

1. If d_k isn't prime, its prime factors are cast out before d_k is tried.

2. No; the algorithm would fail if $p_{t-1} = p_t$, giving "1" as a spurious prime factor.

3. Let P be the product of the first 168 primes. [*Note:* Although $P = 19590\ldots5910$ is a 416-digit number, such a gcd can be computed in much less time than it would take to do 168 divisions, if we just want to test whether or not n is prime.]

4. In the notation of exercise 3.1–11,

$$\sum_{\mu,\,\lambda} 2^{\lceil \lg \max(\mu+1,\lambda)\rceil} P(\mu,\lambda) = \frac{1}{m} \sum_{l \geq 1} f(l) \prod_{1 \leq k < l} \left(1 - \frac{k}{m}\right),$$

where $f(l) = \sum_{1 \leq \lambda \leq l} 2^{\lceil \lg \max(l-\lambda,\lambda)\rceil}$. If $l = 2^{k+\theta}$, where $0 < \theta \leq 1$, we have $f(l) = l^2(3 \cdot 2^{-\theta} - 2 \cdot 2^{-2\theta})$, where the function $3 \cdot 2^{-\theta} - 2 \cdot 2^{-2\theta}$ reaches a maximum of $\frac{9}{8}$ at $\theta = \lg(4/3)$ and has a minimum of 1 at $\theta = 0$ and 1. Therefore the average value of $2^{\lceil \lg \max(\mu+1,\lambda)\rceil}$ lies between 1.0 and 1.125 times the average value of $\mu + \lambda$, and the result follows.

[Algorithm B is a refinement of Pollard's original algorithm, which was based on exercise 3.1–6(b) instead of the (yet undiscovered) result in exercise 3.1–7. He showed that the least n such that $X_{2n} = X_n$ has average value $\sim (\pi^2/12)Q(m)$; this constant $\pi^2/12$ is explained by Eq. 4.5.3–21. Hence the average value of $3n$ in his original method is $\sim (\pi/2)^{5/2}\sqrt{m} = 3.092\sqrt{m}$. Richard Brent has observed that, as $m \to \infty$, the density $\prod_{1 \leq k < l}(1 - k/m) = \exp(-l(l-1)/2m + O(l^3/m^2))$ approaches a normal distribution, and we may assume that θ is uniformly distributed. Then $3 \cdot 2^{-\theta} - 2 \cdot 2^{-2\theta}$ takes the average value $3/(4 \ln 2)$, and the average number of iterations needed by Algorithm B comes to $\sim (3/(4 \ln 2) + \frac{1}{2})\sqrt{\pi m/2} = 1.983\sqrt{m}$. A similar analysis of the more general method in the answer to exercise 3.1–7 gives $\sim 1.926\sqrt{m}$, when $p = 2.4771$ is chosen "optimally" as the root of $(p^2 - 1)\ln p = p^2 - p + 1$.]

5. $x \bmod 3 = 0$; $x \bmod 5 = 0, 1, 4$; $x \bmod 7 = 0, 1, 6$; $x \bmod 8 = 1, 3, 5, 7$; $x > 103$. The first try is $x = 105$; and $(105)^2 - 10541 = 484 = 22^2$. This would also have been found by Algorithm C in a relatively short time. Thus $10541 = 83 \cdot 127$.

6. Let us count the number of solutions (x, y) of the congruence $N \equiv (x - y)(x + y)$ (modulo p), where $0 \le x, y < p$. Since $N \not\equiv 0$ and p is prime, $x + y \not\equiv 0$. For each $v \not\equiv 0$ there is a unique u (modulo p) such that $N \equiv uv$. The congruences $x - y \equiv u$, $x + y \equiv v$ now uniquely determine $x \bmod p$ and $y \bmod p$, since p is odd. Thus the stated congruence has exactly $p - 1$ solutions (x, y). If (x, y) is a solution, so is $(x, p - y)$ if $y \not\equiv 0$, since $(p - y)^2 \equiv y^2$; and if (x, y_1) and (x, y_2) are solutions with $y_1 \not\equiv y_2$, we have $y_1^2 \equiv y_2^2$; hence $y_1 = p - y_2$. Thus the number of different x values among the solutions (x, y) is $(p - 1)/2$ if $N \equiv x^2$ has no solutions, or $(p + 1)/2$ if $N \equiv x^2$ has solutions.

7. One procedure is to keep two indices for each modulus, one for the current word position and one for the current bit position; loading two words of the table and doing an indexed shift command will bring the table entries into proper alignment. (Many computers have special facilities for such bit manipulation.)

8. (We may assume that $N = 2M$ is even.) The following algorithm uses an auxiliary table $X[1], X[2], \ldots, X[M]$, where $X[k]$ represents the primality of $2k + 1$.

S1. Set $X[k] \leftarrow 1$ for $1 \le k \le M$. Also set $j \leftarrow 1$, $p \leftarrow 1$, $p \leftarrow 3$, $q \leftarrow 4$. (During this algorithm $p = 2j + 1$, $q = 2j + 2j^2$; the integer variables j, k, p, q may readily be manipulated in index registers.)

S2. If $X[j] = 0$, go to S4. Otherwise output p, which is prime, and set $k \leftarrow q$.

S3. If $k \le M$, then set $X[k] \leftarrow 0$, $k \leftarrow k + p$, and repeat this step.

S4. Set $j \leftarrow j + 1$, $p \leftarrow p + 2$, $q \leftarrow q + 2p - 2$. If $j \le M$, return to S2. ∎

A major part of this calculation could be made noticeably faster if q (instead of j) were tested against M in step S4, and if a new loop were appended that outputs $2j + 1$ for all remaining $X[j]$ that equal 1, suppressing the manipulation of p and q.

Improvements in the efficiency of sieve methods for generating primes are discussed in exercise 5.2.3–15 and in Section 7.1.

9. If p^2 is a divisor of n for some prime p, then p is a divisor of $\lambda(n)$, but not of $n - 1$. If $n = p_1 p_2$, where $p_1 < p_2$ are primes, then $p_2 - 1$ is a divisor of $\lambda(n)$ and therefore $p_1 p_2 - 1 \equiv 0$ (modulo $p_2 - 1$). Since $p_2 \equiv 1$, this means $p_1 - 1$ is a multiple of $p_2 - 1$, contradicting the assumption $p_1 < p_2$. [Values of n for which $\lambda(n)$ properly divides $n - 1$ are called "Carmichael numbers." For example, here are some small Carmichael numbers with up to six prime factors: $3 \cdot 11 \cdot 17$, $5 \cdot 13 \cdot 17$, $7 \cdot 11 \cdot 13 \cdot 41$, $5 \cdot 7 \cdot 17 \cdot 19 \cdot 73$, $5 \cdot 7 \cdot 17 \cdot 73 \cdot 89 \cdot 107$.]

10. Let k_p be the order of x_p modulo n, and let λ be the least common multiple of all the k_p's. Then λ is a divisor of $n - 1$ but not of any $(n - 1)/p$, so $\lambda = n - 1$. Since $x_p^{\varphi(n)} \bmod n = 1$, $\varphi(n)$ is a multiple of k_p for all p, so $\varphi(n) \ge \lambda$. But $\varphi(n) < n - 1$ when n is not prime. (Another way to carry out the proof is to construct an element x of order $n - 1$ from the x_p's, by the method of exercise 3.2.1.2–15.)

11.

U	V	A	P	S	T	Output
1984	1	0	992	0	—	
1981	1981	1	992	1	1981	
1983	4	495	993	0	1	$993^2 \equiv +2^2$
1983	991	2	98109	1	991	
1981	4	495	2	0	1	$2^2 \equiv +2^2$
1984	1981	1	99099	1	1981	
1984	1	1984	99101	0	1	$99101^2 \equiv +2^0$

The factorization $199 \cdot 991$ is evident from the first or last outputs. The shortness of the cycle, and the appearance of the well-known number 1984, are probably just coincidences.

12. The following algorithm makes use of an auxiliary $(m+1) \times (m+1)$ matrix of single-precision integers E_{jk}, $0 \le j, k \le m$; a single-precision vector $(b_0, b_1, \ldots, b_m)$; and a multiple-precision vector $(x_0, x_1, \ldots, x_m)$ with entries in the range $0 \le x_k < N$.

F1. [Initialize.] Set $b_i \leftarrow -1$ for $0 \le i \le m$; then set $j \leftarrow 0$.

F2. [Next solution.] Get the next output $(x, e_0, e_1, \ldots, e_m)$ produced by Algorithm E. (It is convenient to regard Algorithms E and F as coroutines.) Set $k \leftarrow 0$.

F3. [Search for odd.] If $k > m$ go to step F5. Otherwise if e_k is even, set $k \leftarrow k+1$ and repeat this step.

F4. [Linear dependence?] If $b_k \ge 0$, then set $i \leftarrow b_k$, $x \leftarrow (x_i x) \bmod N$, $e_r \leftarrow e_r + E_{ir}$ for $0 \le r \le m$; set $k \leftarrow k+1$ and return to F3. Otherwise set $b_k \leftarrow j$, $x_j \leftarrow x$, $E_{jr} \leftarrow e_r$ for $0 \le r \le m$; set $j \leftarrow j+1$ and return to F2. (In the latter case we have a new linearly independent solution, modulo 2, whose first odd component is e_k.)

F5. [Try to factor.] (Now e_0, e_1, ..., e_m are even.) Set

$$y \leftarrow \left((-1)^{e_0/2} p_1^{e_1/2} \ldots p_m^{e_m/2}\right) \bmod N.$$

If $x = y$ or if $x + y = N$, return to F2. Otherwise compute $\gcd(x - y, N)$, which is a proper factor of N, and terminate the algorithm. ∎

It can be shown that this algorithm finds a factor, whenever it is possible to deduce one from the given outputs of Algorithm E. [*Proof:* Let the outputs of Algorithm E be $(X_i, E_{i0}, \ldots, E_{im})$ for $1 \le i \le t$, and suppose that we could find a factorization $N = N_1 N_2$ when $x \equiv X_1^{a_1} \ldots X_t^{a_t}$ and $y \equiv (-1)^{e_0/2} p_1^{e_1/2} \ldots p_m^{e_m/2}$ (modulo N), where $e_j = a_1 E_{1j} + \cdots + a_t E_{tj}$ is even for all j. Then $x \equiv \pm y$ (modulo N_1) and $x \equiv \mp y$ (modulo N_2). It is not difficult to see that this solution can be transformed into a pair (x, y) that appears in step F5, by a series of steps that systematically replace (x, y) by (xx', yy') where $x' \equiv \pm y'$ (modulo N).]

13. There are 2^d values of x having the same exponents $(e_0, \ldots, e_m)$, since we can choose the sign of x modulo $q_i^{f_i}$ arbitrarily when $N = q_1^{f_1} \ldots q_d^{f_d}$. Exactly two of these 2^d values will fail to yield a factor.

14. Since $P^2 \equiv kNQ^2$ (modulo p) for any prime divisor p of V, we have $1 \equiv P^{2(p-1)/2} \equiv (kNQ^2)^{(p-1)/2} \equiv (kN)^{(p-1)/2}$ (modulo p), if $P \not\equiv 0$.

15. $U_n = (a^n - b^n)/\sqrt{D}$, where $a = \frac{1}{2}(P+\sqrt{D})$, $b = \frac{1}{2}(P-\sqrt{D})$, $D = P^2-4Q$. Then $2^{n-1}U_n = \sum_k \binom{n}{2k+1} P^{n-2k-1}D^k$; so $U_p \equiv D^{(p-1)/2}$ (modulo p) if p is an odd prime. Similarly, if $V_n = a^n + b^n = U_{n+1} - QU_{n-1}$, then $2^{n-1}V_n = \sum_k \binom{n}{2k} P^{n-2k}D^k$, and $V_p \equiv P^n \equiv P$. Thus if $U_p \equiv -1$, we find that $U_{p+1} \bmod p = 0$. If $U_p \equiv 1$, we find that $(QU_{p-1}) \bmod p = 0$; here if Q is a multiple of p, $U_n \equiv P^{n-1}$ (modulo p) for $n > 0$, so U_n is never a multiple of p; if Q is not a multiple of p, $U_{p-1} \bmod p = 0$. Therefore as in Theorem L, $U_t \bmod N = 0$ if $N = p_1^{e_1}\ldots p_r^{e_r}$, $\gcd(N, Q) = 1$, and $t = \operatorname{lcm}_{1\le j\le r}(p_j^{e_j-1}(p_j + \epsilon_j))$. Under the assumptions of this exercise, the rank of apparition of N is $N+1$; hence N is prime to Q and t is a multiple of $N+1$. Also, the assumptions of this exercise imply that each p_j is odd and each ϵ_j is ± 1, so $t \le 2^{1-r}\prod p_j^{e_j-1}(p_j + \frac{1}{3}p_j) = 2(\frac{2}{3})^r N$; hence $r = 1$ and $t = p_1^{e_1} + \epsilon_1 p_1^{e_1-1}$. Finally, therefore, $e_1 = 1$ and $\epsilon_1 = 1$.

Note: If this test for primality is to be any good, we must choose P and Q in such a way that the test will probably work. Lehmer suggests taking $P = 1$ so that $D = 1 - 4Q$, and choosing Q so that $\gcd(N, QD) = 1$. (If the latter condition fails, we know already that N is not prime, unless $|QD| \ge N$.) Furthermore, the derivation above shows that we will want $\epsilon_1 = 1$, that is, $D^{(N-1)/2} \equiv -1$ (modulo N). This is another condition that determines the choice of Q. Furthermore, if D satisfies this condition, and if $U_{N+1} \bmod N \neq 0$, we know that N is *not* prime.

Example: If $P = 1$ and $Q = -1$, we have the Fibonacci sequence, with $D = 5$. Since $5^{11} \equiv -1$ (modulo 23), we might attempt to prove that 23 is prime by using the Fibonacci sequence:

$$\langle F_n \bmod 23\rangle = 0, 1, 1, 2, 3, 5, 8, 13, 21, 11, 9, 20, 6, 3, 9, 12, 21, 10, 8, 18, 3, 21, 1, 22, 0, \ldots,$$

so 24 is the rank of apparition of 23 and the test works. However, the Fibonacci sequence cannot be used in this way to prove the primality of 13 or 17, since $F_7 \bmod 13 = 0$ and $F_9 \bmod 17 = 0$. When $p \equiv \pm 1$ (modulo 10), we have $5^{(p-1)/2} \bmod p = 1$, so F_{p-1} (not F_{p+1}) is divisible by p.

17. Let $f(q) = 2\lg q - 1$. When $q = 2$ or 3, the tree has at most $f(q)$ nodes. When $q > 3$ is prime, let $q = 1 + q_1 \ldots q_t$ where $t \ge 2$ and $q_1, \ldots, q_t$ are prime. The size of the tree is $\le 1 + \sum f(q_k) = 2 + f(q-1) - t < f(q)$. [*SIAM J. Computing* **7** (1975), 214–220.]

18. $x(G(\alpha) - F(\alpha))$ is the number of $n \le x$ whose second-largest prime factor is $\le x^\alpha$ and whose largest prime factor is $> x^\alpha$. Hence

$$xG'(t)\,dt = (\pi(x^{t+dt}) - \pi(x^t)) \cdot x^{1-t}(G(t/(1-t)) - F(t/(1-t))).$$

The probability that $p_{t-1} \le \sqrt{p_t}$ is $\int_0^1 F(t/2(1-t))t^{-1}\,dt$. [Curiously, it can be shown that this also equals $\int_0^1 F(t/(1-t))\,dt$, the average value of $\log p_t/\log x$, and it also equals Golomb's constant λ of exercises 1.3.3–23 and 3.1–13. The derivative $G'(0)$ can be shown to equal $\int_0^1 F(t/(1-t))t^{-2}\,dt = F(1) + 2F(\frac{1}{2}) + 3F(\frac{1}{3}) + \cdots = e^\gamma$. The third-largest prime factor has $H(\alpha) = \int_0^\alpha (H(t/(1-t)) - G(t/(1-t)))t^{-1}\,dt$ and $H'(0) = \infty$. See P. Billingsley, *Period. Math. Hungar.* **2** (1972), 283–289; J. Galambos, *Acta Arith.* **31** (1976), 213–218; D. E. Knuth and L. Trabb Pardo, *Theoretical Comp. Sci.* **3** (1976), 321–348.]

19. $M = 2^D - 1$ is a multiple of all p for which the order of 2 modulo p divides D. To extend this idea, let $a_1 = 2$ and $a_{j+1} = a_j^{q_j} \bmod N$, where $q_j = p_j^{e_j}$, p_j is the jth prime, and $e_j = \lfloor \log 1000/\log p_j \rfloor$; let $A = a_{169}$. Now compute $b_q = \gcd(A^q - 1, N)$ for all primes q between 10^3 and 10^5. One way to do this is to start with $A^{1009} \bmod N$ and then to multiply alternately by $A^4 \bmod N$ and $A^2 \bmod N$. (A similar method was used in the 1920s by D. N. Lehmer, but he didn't publish it.) As with Algorithm B we can avoid most of the gcd's by batching; e.g., since $b_{30r-k} = \gcd(A^{30r} - A^k, N)$, we might try batches of 8, computing $c_r = (A^{30r} - A^{29})(A^{30r} - A^{23}) \ldots (A^{30r} - A) \bmod N$, then $\gcd(c_r, N)$ for $33 < r \leq 3334$.

22. Algorithm P fails only when the random number x does not reveal the fact that n is nonprime. Say x is *bad* if $x^q \bmod n = 1$ or if one of the numbers $x^{2^j q}$ is $\equiv -1$ (modulo n) for $0 \leq j < k$. Since 1 is bad, we have $p_n = (b_n - 1)/(n-2) < b_n/(n-1)$, where b_n is the number of bad x such that $1 \leq x < n$, when n is not prime.

Every bad x satisfies $x^{n-1} \equiv 1$ (modulo n). When p is prime, the number of solutions to the congruence $x^q \equiv 1$ (modulo p^e) for $1 \leq x \leq p^e$ is the number of solutions of $qy \equiv 0$ (modulo $p^{e-1}(p-1)$) for $0 \leq y < p^{e-1}(p-1)$, namely $\gcd(q, p^{e-1}(p-1))$, since we may replace x by a^y where a is a primitive root.

Let $n = n_1^{e_1} \ldots n_r^{e_r}$, where the n_i are distinct primes. According to the Chinese remainder theorem, the number of solutions to the congruence $x^{n-1} \equiv 1$ (modulo n) is $\prod_{1 \leq i \leq r} \gcd(n-1, n_i^{e_i - 1}(n_i - 1))$, and this is at most $\prod_{1 \leq i \leq r}(n_i - 1)$ since n_i is relatively prime to $n-1$. If some $e_i > 1$, we have $n_i - 1 \leq \frac{2}{9} n_i^{e_i}$, hence the number of solutions is at most $\frac{2}{9}n$; in this case $b_n \leq \frac{2}{9}n \leq \frac{1}{4}(n-1)$, since $n \geq 9$.

Therefore we may assume that n is the product $n_1 \ldots n_r$ of distinct primes. Let $n_i = 1 + 2^{k_i} q_i$, where $k_1 \leq \cdots \leq k_r$. Then $\gcd(n-1, n_i - 1) = 2^{k_i'} q_i'$, where $k_i' = \min(k, k_i)$ and $q_i' = \gcd(q, q_i)$. Modulo n_i, the number of x such that $x^q \equiv 1$ is q_i'; and the number of x such that $x^{2^j q} \equiv -1$ is $2^j q_i'$ for $0 \leq j < k_i'$, otherwise 0. Since $k \geq k_1$, we have $b_n = q_1' \ldots q_r' (1 + \sum_{0 \leq j < k_1} 2^{jr})$.

To complete the proof, it suffices to show that $b_n \leq \frac{1}{4} q_1 \ldots q_r 2^{k_1 + \cdots + k_r} = \frac{1}{4}\varphi(n)$, since $\varphi(n) < n - 1$. We have

$$\begin{aligned}(1 + \textstyle\sum_{0 \leq j < k_1} 2^{jr})/2^{k_1 + \cdots + k_r} &\leq (1 + \textstyle\sum_{0 \leq j < k_1} 2^{jr})/2^{k_1 r} \\ &= 1/(2^r - 1) + (2^r - 2)/(2^{k_1 r}(2^r - 1)) \leq 1/2^{r-1},\end{aligned}$$

so the result follows unless $r = 2$ and $k_1 = k_2$. If $r = 2$, exercise 9 shows that $n - 1$ is not a multiple of both $n_1 - 1$ and $n_2 - 1$. Thus if $k_1 = k_2$ we cannot have both $q_1' = q_1$ and $q_2' = q_2$; it follows that $q_1' q_2' \leq \frac{1}{3} q_1 q_2$ and $b_n \leq \frac{1}{6}\varphi(n)$ in this case.

[*Reference: J. Number Theory* (1980), to appear. The above proof shows that p_n is near $\frac{1}{4}$ in only two cases, when $n = (1+2q_1)(1+4q_1)$ or $(1+2q_1)(1+2q_2)(1+2q_3)$. For example, when $n = 49939 \cdot 99877$ we have $b_n = \frac{1}{4}(49938 \cdot 99876)$ and $p_n \approx .2499925$. See the next answer for further remarks.]

23. (a) The proofs are simple except perhaps for the reciprocity law. Let $p = p_1 \ldots p_s$ and $q = q_1 \ldots q_r$, where the p_i and q_j are prime. Then

$$\left(\frac{p}{q}\right) = \prod_{i,j} \left(\frac{p_i}{q_j}\right) = \prod_{i,j} (-1)^{(p_i - 1)(q_j - 1)/4} \left(\frac{q_j}{p_i}\right) = (-1)^{\sum_{i,j} (p_i - 1)(q_j - 1)/4} \left(\frac{q}{p}\right),$$

so we need only verify that $\sum_{i,j}(p_i-1)(q_j-1)/4 \equiv (p-1)(q-1)/4$ (modulo 2). But $\sum_{i,j}(p_i-1)(q_j-1)/4 = (\sum_i(p_i-1)/2)(\sum_j(q_j-1)/2)$ is odd iff an odd number of the p_i and an odd number of the q_j are $\equiv 3$ (modulo 4), and this holds iff $(p-1)(q-1)/4$ is odd.

(b) As in exercise 22, we may assume that $n = n_1 \ldots n_r$ where the $n_i = 1 + 2^{k_i}q_i$ are distinct primes, and $k_1 \le \cdots \le k_r$; we let $\gcd(n-1, n_i-1) = 2^{k_i'}q_i'$ and we call x *bad* if it falsely makes n look prime. Let $\Pi_n = \prod_{1\le i\le r} q_i' 2^{\min(k_i,k-1)}$ be the number of solutions of $x^{(n-1)/2} \equiv 1$. The number of bad x with $(\frac{x}{n}) = 1$ is Π_n, times an extra factor of $\frac{1}{2}$ if $k_1 < k$. (This factor $\frac{1}{2}$ is needed to ensure that $(\frac{x}{n_i}) = -1$ for an even number of the n_i with $k_i < k$.) The number of bad x with $(\frac{x}{n}) = -1$ is Π_n if $k_1 = k$, otherwise 0. [If $x^{(n-1)/2} \equiv -1$ (modulo n_i), we have $(\frac{x}{n_i}) = -1$ if $k_i = k$, $(\frac{x}{n_i}) = +1$ if $k_i > k$, and a contradiction if $k_i < k$. If $k_1 = k$, there are an odd number of k_i equal to k.]

Notes: The probability of a bad guess is $> \frac{1}{4}$ only if n is a Carmichael number with $k_r < k$; for example, $n = 7 \cdot 13 \cdot 19 = 1729$, a number made famous by Rāmānujan in another context. Louis Monier has extended the above analyses to obtain the following closed formulas for the number of bad x in general:

$$b_n = \left(1 + \frac{2^{rk_1}-1}{2^r-1}\right) \prod_{1\le i\le r} q_i';$$

$$b_n' = \delta_n \prod_{1\le i\le r} \gcd\left(\frac{n-1}{2},\, n_i - 1\right).$$

Here b_n' is the number of bad x in this exercise, and δ_n is either 2 (if $k_1 = k$), or $\frac{1}{2}$ (if $k_i < k$ and e_i is odd for some i), or 1 (otherwise).

(c) If $x^q \bmod n = 1$, then $1 = (\frac{x^q}{n}) = (\frac{x}{n})^q = (\frac{x}{n})$. If $x^{2^j q} \equiv -1$ (modulo n), then the order of x modulo n_i must be an odd multiple of 2^{j+1} for all prime divisors n_i of n. Let $n = n_1^{e_1} \ldots n_r^{e_r}$ and $n_i = 1 + 2^{j+1}q_i''$; then $(\frac{x}{n_i}) = (-1)^{q_i''}$, so $(\frac{x}{n}) = +1$ or -1 according as $\sum e_i q_i''$ is even or odd. Since $n \equiv (1 + 2^{j+1}\sum e_i q_i'')$ (modulo 2^{j+2}), the sum $\sum e_i q_i''$ is odd iff $j + 1 = k$. [Univ. de Paris-Sud, Lab. Rech. Informatique, Rapport 20 (1978).]

24. Let M_1 be a matrix having one row for each nonprime odd number in the range $1 \le n \le N$ and having $N-1$ columns numbered from 2 to N; the entry in row n column x is 1 if n passes the x test of Algorithm P, otherwise it is zero. When $N = qn + r$ and $0 \le r < n$, we know that row n contains at most $\frac{1}{4}qn + \min(\frac{1}{2}n, r) = \frac{1}{4}N + \min(\frac{1}{4}n - \frac{1}{4}r, \frac{3}{4}r) \le \frac{1}{4}N + \frac{3}{16}n < \frac{1}{2}N$ entries equal to 0, so at least half of the entries in the matrix are 1. Thus, some column x_1 of M_1 has at least half of its entries equal to 1. Removing column x_1 and all rows in which this column contains 1 leaves a matrix M_2 having similar properties; a repetition of this construction produces matrix M_r with $N-r$ columns and fewer than $N/2^r$ rows, and with at least $\frac{1}{2}(N-1)$ entries per row equal to 1. [Cf. *Proc. IEEE Symp. Foundations of Comp. Sci.* **19** (1978), 78.]

[A similar proof implies the existence of a *single* infinite sequence $x_1 < x_2 < \cdots$ such that the number $n > 1$ is prime if and only if it passes the x test of Algorithm P for $x = x_1, \ldots, x = x_m$, where $m = \frac{1}{2}\lfloor \lg n \rfloor (\lfloor \lg n \rfloor - 1)$. Does there exist a sequence $x_1 < x_2 < \cdots$ having this property but with $m = O(\log n)$?]

25. This theorem was first proved rigorously by von Mangoldt [*J. für die reine und angew. Math.* **114** (1895), 255–305], who showed in fact that the $O(1)$ term is equal

to $\frac{1}{2}(x \text{ is prime}) + \text{constant} + \int_x^\infty dt/(t^2-1)t\ln t$. The constant is $\operatorname{li} 2 - \ln 2 = \gamma + \ln\ln 2 + \sum_{n\geq 2}(\ln 2)^n/nn! = 0.35201\ 65995\ 57547\ 47542\ 73567\ 67736\ 43656\ 84471+$.

26. If N is not prime, it has a prime factor $q \leq \sqrt{N}$. By hypothesis, every prime divisor p of f has an integer x_p such that the order of x_p modulo q is a divisor of $N-1$ but not of $(N-1)/p$. Therefore if p^k divides f, the order of x_p modulo q is a multiple of p^k. Exercise 3.2.1.2–15 now tells us that there is an element x of order f modulo q. But this is impossible, since it implies that $q^2 \geq (f+1)^2 \geq (f+1)r \geq N$, and equality cannot hold. [*Proc. Camb. Phil. Soc.* **18** (1914), 29–30.]

27. If k is not divisible by 3 and if $k \leq 2^n+1$, the number $k\cdot 2^n+1$ is prime iff $3^{2^{n-1}k} \equiv -1$ (modulo $k\cdot 2^n+1$). For if this condition holds, $k\cdot 2^n+1$ is prime by exercise 26; and if $k\cdot 2^n+1$ is prime, the number 3 is a quadratic nonresidue mod $k\cdot 2^n+1$ by the law of quadratic reciprocity, since $k\cdot 2^n+1 \bmod 12 = 5$. [This test was stated without proof by Proth in *Comptes Rendus* **87** (Paris, 1878), 926.]

To implement Proth's test with the necessary efficiency, we need to be able to compute $x^2 \bmod (k\cdot 2^n+1)$ with about the same speed as we can compute the quantity $x^2 \bmod (2^n-1)$. Let $x^2 = A\cdot 2^n + B$ and let $A = qk + r$ where $0 \leq r < k$; we can determine q and r rapidly, when k is a single-precision number. Then $x^2 \equiv B - q + r\cdot 2^n$ (modulo $k\cdot 2^n+1$), so the remainder is easily obtained.

[To test numbers of the form $3\cdot 2^n+1$ for primality, the job is only slightly more difficult; we first try random single-precision numbers until finding one that is a quadratic nonresidue mod $3\cdot 2^n+1$ by the law of quadratic reciprocity, then use this number in place of "3" in the above test. If $n \bmod 4 \neq 0$, the number 5 can be used. It turns out that $3\cdot 2^n+1$ is prime when $n = 1, 2, 5, 6, 8, 12, 18, 30, 36, 41, 66, 189, 201, 209, 276, 353, 408, 438, 534, 2208, 2816, 3168, 3189, 3912$; and $5\cdot 2^n+1$ is prime when $n = 1, 3, 7, 13, 15, 25, 39, 55, 75, 85, 127, 1947$. See R. M. Robinson, *Proc. Amer. Math. Soc.* **9** (1958), 673–681; the additional numbers listed here were found by M. F. Plass.]

28. $f(p, p^2d) = 2/(p+1) + f(p,d)/p$, since $1/(p+1)$ is the probability that A is a multiple of p. $f(p,pd) = 1/(p+1)$ when $d \bmod p \neq 0$. $f(2, 4k+3) = \frac{1}{3}$ since $A^2 - (4k+3)B^2$ cannot be a multiple of 4; $f(2, 8k+5) = \frac{2}{3}$ since $A^2 - (8k+5)B^2$ cannot be a multiple of 8; $f(2, 8k+1) = \frac{1}{3} + \frac{1}{3} + \frac{1}{3} + \frac{1}{6} + \frac{1}{12} + \cdots = \frac{4}{3}$. $f(p,d) = (2p/(p^2-1), 0)$ if $d^{(p-1)/2} \bmod p = (1, p-1)$, respectively, for odd p.

29. The number of solutions to the equation $x_1 + \cdots + x_m \leq r$ in nonnegative integers x_i is $\binom{m+r}{r} \geq m^r/r!$, and each of these corresponds to a unique integer $p_1^{x_1}\ldots p_m^{x_m} \leq n$. [For sharper estimates, in the special case that p_j is the jth prime for all j, see N. G. de Bruijn, *Indag. Math.* **28** (1966), 240–247; H. Halberstam, *Proc. London Math. Soc.* (3) **21** (1970), 102–107.]

30. If $p_1^{e_1}\ldots p_m^{e_m} \equiv x_i^2$ (modulo q_i), we can find y_i such that $p_1^{e_1}\ldots p_m^{e_m} \equiv (\pm y_i)^2$ (modulo $q_i^{d_i}$), hence by the Chinese remainder theorem we obtain 2^d values of X such that $X^2 \equiv p_1^{e_1}\ldots p_m^{e_m}$ (modulo N). Such $(e_1, \ldots, e_m)$ correspond to at most $\binom{r}{r/2}$ pairs $(e'_1, \ldots, e'_m; e''_1, \ldots, e''_m)$ having the hinted properties. Now for each of the 2^d binary numbers $a = (a_1 \ldots a_d)_2$, let n_a be the number of exponents $(e'_1, \ldots, e'_m)$ such that $(p_1^{e'_1}\ldots p_m^{e'_m})^{(q_i-1)/2} \equiv (-1)^{a_i}$ (modulo q_i); we have proved that the required number of integers X is $\geq 2^d(\sum_a n_a^2)/\binom{r}{r/2}$. Since $\sum_a n_a$ is the number of ways to choose at most $r/2$ objects from a set of m objects with repetitions permitted, namely $\binom{m+r/2}{r/2}$, we have $\sum_a n_a^2 \geq \binom{m+r/2}{r/2}^2/2^d \geq m^r/(2^d(r/2)!)$. [Cf. J. *Number Theory*, to appear.]

31. Set $r = M$, $qM = 4m$, $\epsilon M = 2m$.

32. Let $M = \lfloor \sqrt[3]{N} \rfloor$, and let the places x_i of each message be restricted to the range $0 \le x < M^3 - M^2$. If $x \ge M$, encode it as $x^3 \bmod N$ as before, but if $x < M$ change the encoding to $(x + yM)^3 \bmod N$, where y is a random number in the range $M^2 - M \le y \le M^2$. To decode, first take the cube root; and if the result is $M^3 - M^2$ or more, take the remainder mod M.

34. Let P be the probability that $x^m \bmod p = 1$ and let Q be the probability that $x^m \bmod q = 1$. The probability that $\gcd(x^m - 1, N) = p$ or q is $P(1-Q) + Q(1-P) = P + Q - 2PQ$. If $P \le \frac{1}{2}$ or $Q \le \frac{1}{2}$, this probability is $\ge \frac{1}{2}\max(P, Q) \ge \frac{1}{2}10^{-6}$, so we have a good chance of finding a factor after about $10^6 \log m$ arithmetic operations modulo N. On the other hand if $P > \frac{1}{2}$ and $Q > \frac{1}{2}$ then $P \approx Q \approx 1$, since we have the general formula $P = \gcd(m, p-1)/p$; thus m is a multiple of $\operatorname{lcm}(p-1, q-1)$ in this case. Let $m = 2^k r$ where r is odd, and form the sequence $x^r \bmod N$, $x^{2r} \bmod N$, $\ldots$, $x^{2^k r} \bmod N$; with high probability we find that the first appearance of 1 is preceded by a value y other than $N - 1$, as in Algorithm P, hence $\gcd(y - 1, N) = p$ or q.

35. Let $f = (p^{q-1} - q^{p-1}) \bmod N$. Since $p \bmod 4 = q \bmod 4 = 3$, we have $(\frac{-1}{p}) = (\frac{-1}{q}) = (\frac{f}{p}) = -(\frac{f}{q}) = -1$, and we also have $(\frac{2}{p}) = -(\frac{2}{q}) = 1$. Given a message x in the range $0 \le x \le \frac{1}{8}(N - 5)$, let $\bar{x} = 4x + 2$ or $8x + 4$, whichever satisfies $(\frac{\bar{x}}{N}) = 1$; then transmit the message $\bar{x}^2 \bmod N$.

To decode this message, we first use a SQRT box to find the unique number y such that $y^2 \equiv \bar{x}^2 \bmod N$ and $(\frac{y}{N}) = 1$ and y is even. Then $y = \bar{x}$, since the other three square roots of $\bar{x}^2$ are $N - \bar{x}$ and $(\pm f\bar{x}) \bmod N$; the first of these is odd, and the other two have negative Jacobi symbols. The decoding is now completed by setting $x = \lfloor y/4 \rfloor$ if $y \bmod 4 = 2$, otherwise $x \leftarrow \lfloor y/8 \rfloor$.

Anybody who can decode such encodings can also find the factors of N, because the decoding of a false message $\bar{x}^2 \bmod N$ when $(\frac{\bar{x}}{N}) = -1$ reveals $(\pm f) \bmod N$, a number that has a nontrivial gcd with N.

36. The mth prime equals

$$m \ln m + m \ln \ln m - m + m \ln \ln m / \ln m - 2m/\ln m + O(m(\log\log m)^2 (\log m)^{-2}),$$

by (4), although for this problem we need only the weaker estimate $p_m = m \ln m + O(m \log \log m)$. (We will assume that p_m is the mth prime, since this corresponds to the assumption that V is uniformly distributed.) If we choose $\ln m = \frac{1}{2}c\sqrt{\ln N \ln \ln N}$, where $c = O(1)$, we find that $r = c^{-1}\sqrt{\ln N / \ln \ln N} - c^{-2} - c^{-2}(\ln \ln \ln N / \ln \ln N) - 2c^{-2}(\ln \frac{1}{2}c)/\ln \ln N + O(\sqrt{\ln \ln N / \ln N})$. The estimated running time (21) now simplifies somewhat surprisingly to the formula $\exp(f(c, N)\sqrt{\ln N \ln \ln N} + O(\log \log N))$, where we have $f(c, N) = c + (1 - (1 + \ln 2)/\ln \ln N)c^{-1}$. The value of c that minimizes $f(c, N)$ is $\sqrt{1 - (1 + \ln 2)/\ln \ln N}$, so we obtain the estimate

$$\exp(2\sqrt{\ln N \ln \ln N}\sqrt{1 - (1 + \ln 2)/\ln \ln N} + O(\log \log N)).$$

When $N = 10^{50}$ this gives $\epsilon(N) \approx .33$, which is still much larger than the observed behavior.

Note: The partial quotients of $\sqrt{D}$ seem to behave according to the distribution obtained for random real numbers in Section 4.5.3. For example, the first million partial quotients of the number $10^{18} + 314159$ include exactly (415236, 169719, 93180, 58606)

cases where A_n is respectively $(1, 2, 3, 4)$. Since V_n lies between $(\sqrt{D}+1)/(A_n+1)$ and $2\sqrt{D}/A_n$, it is likely that $V_n \le 2\sqrt{D}y$ with probability about $\lg(1+y)$. This is not much different from a uniform distribution, so something besides the size of V_n must account for the unreasonable effectiveness of Algorithm E.

37. Apply exercise 4.5.3–12 to the number $\sqrt{D}+R$, to see that the periodic part begins immediately, and run the period backwards to verify the palindromic property. [It follows that the second half of the period gives the same V's as the first, and Algorithm E could be shut down earlier by terminating it when $U = U'$ or $V = V'$ in step E5. However, the period is generally so long, we never even get close to halfway through it, so there is no point in making the algorithm more complicated.]

38. [*Inf. Proc. Letters* **8** (1979), 28–31.] Note that $x \bmod y = x - y\lfloor x/y \rfloor$ can be computed easily on such a machine, and we can get simple constants like $0 = x - x$, $1 = \lfloor x/x \rfloor$, $2 = 1+1$; we can test $x > 0$ by testing whether $x = 1$ or $\lfloor x/(x-1) \rfloor \neq 0$.

(a) First compute $l = \lfloor \lg n \rfloor$ in $O(\log n)$ steps, by repeatedly dividing by 2; at the same time compute $k = 2^l$ and $A \leftarrow 2^{2^{l+1}}$ in $O(\log n)$ steps by repeatedly setting $k \leftarrow 2k$, $A \leftarrow A^2$. For the main computation, suppose we know that $t = A^m$, $u = (A+1)^m$, and $v = m!$; then we can increase the value of m by 1 by setting $m \leftarrow m+1$, $t \leftarrow At$, $u \leftarrow (A+1)u$, $v \leftarrow vm$; and we can *double* the value of m by setting $m \leftarrow 2m$, $u \leftarrow u^2$, $v \leftarrow (\lfloor u/t \rfloor \bmod A)v^2$, $t \leftarrow t^2$, provided that A is sufficiently large. (Consider the number u in radix-A notation; A must be greater than $\binom{2m}{m}$.) Now if $n = (a_l \ldots a_0)_2$, let $n_j = (a_l \ldots a_j)_2$; if $m = n_j$ and $k = 2^j$ and $j > 0$ we can decrease j by 1 by setting $k \leftarrow \lfloor k/2 \rfloor$, $m \leftarrow 2m + (\lfloor n/k \rfloor \bmod 2)$. Hence we can compute $n_j!$ for $j = l, l-1, \ldots, 0$ in $O(\log n)$ steps. [Another solution, due to Julia Robinson, is to compute $n! = \lfloor B^n / \binom{B}{n} \rfloor$ when $B > (2n)^{n+1}$; cf. *AMM* **80** (1973), 250–251, 266.]

(b) First compute $A = 2^{2^{l+2}}$ as in (a), then find the least $k \ge 0$ such that $2^{k+1}! \bmod n = 0$. If $\gcd(n, 2^k!) \neq 1$, let $f(n)$ be this value; note that this gcd can be computed in $O(\log n)$ steps by Euclid's algorithm. Otherwise we will find the least integer m such that $\binom{m}{\lfloor m/2 \rfloor} \bmod n = 0$, and let $f(n) = \gcd(m, n)$. (Note that in this case $2^k < m \le 2^{k+1}$, hence $\lceil m/2 \rceil \le 2^k$ and $\lceil m/2 \rceil !$ is relatively prime to n; therefore $\binom{m}{\lfloor m/2 \rfloor} \bmod n = 0$ iff $m! \bmod n = 0$. Furthermore $n \neq 4$.)

To compute m with a bounded number of registers, we can use Fibonacci numbers (cf. Algorithm 6.2.1F). Suppose we know that $s = F_j$, $s' = F_{j+1}$, $t = A^{F_j}$, $t' = A^{F_{j+1}}$, $u = (A+1)^{2F_j}$, $u' = (A+1)^{2F_{j+1}}$, $v = A^m$, $w = (A+1)^{2m}$, $\binom{2m}{m} \bmod n \neq 0$, and $\binom{2(m+s)}{m+s} = 0$. It is easy to reach this state of affairs with $m = F_{j+1}$, for suitably large j, in $O(\log n)$ steps; furthermore A will be larger than $2^{2(m+s)}$. If $s = 1$, we set $f(n) = \gcd(2m+1, n)$ or $\gcd(2m+2, n)$, whichever is $\neq 1$, and terminate the algorithm. Otherwise we reduce j by 1 as follows: Set $r \leftarrow s$, $s \leftarrow s' - s$, $s \leftarrow r$, $r \leftarrow t$, $t \leftarrow \lfloor t'/t \rfloor$, $t' \leftarrow r$, $r \leftarrow u$, $u \leftarrow \lfloor u'/u \rfloor$, $u' \leftarrow r$; then if $(\lfloor wu/vt \rfloor \bmod A) \bmod n \neq 0$, set $m \leftarrow m+s$, $w \leftarrow wu$, $v \leftarrow vt$.

[Can this problem be solved with fewer than $O(\log n)$ operations? Can the smallest, or the largest, prime factor of n be computed in $O(\log n)$ operations?]

SECTION 4.6

1. $9x^2 + 7x + 9$; $5x^3 + 7x^2 + 2x + 6$.

2. (a) True. (b) False if the algebraic system S contains "zero divisors," nonzero numbers whose product is zero, as in exercise 1; otherwise true. (c) True when $m \neq n$, but false in general when $m = n$, since the leading coefficients might cancel.

3. Assume that $r \leq s$. For $0 \leq k \leq r$ the maximum is $m_1m_2(k+1)$; for $r \leq k \leq s$ it is $m_1m_2(r+1)$; for $s \leq k \leq r+s$ it is $m_1m_2(r+s+1-k)$. The least upper bound valid for all k is $m_1m_2(r+1)$. (The solver of this exercise will know how to factor the polynomial $x^7 + 2x^6 + 3x^5 + 3x^4 + 3x^3 + 3x^2 + 2x + 1$.)

4. If one of the polynomials has fewer than 2^t nonzero coefficients, the product can be formed by putting exactly $t-1$ zeros between each of the coefficients, then multiplying in the binary number system, and finally using a logical **AND** instruction (present on most binary computers, cf. Section 4.5.4) to zero out the extra bits. For example, if $t = 3$, the multiplication in the text would become $(1001000001)_2 \times (1000001001)_2 = (1001001011001001001)_2$; if we **AND** this result with the constant $(1001001\ldots1001)_2$, the desired answer is obtained. A similar technique can be used to multiply polynomials with nonnegative coefficients, when it is known that the coefficients will not be too large.

5. Polynomials of degree $\leq 2n$ can be represented as $U_1(x)x^n + U_0(x)$ where $\deg(U_1)$ and $\deg(U_0) \leq n$; and $(U_1(x)x^n + U_0(x))(V_1(x)x^n + V_0(x)) = U_1(x)V_1(x)(x^{2n} + x^n) + (U_1(x) + U_0(x))(V_1(x) + V_0(x))x^n + U_0(x)V_0(x)(x^n + 1)$. (This equation assumes that arithmetic is being done modulo 2.) Thus Eqs. 4.3.3–3, 4, 5 hold.

Notes: S. A. Cook has shown that Algorithm 4.3.3C can be extended in a similar way, and exercise 4.6.4–57 describes a method requiring even fewer operations for large n. But these ideas are not useful for "sparse" polynomials (having mostly zero coefficients).

SECTION 4.6.1

1. $q(x) = 1 \cdot 2^3x^3 + 0 \cdot 2^2x^2 - 2 \cdot 2x + 8 = 8x^3 - 4x + 8$; $r(x) = 28x^2 + 4x + 8$.

2. The monic sequence of polynomials produced during Euclid's algorithm has the coefficients $(1, 5, 6, 6, 1, 6, 3)$, $(1, 2, 5, 2, 2, 4, 5)$, $(1, 5, 6, 2, 3, 4)$, $(1, 3, 4, 6)$, 0. Hence the greatest common divisor is $x^3 + 3x^2 + 4x + 6$. (The greatest common divisor of a polynomial and its reverse is always symmetric, in the sense that it is a unit multiple of its own reverse.)

3. The procedure of Algorithm 4.5.2X is valid, with polynomials over S substituted for integers. When the algorithm terminates, we have $U(x) = u_2(x)$, $V(x) = u_1(x)$. Let $m = \deg(u)$, $n = \deg(v)$. It is easy to prove by induction that $\deg(u_3) + \deg(v_1) = n$, $\deg(u_3) + \deg(v_2) = m$, after step X3, throughout the execution of the algorithm, provided that $m \geq n$. Hence if m and n are greater than $d = \deg(\gcd(u, v))$ we have $\deg(U) < m - d$, $\deg(V) < n - d$; the exact degrees are $m - d_1$ and $n - d_1$, where d_1 is the degree of the second-last nonzero remainder. If $d = \min(m, n)$, say $d = n$, we have $U(x) = 0$ and $V(x) = 1$.

When $u(x) = x^m - 1$ and $v(x) = x^n - 1$, the identity $(x^m - 1) \bmod (x^n - 1) = x^{m \bmod n} - 1$ shows that all polynomials occurring during the calculation are monic, with integer coefficients. When $u(x) = x^{21} - 1$ and $v(x) = x^{13} - 1$, we have $V(x) = x^{11} + x^8 + x^6 + x^3 + 1$ and $U(x) = -(x^{19} + x^{16} + x^{14} + x^{11} + x^8 + x^6 + x^3 + x)$. [See also Eq. 3.3.3–29, which gives an alternative formula for $U(x)$ and $V(x)$.]

4. Since the quotient $q(x)$ depends only on $v(x)$ and the first $m - n$ coefficients of $u(x)$, the remainder $r(x) = u(x) - q(x)v(x)$ is uniformly distributed and independent of $v(x)$. Hence each step of the algorithm may be regarded as independent of the others; this algorithm is much more well-behaved than Euclid's algorithm over the integers.

The probability that $n_1 = n - k$ is $p^{1-k}(1 - 1/p)$, and $t = 0$ with probability p^{-n}. Each succeeding step has essentially the same behavior; hence we can see that any given sequence of degrees $n, n_1, \ldots, n_t, -\infty$ occurs with probability $(p-1)^t/p^n$. To find the average value of $f(n_1, \ldots, n_t)$, let S_t be the sum of $f(n_1, \ldots, n_t)$ over all sequences $n > n_1 > \cdots > n_t \geq 0$ having a given value of t; then the average is $\sum_t S_t(p-1)^t/p^n$.

Let $f(n_1, \ldots, n_t) = t$; then $S_t = \binom{n}{t}(t+1)$, so the average is $n(1 - 1/p)$. Similarly, if $f(n_1, \ldots, n_t) = n_1 + \cdots + n_t$, then $S_t = \binom{n}{2}\binom{n-1}{t-1}$, and the average is $\binom{n}{2}(1 - 1/p)$. Finally, if $f(n_1, \ldots, n_t) = (n - n_1)n_1 + \cdots + (n_{t-1} - n_t)n_t$, then $S_t = \binom{n+2}{t+2} - (n+1)\binom{n+1}{t+1} + \binom{n+1}{2}\binom{n}{t}$, and the average is $\binom{n+1}{2} - (n+1)p/(p-1) + (p/(p-1))^2(1 - 1/p^{n+1})$.

As a consequence we can see that if p is large there is very high probability that $n_{j+1} = n_j - 1$ for all j. (If this condition fails over the rational numbers, it fails for all p, so we have further evidence for the text's claim that Algorithm C almost always finds $\delta_2 = \cdots = 1$.)

5. Using the formulas developed in exercise 4, with $f(n_1, \ldots, n_t) = \delta_{n_t 0}$, we find that the probability is $1 - 1/p$ if $n > 0$, 1 if $n = 0$.

6. Assuming that the constant terms $u(0)$ and $v(0)$ are nonzero, imagine a "right-to-left" division algorithm, $u(x) = v(x)q(x) + x^{m-n}r(x)$, where $\deg(r) < \deg(v)$. We obtain a gcd algorithm analogous to Algorithm 4.5.2B, which is essentially Euclid's algorithm applied to the "reverse" of the original inputs (cf. exercise 2), afterwards reversing the answer and multiplying by an appropriate power of x.

7. The units of S (as polynomials of degree zero).

8. If $u(x) = v(x)w(x)$, where $u(x)$ has integer coefficients while $v(x)$ and $w(x)$ have rational coefficients, there are integers m and n such that $m \cdot v(x)$ and $n \cdot w(x)$ have integer coefficients. Now $u(x)$ is primitive, so we have

$$u(x) = \pm\, \mathrm{pp}(m \cdot v(x))\, \mathrm{pp}(n \cdot w(x)).$$

9. We can extend Algorithm E as follows: Let $(u_1(x), u_2(x), u_3, u_4(x))$ and $(v_1(x), v_2(x), v_3, v_4(x))$ be quadruples that satisfy the relations $u_1(x)u(x) + u_2(x)v(x) = u_3u_4(x)$, $v_1(x)u(x) + v_2(x)v(x) = v_3v_4(x)$. The extended algorithm starts with the quadruples $(1, 0, \mathrm{cont}(u), \mathrm{pp}(u(x)))$ and $(0, 1, \mathrm{cont}(v), \mathrm{pp}(v(x)))$ and manipulates them in such a way as to preserve the above conditions, where $u_4(x)$ and $v_4(x)$ run through the same sequence as $u(x)$ and $v(x)$ do in Algorithm E. If $au_4(x) = q(x)v_4(x) + br(x)$, we have $av_3(u_1(x), u_2(x)) - q(x)u_3(v_1(x), v_2(x)) = (r_1(x), r_2(x))$, where $r_1(x)u(x) + r_2(x)v(x) = bu_3v_3r(x)$, so the extended algorithm can preserve the desired relations. If $u(x)$ and $v(x)$ are relatively prime, the extended algorithm eventually finds $r(x)$ of degree zero, and we obtain $U(x) = r_2(x)$, $V(x) = r_1(x)$ as desired. (In practice we would divide $r_1(x)$, $r_2(x)$, and bu_3v_3 by $\gcd(\mathrm{cont}(r_1), \mathrm{cont}(r_2))$.) Conversely, if such $U(x)$ and $V(x)$ exist, then $u(x)$ and $v(x)$ have no common prime divisors, since they are primitive and have no common divisors of positive degree.

10. By successively factoring reducible polynomials into polynomials of smaller degree, we must obtain a finite factorization of any polynomial into irreducibles. The factorization of the *content* is unique. To show that there is at most one factorization of the primitive part, the key result is to prove that if $u(x)$ is an irreducible factor of $v(x)w(x)$, but not a unit multiple of the irreducible polynomial $v(x)$, then $u(x)$ is a factor of $w(x)$. This can be proved by observing that $u(x)$ is a factor of $v(x)w(x)U(x) = rw(x) - w(x)u(x)V(x)$ by the result of exercise 9, where r is a nonzero constant.

11. The only row names needed would be A_1, A_0, B_4, B_3, B_2, B_1, B_0, C_1, C_0, D_0. In general, let $u_{j+2}(x) = 0$; then the rows needed for the proof are $A_{n_2-n_j}$ through A_0, $B_{n_1-n_j}$ through B_0, $C_{n_2-n_j}$ through C_0, $D_{n_3-n_j}$ through D_0, etc.

12. If $n_k = 0$, the text's proof of (24) shows that the value of the determinant is $\pm h_k$, and this equals $\pm \ell_k^{n_k-1} / \prod_{1<j<k} \ell_j^{\delta_{j-1}(\delta_j-1)}$. If the polynomials have a factor of positive degree, we can artificially assume that the polynomial zero has degree zero and use the same formula with $\ell_k = 0$.

Notes: The value $R(u, v)$ of Sylvester's determinant is called the *resultant* of u and v, and the quantity $(-1)^{\deg(u)(\deg(u)-1)/2}\ell(u)^{-1}R(u, u')$ is called the *discriminant* of u, where u' is the derivative of u. If $u(x)$ has the factored form $a(x-\alpha_1)\dots(x-\alpha_m)$, and if $v(x) = b(x-\beta_1)\dots(x-\beta_n)$, the resultant $R(u, v)$ is $a^n v(\alpha_1)\dots v(\alpha_m) = (-1)^{mn}b^m u(\beta_1)\dots u(\beta_n) = a^n b^m \prod_{1\le i\le m, 1\le j\le n}(\alpha_i - \beta_j)$. It follows that the polynomials of degree mn in y defined as the respective resultants with $v(x)$ of $u(y-x)$, $u(y+x)$, $x^m u(y/x)$, and $u(yx)$ have as respective roots the sums $\alpha_i + \beta_j$, differences $\alpha_i - \beta_j$, products $\alpha_i\beta_j$, and quotients α_i/β_j (when $v(0) \neq 0$). This idea has been used by R. G. K. Loos to construct algorithms for arithmetic on algebraic numbers [*SIAM J. Computing*, to appear].

If we replace each row A_i in Sylvester's matrix by

$$(b_0 A_i + b_1 A_{i+1} + \cdots + b_{n_2-1-i}A_{n_2-1}) - (a_0 B_i + a_1 B_{i+1} + \cdots + a_{n_2-1-i}B_{n_2-1}),$$

and then delete rows B_{n_2-1} through B_0 and the last n_2 columns, we obtain an $n_1 \times n_1$ determinant for the resultant instead of the original $(n_1+n_2)\times(n_1+n_2)$ determinant. In some cases the resultant can be evaluated efficiently by means of this determinant; see *CACM* **12** (1969), 23–30, 302–303.

J. T. Schwartz has shown that it is possible to evaluate resultants and Sturm sequences for polynomials of degree n with a total of $O(n(\log n)^2)$ arithmetic operations as $n \to \infty$. [*JACM*, to appear.]

13. One can show by induction on j that the values of $(u_{j+1}(x), g_{j+1}, h_j)$ are replaced respectively by $(\ell^{1+p_j} w(x)u_j(x), \ell^{2+p_j} g_j, \ell^{p_j} h_j)$ for $j \ge 2$, where $p_j = n_1 + n_2 - 2n_j$. [In spite of this growth, the bound (26) remains valid.]

14. Let p be a prime of the domain, and let j, k be maximum such that $p^k \setminus v_n = \ell(v)$, $p^j \setminus v_{n-1}$. Let $P = p^k$. By Algorithm R we may write $q(x) = a_0 + Pa_1 x + \cdots + P^s a_s x^s$, where $s = m - n \ge 2$. Let us look at the coefficients of x^{n+1}, x^n, and x^{n-1} in $v(x)q(x)$, namely $Pa_1 v_n + P^2 a_2 v_{n-1} + \cdots$, $a_0 v_n + Pa_1 v_{n-1} + \cdots$, and $a_0 v_{n-1} + Pa_1 v_{n-2} + \cdots$, each of which is a multiple of P^3. We conclude from the first that $p^j \setminus a_1$, from the second that $p^{\min(k,2j)} \setminus a_0$, then from the third that $P \setminus a_0$. Hence $P \setminus r(x)$. [If m were only $n+1$, the best we could prove would be that $p^{\lceil k/2 \rceil}$ divides $r(x)$; e.g., consider $u(x) = x^3 + 1$, $v(x) = 4x^2 + 2x + 1$, $r(x) = 18$. On the other hand, an argument based on determinants of matrices like (21) and (22) can be used to show that $\ell(r)^{\deg(v)-\deg(r)-1} r(x)$ is always a multiple of $\ell(v)^{(\deg(u)-\deg(v))(\deg(v)-\deg(r)-1)}$.]

15. Let $c_{ij} = a_{i1}a_{j1} + \cdots + a_{in}a_{jn}$; we may assume that $c_{ii} > 0$ for all i. If $c_{ij} \neq 0$ for some $i \neq j$, we can replace row i by $(a_{i1} - ca_{j1}, \ldots, a_{in} - ca_{jn})$, where $c = c_{ij}/c_{jj}$; this does not change the value of the determinant, and it decreases the value of the upper bound we wish to prove, since c_{ii} is replaced by $c_{ii} - c_{ij}^2/c_{ij}$. These replacements can be done in a systematic way for increasing i and for $j < i$, until $c_{ij} = 0$ for all $i \neq j$. [The latter algorithm is called "Schmidt's orthogonalization process"; see *Math. Annalen* **63** (1907), 442.] Then $\det(A)^2 = \det(AA^T) = c_{11} \ldots c_{nn}$.

16. Let $f(x_1, \ldots, x_n) = g_m(x_2, \ldots, x_n)x_1^m + \cdots + g_0(x_2, \ldots, x_n)$ and $g(x_2, \ldots, x_n) = g_m(x_2, \ldots, x_n)^2 + \cdots + g_0(x_2, \ldots, x_n)^2$; the latter is not identically zero. We have

$$a_N \leq m(2N+1)^{n-1} + (2N+1)b_N,$$

where b_N counts the integer solutions of $g(x_2, \ldots, x_n) = 0$ with variables bounded by N. Hence $\lim_{N\to\infty} a_N/(2N+1)^n = \lim_{N\to\infty} b_N/(2N+1)^{n-1}$, and this is zero by induction.

17. (a) For convenience, let us describe the algorithm only for $A = \{a, b\}$. The hypotheses imply that $\deg(Q_1U) = \deg(Q_2V) \geq 0$, $\deg(Q_1) \leq \deg(Q_2)$. If $\deg(Q_1) = 0$, then Q_1 is just a nonzero rational number, so we set $Q = Q_2/Q_1$. Otherwise we let $Q_1 = aQ_{11} + bQ_{12} + r_1$, $Q_2 = aQ_{21} + bQ_{22} + r_2$, where r_1 and r_2 are rational numbers; it follows that

$$Q_1U - Q_2V = a(Q_{11}U - Q_{21}V) + b(Q_{12}U - Q_{22}V) + r_1U - r_2V.$$

We must have either $\deg(Q_{11}) = \deg(Q_1) - 1$ or $\deg(Q_{12}) = \deg(Q_1) - 1$. In the former case, $\deg(Q_{11}U - Q_{21}V) < \deg(Q_{11}U)$, by considering the terms of highest degree that start with a; so we may replace Q_1 by Q_{11}, Q_2 by Q_{21}, and repeat the process. Similarly in the latter case, we may replace (Q_1, Q_2) by (Q_{12}, Q_{22}) and repeat the process.

(b) We may assume that $\deg(U) \geq \deg(V)$. If $\deg(R) \geq \deg(V)$, note that $Q_1U - Q_2V = Q_1R - (Q_2 - Q_1Q)V$ has degree less than $\deg(V) \leq \deg(Q_1R)$, so we can repeat the process with U replaced by R; we obtain $R = Q'V + R'$, $U = (Q + Q')V + R'$, where $\deg(R') < \deg(R)$, so eventually a solution will be obtained.

(c) The algorithm of (b) gives $V_1 = UV_2 + R$, $\deg(R) < \deg(V_2)$; by homogeneity, $R = 0$ and U is homogeneous.

(d) We may assume that $\deg(V) \leq \deg(U)$. If $\deg(V) = 0$, set $W \leftarrow U$; otherwise use (c) to find $U = QV$, so that $QVV = VQV$, $(QV - VQ)V = 0$. This implies that $QV = VQ$, so we can set $U \leftarrow V$, $V \leftarrow Q$ and repeat the process.

For further details about the subject of this exercise, see P. M. Cohn, *Proc. Cambridge Phil. Soc.* **57** (1961), 18–30. The considerably more difficult problem of characterizing *all* string polynomials such that $UV = VU$ has been solved by G. M. Bergman [Ph.D. thesis, Harvard University, 1967].

18. [P. M. Cohn, *Transactions Amer. Math. Soc.* **109** (1963), 332–356.]

C1. Set $u_1 \leftarrow U_1$, $u_2 \leftarrow U_2$, $v_1 \leftarrow V_1$, $v_2 \leftarrow V_2$, $z_1 \leftarrow z_2' \leftarrow w_1 \leftarrow w_2' \leftarrow 1$, $z_1' \leftarrow z_2 \leftarrow w_1' \leftarrow w_2 \leftarrow 0$, $n \leftarrow 0$.

C2. (At this point the identities given in the exercise hold, and $u_1v_1 = u_1v_2$; $v_2 = 0$ if and only if $u_1 = 0$.) If $v_2 = 0$, the algorithm terminates with $\operatorname{gcrd}(V_1, V_2) = v_1$, $\operatorname{lclm}(V_1, V_2) = z_1'V_1 = -z_2'V_2$. (Also, by symmetry, we have $\operatorname{gcld}(U_1, U_2) = u_2$ and $\operatorname{lcrm}(U_1, U_2) = U_1w_1 = -U_2w_2$.)

C3. Find Q and R such that $v_1 = Qv_2 + R$, where $\deg(R) < \deg(v_2)$. (We have $u_1(Qv_2 + R) = u_2v_2$, so $u_1R = (u_2 - u_1Q)v_2 = R'v_2$.)

C4. Set $(w_1, w_2, w_1', w_2', z_1, z_2, z_1', z_2', u_1, u_2, v_1, v_2) \leftarrow (w_1' - w_1Q, w_2' - w_2Q, w_1, w_2, z_1', z_2', z_1 - Qz_1', z_2 - Qz_2', u_2 - u_1Q, u_1, v_2, v_1 - Qv_2)$ and $n \leftarrow n + 1$. Go back to C2. ∎

This extension of Euclid's algorithm includes most of the features we have seen in previous extensions, all at the same time, so it provides new insight into the special cases already considered. To prove that it is valid, note first that $\deg(v_2)$ decreases in step C4, so the algorithm certainly terminates. At the conclusion of the algorithm, v_1 is a common right divisor of V_1 and V_2, since $w_1v_1 = (-1)^nV_1$ and $-w_2v_1 = (-1)^nV_2$; also if d is any common right divisor of V_1 and V_2, it is a right divisor of $z_1V_1 + z_2V_2 = v_1$. Hence $v_1 = \gcrd(V_1, V_2)$. Also if m is any common left multiple of V_1 and V_2, we may assume without loss of generality that $m = U_1V_1 = U_2V_2$, since the sequence of values of Q does not depend on U_1 and U_2. Hence $m = (-1)^n(-u_2z_1')V_1 = (-1)^n(u_2z_2')V_2$ is a multiple of $z_1'V_1$.

In practice, if we just want to calculate $\gcrd(V_1, V_2)$, we may suppress the computation of n, w_1, w_2, w_1', w_2', z_1, z_2, z_1', z_2'. These additional quantities were added to the algorithm primarily to make its validity more readily established.

Note: Nontrivial factorizations of string polynomials, such as the example given with this exercise, can be found from matrix identities such as

$$\begin{pmatrix} a & 1 \\ 1 & 0 \end{pmatrix}\begin{pmatrix} b & 1 \\ 1 & 0 \end{pmatrix}\begin{pmatrix} c & 1 \\ 1 & 0 \end{pmatrix}\begin{pmatrix} 0 & 1 \\ 1 & -c \end{pmatrix}\begin{pmatrix} 0 & 1 \\ 1 & -b \end{pmatrix}\begin{pmatrix} 0 & 1 \\ 1 & -a \end{pmatrix} = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix},$$

since these identities hold even when multiplication is not commutative. For example,

$$(abc + a + c)(1 + ba) = (ab + 1)(cba + a + c).$$

(Compare this with the "continuant polynomials" of Section 4.5.3.)

19. [Cf. Eugène Cahen, *Théorie des Nombres* **1** (Paris: A. Hermann & fils, 1914), 336–338.] If such an algorithm exists, D is a gcrd by the argument in exercise 18. Let us regard A and B as a single $2n \times n$ matrix C whose first n rows are those of A, and whose second n rows are those of B. Similarly, P and Q can be combined into a $2n \times n$ matrix R; X and Y can be combined into an $n \times 2n$ matrix Z. The desired conditions now reduce to two equations $C = RD$, $D = ZC$. If we can find a $2n \times 2n$ integer matrix U with determinant ± 1 such that the last n rows of $U^{-1}C$ are all zero, then $R =$ (first n columns of U), $D =$ (first n rows of $U^{-1}C$), $Z =$ (first n rows of U^{-1}) solves the desired conditions. Hence, for example, the following algorithm may be used (with $m = 2n$):

Algorithm T (*Triangularization*). Let C be an $m \times n$ matrix of integers. This algorithm finds $m \times m$ integer matrices U and V such that $UV = I$ and VC is "upper triangular." (The entry in row i and column j of VC is zero if $i > j$.)

T1. [Initialize.] Set $U \leftarrow V \leftarrow I$, the $m \times m$ identity matrix; and set $T \leftarrow C$. (Throughout the algorithm we will have $T = VC$ and $UV = 1$.)

T2. [Iterate on j.] Do step T3 for $j = 1, 2, \ldots, \min(m, n)$, and terminate the algorithm.

T3. [Zero out column j.] Perform the following transformation zero or more times until T_{ij} is zero for all $i > j$: Let T_{kj} be a nonzero element of $\{T_{ij}, T_{(j+1)j}, \ldots, T_{mj}\}$ having the smallest absolute value. Interchange rows k and j of T and of V; interchange columns k and j of U. Then subtract $\lfloor T_{ij}/T_{jj} \rfloor$ times row j from row i, in matrices T and V, and add the same multiple of column i to column j in matrix U, for $j < i \leq m$. ∎

For the stated example, the algorithm yields $\left(\begin{smallmatrix}1&2\\3&4\end{smallmatrix}\right) = \left(\begin{smallmatrix}1&0\\3&2\end{smallmatrix}\right)\left(\begin{smallmatrix}1&2\\0&-1\end{smallmatrix}\right)$, $\left(\begin{smallmatrix}4&3\\2&1\end{smallmatrix}\right) = \left(\begin{smallmatrix}4&5\\2&3\end{smallmatrix}\right)\left(\begin{smallmatrix}1&2\\0&-1\end{smallmatrix}\right)$, $\left(\begin{smallmatrix}1&2\\0&-1\end{smallmatrix}\right) = \left(\begin{smallmatrix}1&0\\2&-2\end{smallmatrix}\right)\left(\begin{smallmatrix}1&2\\3&4\end{smallmatrix}\right) + \left(\begin{smallmatrix}0&0\\1&0\end{smallmatrix}\right)\left(\begin{smallmatrix}4&3\\2&1\end{smallmatrix}\right)$. (Actually *any* matrix with determinant ± 1 would be a gcrd in this particular case.)

20. It may be helpful to consider the construction of exercise 4.6.2–22, with p^m replaced by a small number ϵ.

21. Note that Algorithm R is used only when $m - n \leq 1$; furthermore, the coefficients are bounded by (25) with $m = n$. [The stated formula is, in fact, the execution time observed in practice, not merely an upper bound. For more detailed information see G. E. Collins, *Proc. 1968 Summer Inst. on Symbolic Math. Comp.*, Robert G. Tobey, ed. (IBM Federal Systems Center: June 1969), 195–231.]

22. A sequence of signs cannot contain two consecutive zeros, since $u_{k+1}(x)$ is a nonzero constant in (29). Moreover we cannot have "+, 0, +" or "−, 0, −" as subsequences. The formula $V(u, a) - V(u, b)$ is clearly valid when $b = a$, so we must only verify it as b increases. The polynomials $u_j(x)$ have finitely many roots, and $V(u, b)$ changes only when b encounters or passes such roots. Let x be a root of some (possibly several) u_j. When b increases from $x - \epsilon$ to x, the sign sequence near j goes from "+, $\pm$, −" to "+, 0, −" or from "−, $\pm$, +" to "−, 0, +" if $j > 0$; and from "+, −" to "0, −" or from "−, +" to "0, +" if $j = 0$. (Since $u'(x)$ is the derivative, $u'(x)$ is negative when $u(x)$ is decreasing.) Thus the net change in V is $-\delta_{j0}$. When b increases from x to $x + \epsilon$, a similar argument shows that V remains unchanged.

[L. E. Heindel, *JACM* **18** (1971), 533–548, has applied these ideas to construct algorithms for isolating the real zeros of a given polynomial $u(x)$, in time bounded by a polynomial in $\deg(u)$ and $\log N$, where all coefficients y_j are integers with $|u_j| \leq N$, and all operations are guaranteed to be exact.]

23. If v has $n-1$ real roots occurring between the n real roots of u, then (by considering sign changes) $u(x) \bmod v(x)$ has $n - 2$ real roots lying between the $n - 1$ roots of v.

24. First show that $h_j = g_j^{\delta_{j-1}} g_{j-1}^{\delta_{j-2}(1-\delta_{j-1})} \ldots g_2^{\delta_1(1-\delta_2)\ldots(1-\delta_{j-1})}$. Then show that the exponent of g_2 on the left-hand side of (18) has the form $\delta_2 + \delta_1 x$, where $x = \delta_2 + \cdots + \delta_{j-1} + 1 - \delta_2(\delta_3 + \cdots + \delta_{j-1} + 1) - \delta_3(1 - \delta_2)(\delta_4 + \cdots + \delta_{j-1} + 1) - \cdots - \delta_{j-1}(1 - \delta_2)\ldots(1 - \delta_{j-2})(1)$. But $x = 1$, since it is seen to be independent of δ_{j-1} and we can set $\delta_{j-1} = 0$, etc. A similar derivation works for g_3, g_4, ..., and a simpler derivation works for (23).

25. Each coefficient of $u_j(x)$ can be expressed as a determinant in which one column contains only $\ell(u)$, $\ell(v)$, and zeros. To use this fact, modify Algorithm C as follows: In step C1, set $g \leftarrow \gcd(\ell(u), \ell(v))$ and $h \leftarrow 0$. In step C3, if $h = 0$, set $u(x) \leftarrow v(x)$, $v(x) \leftarrow r(x)/g$, $h \leftarrow \ell(u)^\delta/g$, $g \leftarrow \ell(u)$, and return to C2; otherwise proceed as in the unmodified algorithm. The effect of this new initialization is simply to replace $u_j(x)$ by $u_j(x)/\gcd(\ell(u), \ell(v))$ for all $j \geq 3$; thus, ℓ^{2j-4} will become ℓ^{2j-5} in (28).

26. In fact, even more is true. Note that the algorithm in exercise 3 computes $\pm p_n(x)$ and $\mp q_n(x)$ for $n \geq -1$. Let $e_n = \deg(q_n)$ and $d_n = \deg(p_n u - q_n v)$; we observed in exercise 3 that $d_{n-1} + e_n = \deg(u)$ for $n \geq 0$. We shall prove that the conditions $\deg(q) < e_n$ and $\deg(pu - qv) < d_{n-2}$ imply that $p(x) = c(x)p_{n-1}(x)$ and $q(x) = c(x)q_{n-1}(x)$: Given such p and q, we can find $c(x)$ and $d(x)$ such that $p(x) = c(x)p_{n-1}(x) + d(x)p_n(x)$ and $q(x) = c(x)q_{n-1}(x) + d(x)q_n(x)$, since $p_{n-1}(x)q_n(x) - p_n(x)q_{n-1}(x) = \pm 1$. Hence $pu - qv = c(p_{n-1}u - q_{n-1}v) + d(p_n u - q_n v)$. If $d(x) \neq 0$, we must have $\deg(c) + e_{n-1} = \deg(d) + e_n$, since $\deg(q) < \deg(q_n)$; it follows that $\deg(c) + d_{n-1} > \deg(d) + d_n$, since this is surely true if $d_n = -\infty$ and otherwise we

have $d_{n-1}+e_n = d_n+e_{n+1} > d_n+e_{n-1}$. Therefore $\deg(pu-qv) = \deg(c)+d_{n-1}$; but we have assumed that $\deg(pu-qv) < d_{n-2} = d_{n-1}+e_n-e_{n-1}$, so $\deg(c) < e_n - e_{n-1}$ and $\deg(d) < 0$, a contradiction.

[This result is essentially due to L. Kronecker, *Monatsberichte Königl. Preuß. Akad. Wiss.* (Berlin: 1881), 535–600. It implies the following theorem: "Let $u(x)$ and $v(x)$ be relatively prime polynomials over a field and let $d \le \deg(v) < \deg(u)$. If $q(x)$ is a polynomial of least degree such that there exist polynomials $p(x)$ and $r(x)$ with $p(x)u(x) - q(x)v(x) = r(x)$ and $\deg(r) = d$, then $p(x)/q(x) = p_n(x)/q_n(x)$ for some n." For if $d_{n-2} > d \ge d_{n-1}$, there are solutions $q(x)$ with $\deg(q) = e_{n-1}+d-d_{n-1} < e_n$, and we have proved that all solutions of such low degree have the stated property.]

SECTION 4.6.2

1. By the principle of inclusion and exclusion (Section 1.3.3), the number of polynomials without linear factors is $\sum_{k\le n}\binom{p}{k}p^{n-k}(-1)^k = p^{n-p}(p-1)^p$. The stated probability when $n \ge p$ is therefore $1-(1-1/p)^p$, which is greater than $\frac{1}{2}$. [In fact, the stated probability is greater than $\frac{1}{2}$ for all $n \ge 1$.] The average number of linear factors is p times the average number of times x is a factor, so it is $\frac{p}{p-1}(1-p^{-n}) = 1+p^{-1}+\cdots+p^{1-n}$. [See answer 38 for further comments on the average number of linear factors.]

2. (a) We know that $u(x)$ has a representation as a product of irreducible polynomials; and the leading coefficients of these polynomials must be units, since they divide the leading coefficient of $u(x)$. Therefore we may assume that $u(x)$ has a representation as a product of monic irreducible polynomials $p_1(x)^{e_1}\ldots p_r(x)^{e_r}$, where $p_1(x)$, ..., $p_r(x)$ are distinct. This representation is unique, except for the order of the factors, so the conditions on $u(x)$, $v(x)$, $w(x)$ are satisfied if and only if

$$v(x) = p_1(x)^{\lfloor e_1/2\rfloor}\ldots p_r(x)^{\lfloor e_r/2\rfloor}, \qquad w(x) = p_1(x)^{e_1 \bmod 2}\ldots p_r(x)^{e_r \bmod 2}.$$

(b) The generating function for the number of monic polynomials of degree n is $1+pz+p^2z^2+\cdots = 1/(1-pz)$. The generating function for the number of polynomials of degree n having the form $v(x)^2$, where $v(x)$ is monic, is $1+pz^2+p^2z^4+\cdots = 1/(1-pz^2)$. If the generating function for the number of monic squarefree polynomials of degree n is $q(z)$, then by part (a) we must have $1/(1-pz) = q(z)/(1-pz^2)$. Hence $q(z) = (1-pz^2)/(1-pz) = 1+pz+(p^2-p)z^2+(p^3-p^2)z^3+\cdots$. The answer is p^n-p^{n-1} for $n \ge 2$. [Curiously, this proves that $\gcd(u(x), u'(x)) = 1$ with probability $1-1/p$; it is the same as the probability that $\gcd(u(x), v(x)) = 1$ when $u(x)$ and $v(x)$ are *independent*, by exercise 4.6.1–5.]

Note: By a similar argument, every $u(x)$ has a unique representation $v(x)w(x)^r$, where $v(x)$ is not divisible by the rth power of any irreducible; the number of such monic polynomials $v(x)$ is $p^n - p^{n-r+1}$ for $n \ge r$.

3. Let $u(x) = u_1(x)\ldots u_r(x)$. There is *at most* one such $v(x)$, by the argument of Theorem 4.3.2C. There is *at least* one if, for each j, we can solve the system with $w_j(x) = 1$ and $w_k(x) = 0$ for $k \ne j$. A solution to the latter is $v_1(x)\prod_{k\ne j}u_k(x)$, where $v_1(x)$ and $v_2(x)$ can be found satisfying

$$v_1(x)\textstyle\prod_{k\ne j}u_k(x) + v_2(x)u_j(x) = 1, \qquad \deg(v_1) < \deg(u_j),$$

by the extension of Euclid's algorithm (exercise 4.6.1–3).

4. By unique factorization, we have $(1-pz)^{-1} = \prod_{n\ge1}(1-z^n)^{-a_{np}}$; after taking logarithms, this can be rewritten

$$\sum_{j\ge1} G_p(z^j)/j = \sum_{k,j\ge1} a_{kp} z^{kj}/j = \ln(1/(1-pz)).$$

The stated identity now yields the answer $G_p(z) = \sum_{m\ge1} \mu(m) m^{-1} \ln(1/(1-pz^m))$, from which we obtain $a_{np} = \sum_{d\backslash n} \mu(n/d) n^{-1} p^d$; thus $\lim_{p\to\infty} a_{np}/p^n = 1/n$. To prove the stated identity, note that

$$\sum_{n,j\ge1} \mu(n) g(z^{nj}) n^{-t} j^{-t} = \sum_{m\ge1} g(z^m) m^{-t} \sum_{n\backslash m} \mu(n) = g(z).$$

5. Let a_{npr} be the number of monic polynomials of degree n modulo p having exactly r irreducible factors. Then $\mathcal{G}_p(z,w) = \sum_{n,r\ge0} a_{npr} z^n w^r = \exp(\sum_{k\ge1} G_p(z^k) w^k/k)$, where G_p is the generating function in exercise 4; cf. Eq. 1.2.9–34. We have

$$\begin{aligned}\sum_{n\ge0} A_{np} z^n = d\mathcal{G}_p(z/p,w)/dw\,|_{w=1} &= (\textstyle\sum_{k\ge1} G_p(z^k/p^k)) \exp(\ln(1/(1-z))) \\ &= (\textstyle\sum_{n\ge1} \ln(1/(1-p^{1-n}z^n))\varphi(n)/n)/(1-z),\end{aligned}$$

hence $A_{np} = H_n + 1/2p + O(p^{-2})$ for $n \ge 2$. The average value of 2^r is the coefficient of z^n in $\mathcal{G}_p(z/p, 2)$, namely $n+1+(n-1)/p+O(p^{-2})$. (The variance is of order n^3, however: set $w = 4$.)

6. For $0 \le s < p$, $x - s$ is a factor of $x^p - x$ (modulo p) by Fermat's theorem. So $x^p - x$ is a multiple of $\operatorname{lcm}(x, x-1, \ldots, x-(p-1)) = x^{\underline{p}}$. [*Note:* Therefore the Stirling numbers $\left[{p \atop k}\right]$ are multiples of p except when $k = 1$, $k = p$. Equation 1.2.6–41 shows that the same statement is valid for Stirling numbers $\left\{{p \atop k}\right\}$ of the other kind.]

7. The factors on the right are relatively prime, and each is a divisor of $u(x)$, so their product divides $u(x)$. On the other hand, $u(x)$ divides

$$v(x)^p - v(x) = \prod_{0\le s<p} (v(x) - s),$$

so it divides the right-hand side by exercise 4.5.2–2.

8. The vector (18) is the only output whose kth component is nonzero.

9. For example, start with $x \leftarrow 1$ and $y \leftarrow 1$; then repeatedly set $R[x] \leftarrow y$, $x \leftarrow 2x \bmod 101$, $y \leftarrow 51y \bmod 101$, one hundred times.

10. The matrix $Q - I$ below has a null space generated by the two vectors $v^{[1]} = (1,0,0,0,0,0,0,0)$, $v^{[2]} = (0,1,1,0,0,1,1,1)$. The factorization is

$$(x^6 + x^5 + x^4 + x + 1)(x^2 + x + 1).$$

$p = 2$

$$\begin{pmatrix} 0&0&0&0&0&0&0&0\\ 0&1&1&0&0&0&0&0\\ 0&0&1&0&1&0&0&0\\ 0&0&0&1&0&0&1&0\\ 1&0&0&1&0&0&1&0\\ 1&0&1&1&1&0&0&0\\ 0&0&1&0&1&1&0&1\\ 1&1&0&1&1&1&0&1 \end{pmatrix}$$

$p = 5$

$$\begin{pmatrix} 0&0&0&0&0&0&0\\ 0&4&0&0&0&1&0\\ 0&2&2&0&4&3&4\\ 0&1&4&4&4&2&1\\ 2&2&2&3&4&3&2\\ 0&0&4&0&1&3&2\\ 3&0&2&1&4&2&1 \end{pmatrix}$$

11. Removing the trivial factor x, the matrix $Q - I$ on the previous page has a null space generated by $(1,0,0,0,0,0,0)$ and $(0,3,1,4,1,2,1)$. The factorization is

$$x(x^2 + 3x + 4)(x^5 + 2x^4 + x^3 + 4x^2 + x + 3).$$

12. If $p = 2$, $(x+1)^4 = x^4 + 1$. If $p = 8k+1$, $Q - I$ is the zero matrix, so there are four factors. For other values of p we have

$$\begin{matrix} & p = 8k+3 & & p = 8k+5 & & p = 8k+7 \\ Q - I = & \begin{pmatrix} 0 & 0 & 0 & 0 \\ 0 & -1 & 0 & 1 \\ 0 & 0 & -2 & 0 \\ 0 & 1 & 0 & -1 \end{pmatrix} & \begin{pmatrix} 0 & 0 & 0 & 0 \\ 0 & -2 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & -2 \end{pmatrix} & \begin{pmatrix} 0 & 0 & 0 & 0 \\ 0 & -1 & 0 & -1 \\ 0 & 0 & -2 & 0 \\ 0 & -1 & 0 & -1 \end{pmatrix} \end{matrix}$$

Here $Q-I$ has rank 2, so there are $4-2 = 2$ factors. [But it is easy to prove that x^4+1 is irreducible over the integers, since it has no linear factors and the coefficient of x in any factor of degree two must be less than or equal to 2 in absolute value by exercise 20. For all $k \geq 2$, H. P. F. Swinnerton-Dyer has exhibited polynomials of degree 2^k that are irreducible over the integers, but they split completely into linear and quadratic factors modulo every prime. For degree 8, his example is $x^8 - 16x^6 + 88x^4 + 192x^2 + 144$, having roots $\pm\sqrt{2} \pm \sqrt{3} \pm i$ [see *Math. Comp.* **24** (1970), 733–734]. According to the theorem of Frobenius cited in exercise 37, any irreducible polynomial of degree n whose Galois group contains no n-cycles will have factors modulo almost all primes.]

13. $p = 8k+1$: $(x + (1+\sqrt{-1})/\sqrt{2})(x + (1-\sqrt{-1})/\sqrt{2})(x - (1+\sqrt{-1})/\sqrt{2})\times$ $(x - (1-\sqrt{-1})/\sqrt{2})$. $p = 8k+3$: $(x^2 - \sqrt{-2}x - 1)(x^2 - \sqrt{-2}x - 1)$. $p = 8k+5$: $(x^2 - \sqrt{-1})(x^2 - \sqrt{-1})$. $p = 8k+7$: $(x^2 - \sqrt{2}x + 1)(x^2 + \sqrt{2}x + 1)$. The latter factorization also holds over the field of real numbers.

14. Algorithm N can be adapted to find the coefficients of w: Let A be the $(r+1) \times n$ matrix whose kth row contains the coefficients of $v(x)^k \bmod u(x)$, for $0 \leq k \leq r$. Apply the method of Algorithm N until the first dependence is found in step N3; then the algorithm terminates with $w(x) = v_0 + v_1 x + \cdots + v_k x^k$, where v_j is defined in (18). At this point $2 \leq k \leq r$; it is not necessary to know r in advance, since we can check for dependency after generating each row of A.

15. We may assume that $u \neq 0$ and that p is odd. Berlekamp's method applied to the polynomial $x^2 - u$ tells us that a square root exists if and only if $u^{(p-1)/2} \bmod p = 1$; let us assume that this condition holds.

Let $p - 1 = 2^e \cdot q$, where q is odd. Zassenhaus's factoring procedure suggests the following square-root extraction algorithm: Set $t \leftarrow 0$. Evaluate

$$\gcd((x+t)^q - 1, x^2 - u),\ \gcd((x+t)^{2q} - 1, x^2 - u),$$
$$\gcd((x+t)^{4q} - 1, x^2 - u),\ \gcd((x+t)^{8q} - 1, x^2 - u),\ \ldots,$$

until finding the first case where the gcd is not 1 (modulo p). If the gcd is $x - v$, then $\sqrt{u} = \pm v$. If the gcd is $x^2 - u$, set $t \leftarrow t + 1$ and repeat the calculation.

Notes: If $(x+t)^k \bmod (x^2 - u) = ax + b$, then we have $(x+t)^{k+1} \bmod (x^2 - u) = (b + at)x + (bt + au)$, and $(x+t)^{2k} \bmod (x^2 - u) = 2abx + (b^2 + a^2 u)$; hence $(x+t)^q$, $(x+t)^{2q}$, ... are easy to evaluate efficiently, and the calculation for fixed t takes $O((\log p)^3)$ units of time. The square root will be found when $t = 0$ with probability

$1/2^{e-1}$; thus it will always be found immediately when $p \bmod 4 = 3$. If we choose t at random instead of increasing it sequentially, exercise 29 gives a rigorous proof that each t gives success at least about half of the time; but for practical purposes this random choice isn't needed.

Another square-root method has been suggested by D. Shanks. When $e > 1$ it requires an auxiliary constant z (depending only on p) such that $z^{2^{e-1}} \equiv -1$ (modulo p). The value $z = n^q \bmod p$ will work for almost one half of all integers n; once z is known, the following algorithm requires no more probabilistic calculation:

S1. Set $y \leftarrow z$, $r \leftarrow e$, $v \leftarrow u^{(q+1)/2} \bmod p$, $w \leftarrow u^q \bmod p$.

S2. If $w = 1$, stop; v is the answer. Otherwise find the smallest k such that $w^{2^k} \bmod p$ is equal to 1. If $k = r$, stop (there is no answer); otherwise set

$$(y, r, v, w) \leftarrow (y^{2^{r-k}}, k, vy^{2^{r-k-1}}, wy^{2^{r-k}})$$

and repeat step S2. ∎

The validity of this algorithm follows from the invariant congruences $uw \equiv v^2$, $y^{2^{r-1}} \equiv -1$, $w^{2^{r-1}} \equiv 1$ (modulo p). On the average, step S2 will require about $\frac{1}{4}e^2$ multiplications mod p. Reference: *Proc. Second Manitoba Conf. Numer. Math.* (1972), 58–62. A related method was published by A. Tonelli, *Göttinger Nachrichten* (1891), 344–346.

16. (a) Substitute polynomials modulo p for integers, in the proof for $n = 1$. (b) The proof for $n = 1$ carries over to any finite field. (c) Since $x = \xi^k$ for some k, $x^{p^n} = x$ in the field defined by $f(x)$. Furthermore, the elements y that satisfy the equation $y^{p^m} = y$ in the field are closed under addition, and closed under multiplication; so if $x^{p^m} = x$, then ξ (being a polynomial in x with integer coefficients) satisfies $\xi^{p^m} = \xi$.

17. If ξ is a primitive root, each nonzero element is some power of ξ. Hence the order must be a divisor of $13^2 - 1 = 2^3 \cdot 3 \cdot 7$, and $\varphi(f)$ elements have order f.

f	$\varphi(f)$	f	$\varphi(f)$	f	$\varphi(f)$	f	$\varphi(f)$
1	1	3	2	7	6	21	12
2	1	6	2	14	6	42	12
4	2	12	4	28	12	84	24
8	4	24	8	56	24	168	48

18. (a) $\operatorname{pp}(p_1(u_n x)) \ldots \operatorname{pp}(p_r(u_n x))$, by Gauss's lemma. For example, let

$$u(x) = 6x^3 - 3x^2 + 2x - 1, \qquad v(x) = x^3 - 3x^2 + 12x - 36 = (x^2 + 12)(x - 3);$$

then $\operatorname{pp}(36x^2 + 12) = 3x^2 + 1$, $\operatorname{pp}(6x - 3) = 2x - 1$. (This is a modern version of a fourteenth-century trick used for many years to help solve algebraic equations.)

(b) Let $\operatorname{pp}(w(u_n x)) = \bar{w}_m x^m + \cdots + \bar{w}_0 = w(u_n x)/c$, where c is the content of $w(u_n x)$ as a polynomial in x. Then $w(x) = (c\bar{w}/u_n^m)x^m + \cdots + c\bar{w}_0$, hence $c\bar{w}_m = u_n^m$; since $\bar{w}_m$ is a divisor of u_n, c is a multiple of u_n^{m-1}.

19. If $u(x) = v(x)w(x)$ with $\deg(v)\deg(w) \geq 1$, then $u_n x^n \equiv v(x)w(x)$ (modulo p). By unique factorization modulo p, all but the leading coefficients of v and w are multiples of p, and p^2 divides $v_0 w_0 = u_0$.

20. (a) $\sum(\alpha u_j - u_{j-1})(\bar\alpha\bar u_j - \bar u_{j-1}) = \sum(u_j - \bar\alpha u_{j-1})(\bar u_j - \alpha\bar u_{j-1})$. (b) We may assume that $u_0 \neq 0$. Let $m(u) = \prod_{1\le j\le n}\min(1,|\alpha_j|) = u_0/M(u)u_n$. Whenever $|\alpha_j| < 1$, change the factor $x - \alpha_j$ to $\bar\alpha_j x - 1$ in $u(x)$; this doesn't affect $|u|$. Now looking at the leading and trailing coefficients only, we have $|u|^2 \ge |u_n|^2 m(u)^2 + |u_n|^2 M(u)^2$; hence we obtain the slightly stronger result $M(u)^2 \le (|u|^2 + (|u|^4 - 4|u_0u_n|^2)^{1/2})/2|u_n|^2$. [A further improvement in the estimate of $M(u)$ can often be obtained by replacing $u(x)$ by the polynomial $\hat u(x) = (x^k - s_k/|u|^2)u(x)$, where $s_k = \sum_j \bar u_j u_{j-k}$; since $M(\hat u) = M(u)$ and $|\hat u|^2 = |u|^2 - |s_k|^2/|u|^2$, we obtain the inequality $|u|^2 - |s_k|^2/|u|^2 \ge |u_0|^2|s_k|^2/(|u|^4 M(u)^2) + |u_n|^2 M(u)^2$ for $1 \le k < n$. In the case of polynomial (22), we have $s_2 = -72$ and we obtain the bound $M(u) < 8.1837$.] (c) $u_j = u_m \sum \alpha_{i_1}\dots\alpha_{i_{m-j}}$, an elementary symmetric function, hence $|u_j| \le |u_m|\sum \beta_{i_1}\dots\beta_{i_{m-j}}$ where $\beta_i = \max(1,|\alpha_i|)$. We complete the proof by showing that when $x_1 \ge 1, \dots, x_n \ge 1$, and $x_1\dots x_n = M$, the elementary symmetric function $\sigma_{nk} = \sum x_{i_1}\dots x_{i_k}$ is $\le \binom{n-1}{k-1}M + \binom{n-1}{k}$, the value assumed when $x_1 = \cdots = x_{n-1} = 1$ and $x_n = M$. (For if $x_1 \le \cdots \le x_n < M$, the transformation $x_n \leftarrow x_{n-1}x_n$, $x_{n-1} \leftarrow 1$ increases σ_{nk} by $\sigma_{(n-2)(k-1)}(x_n - 1)(x_{n-1} - 1)$, which is positive.) (d) $|v_j| \le |v_m|\big(\binom{m-1}{j}M(v) + \binom{m-1}{j-1}\big) \le |u_n|\big(\binom{m-1}{j}M(u) + \binom{m-1}{j-1}\big)$ since $|v_m| \le |u_n|$ and $M(v) \le M(u)$. [See J. Vicente Gonçalves, *Revista de Faculdade de Ciências* (2) A **1** (Univ. Lisbon, 1950), 167–171; M. Mignotte, *Math. Comp.* **28** (1974), 1153–1157; Mignotte and Payafar, *RAIRO Analyse numér.* **13** (1979), 181–192.]

21. (a) $\int_0^1 (u_n e(n\theta) + \cdots + u_0)(\bar u_n e(-n\theta) + \cdots + \bar u_0)\,d\theta = |u_n|^2 + \cdots + |u_0|^2$ since $\int_0^1 e(j\theta)e(-k\theta)\,d\theta = \delta_{jk}$; now use induction on t. (b) Since $|v_j| \le \binom{m}{j}M(v)|v_m|$ we conclude that $|v|^2 \le \binom{2m}{m}M(v)^2|v_m|^2$. Hence $|v|^2|w|^2 \le \binom{2m}{m}\binom{2k}{k}M(v)^2M(w)^2|v_m w_k|^2 = f(m,k)M(u)^2|u_n|^2 \le f(m,k)|u|^2$. [Slightly better values for $f(m,k)$ are possible based on the more detailed information in exercise 20.] (c) The case $t = 3$ suffices to show how to get from $t-1$ to t. When $t = 2$ we have shown that, for all θ_1,

$$\int_0^1\int_0^1\int_0^1\int_0^1 \big|v(e(\theta_1),e(\phi_2),e(\phi_3))\big|^2\big|w(e(\theta_1),e(\psi_2),e(\psi_3))\big|^2\,d\phi_2\,d\phi_3\,d\psi_2\,d\psi_3$$
$$\le f(m_2,k_2)f(m_3,k_3)\int_0^1\int_0^1 \big|v(e(\theta_1),e(\theta_2),e(\theta_3))\big|^2\big|w(e(\theta_1),e(\theta_2),e(\theta_3))\big|^2\,d\theta_2\,d\theta_3.$$

For all ϕ_2, ϕ_3, ψ_2, ψ_3 we have also shown that

$$\int_0^1\int_0^1 \big|v(e(\phi_1),e(\phi_2),e(\phi_3))\big|^2\big|w(e(\psi_1),e(\psi_2),e(\psi_3))\big|^2\,d\phi_1\,d\psi_1$$
$$\le f(m_1,k_1)\int_0^1 \big|v(e(\theta_1),e(\phi_2),e(\phi_3))\big|^2\big|w(e(\theta_1),e(\psi_2),e(\psi_3))\big|^2\,d\theta_1.$$

Integrate the former inequality with respect to θ_1 and the latter with respect to ϕ_2, ϕ_3, ψ_2, ψ_3. [This method was used by A. O. Gel'fond in *Transcendental and Algebraic Numbers* (New York: Dover, 1960), Section 3.4, to derive a slightly different result.]

22. More generally, assume that $u(x) \equiv v(x)w(x)$ (modulo q), $a(x)v(x) + b(x)w(x) \equiv 1$ (modulo p), and $c\ell(v) \equiv 1$ (modulo r), $\deg(a) < \deg(w)$, $\deg(b) < \deg(v)$, $\deg(u) = \deg(v) + \deg(w)$, where $r = \gcd(p,q)$ and p, q needn't be prime. We shall construct polynomials $V(x) \equiv v(x)$ and $W(x) \equiv w(x)$ (modulo q) such that $u(x) \equiv V(x)W(x)$ (modulo qr), $\ell(V) = \ell(v)$, $\deg(V) = \deg(v)$, $\deg(W) = \deg(w)$; furthermore, if r is prime, the results will be unique modulo qr.

The problem asks us to find $\bar v(x)$ and $\bar w(x)$ with $V(x) = v(x) + q\bar v(x)$, $W(x) = w(x) + q\bar w(x)$, $\deg(\bar v) < \deg(v)$, $\deg(\bar w) \le \deg(w)$; and the other condition

$$(v(x) + q\bar v(x))(w(x) + q\bar w(x)) \equiv u(x) \pmod{qr}$$

is equivalent to $\bar{w}(x)v(x) + \bar{v}(x)w(x) \equiv f(x)$ (modulo r), where $f(x)$ satisfies $u(x) \equiv v(x)w(x) + qf(x)$ (modulo qr). We have

$$(a(x)f(x) + t(x)w(x))v(x) + (b(x)f(x) - t(x)v(x))w(x) \equiv f(x) \pmod{r}$$

for all $t(x)$. Since $\ell(v)$ has an inverse modulo r, we can find a quotient $t(x)$ by Algorithm 4.6.1D such that $\deg(bf - tv) < \deg(v)$; for this $t(x)$, $\deg(af + tw) \leq \deg(w)$, since we have $\deg(f) \leq \deg(u) = \deg(v) + \deg(w)$. Thus the desired solution is $\bar{v}(x) = b(x)f(x) - t(x)v(x) = b(x)f(x) \bmod v(x)$, $\bar{w}(x) = a(x)f(x) + t(x)w(x)$. If $(\bar{\bar{v}}(x), \bar{\bar{w}}(x))$ is another solution, we have $(\bar{w}(x) - \bar{\bar{w}}(x))v(x) \equiv (\bar{\bar{v}}(x) - \bar{v}(x))w(x)$ (modulo r). Thus if r is prime, $v(x)$ must divide $\bar{\bar{v}}(x) - \bar{v}(x)$; but $\deg(\bar{\bar{v}} - \bar{v}) < \deg(v)$, so $\bar{\bar{v}}(x) = \bar{v}(x)$ and $\bar{\bar{w}}(x) = \bar{w}(x)$.

For $p = 2$, the factorization proceeds as follows (writing only the coefficients, and using bars for negative digits): Exercise 10 says that $v_1(x) = (\bar{1}\,\bar{1}\,\bar{1})$, $w_1(x) = (\bar{1}\,\bar{1}\,\bar{1}\,0\,0\,\bar{1}\,\bar{1})$ in one-bit two's complement notation. Euclid's extended algorithm yields $a(x) = (1\,0\,0\,0\,0\,1), b(x) = (1\,0)$. The factor $v(x) = x^2 + c_1x + c_0$ must have $|c_1| \leq \lfloor 1 + \sqrt{113} \rfloor = 11$, $|c_0| \leq 10$, by exercise 20. Three applications of Hensel's lemma yield $v_4(x) = (1\,3\,\bar{1})$, $w_4(x) = (1\,\bar{3}\,\bar{5}\,\bar{4}\,4\,\bar{3}\,5)$. Thus $c_1 \equiv 3$ and $c_0 \equiv -1$ (modulo 16); the only possible quadratic factor of $u(x)$ is $x^2 + 3x - 1$. Division fails, so $u(x)$ is irreducible. (Since we have now proved the irreducibility of this beloved polynomial by four separate methods, it is unlikely that it has any factors.)

Hans Zassenhaus has observed that we can often speed up such calculations by increasing p as well as q: In the above notation, we can find $A(x)$, $B(x)$ such that $A(x)V(x) + B(x)W(x) \equiv 1$ (modulo pr), namely by taking $A(x) = a(x) + p\bar{a}(x)$, $B(x) = b(x) + p\bar{b}(x)$, where $\bar{a}(x)V(x) + \bar{b}(x)W(x) \equiv g(x)$ (modulo r), $a(x)V(x) + b(x)W(x) \equiv 1 - pg(x)$ (modulo pr). We can also find C with $\ell(V)C \equiv 1$ (modulo pr). In this way we can lift a squarefree factorization $u(x) \equiv v(x)w(x)$ (modulo p) to its unique extensions modulo p^2, p^4, p^8, p^{16}, etc. However, this "accelerated" procedure reaches a point of diminishing returns in practice, as soon as we get to double-precision moduli, since the time for multiplying multiprecision numbers in practical ranges outweighs the advantage of squaring the modulus directly. From a computational standpoint it seems best to work with the successive moduli p, p^2, p^4, p^8, ..., p^E, p^{E+e}, p^{E+2e}, p^{E+3e}, ..., where E is the smallest power of 2 with p^E greater than single precision and e is the largest integer such that p^e has single precision.

Hensel's lemma, which K. Hensel introduced in order to demonstrate the factorization of polynomials over the field of p-adic numbers (see exercise 4.1–31), can be generalized in several ways. First, if there are more factors, say $u(x) \equiv v_1(x)v_2(x)v_3(x)$ (modulo p), we can find $a_1(x)$, $a_2(x)$, $a_3(x)$ such that $a_1(x)v_2(x)v_3(x) + a_2(x)v_1(x)v_3(x) + a_3(x)v_1(x)v_2(x) \equiv 1$ (modulo p) and $\deg(a_i) < \deg(v_i)$. (In essence, $1/u(x)$ is expanded in partial fractions as $\sum a_i(x)/v_i(x)$.) An exactly analogous construction now allows us to lift the factorization without changing the leading coefficients of v_1 and v_2; we take $\bar{v}_1(x) = a_1(x)f(x) \bmod v_1(x)$, $\bar{v}_2(x) = a_2(x)f(x) \bmod v_2(x)$, etc. Another important generalization is to several simultaneous moduli, of the respective forms p^e, $(x_2 - a_2)^{n_2}$, ..., $(x_t - a_t)^{n_t}$, when performing multivariate gcds and factorizations. Cf. D. Y. Y. Yun, Ph.D. Thesis (M.I.T., 1974).

23. The discriminant of $\mathrm{pp}(u(x))$ is a nonzero integer (cf. exercise 4.6.1–12), and there are multiple factors modulo p iff p divides the discriminant. [The factorization of (22) modulo 3 is $(x+1)(x^2 - x - 1)^2(x^3 + x^2 - x + 1)$; squared factors for this polynomial occur only for $p = 3$, 23, 233, and 121702457. It is not difficult to prove that the

smallest prime that is not unlucky is at most $O(n \log Nn)$, if $n = \deg(u)$ and N bounds the coefficients of $u(x)$.]

24. Multiply a monic polynomial with rational coefficients by a suitable nonzero integer, to get a primitive polynomial over the integers. Factor this polynomial over the integers, and then convert the factors back to monic. (No factorizations are lost in this way; see exercise 4.6.1–8.)

25. Consideration of the constant term shows there are no factors of degree 1, so if the polynomial is reducible, it must have one factor of degree 2 and one of degree 3. Modulo 2 the factors are $x(x+1)^2(x^2+x+1)$; this is not much help. Modulo 3 the factors are $(x+2)^2(x^3+2x+2)$. Modulo 5 they are $(x^2+x+1)(x^3+4x+2)$. So we see that the answer is $(x^2+x+1)(x^3-x+2)$.

26. Begin with $D \leftarrow (0\ldots01)$, representing the set $\{0\}$. Then for $1 \le j \le r$, set $D \leftarrow D \vee (D \uparrow d_j)$, where $\vee$ denotes logical "or" and $D \uparrow d$ denotes D shifted left d bit positions. (Actually we need only work with a bit vector of length $\lceil (n+1)/2 \rceil$, since $n-m$ is in the set iff m is.)

27. Exercise 4 says that a random polynomial of degree n is irreducible modulo p with rather low probability, about $1/n$. But the Chinese remainder theorem implies that a random monic polynomial of degree n over the integers will be reducible with respect to each of k distinct primes with probability about $(1-1/n)^k$, and this approaches zero as $k \to \infty$. Hence almost all polynomials over the integers are irreducible with respect to infinitely many primes; and almost all primitive polynomials over the integers are irreducible. [Another proof has been given by W. S. Brown, *AMM* **70** (1963), 965–969. See also the generalization cited in the answer to exercise 36.]

28. Cf. exercise 4; the probability is the coefficient of z^n in $(1+a_{1p}z/p)(1+a_{2p}z^2/p^2)\times(1+a_{3p}z^3/p^3)\ldots$, which has the limiting value $g(z) = (1+z)(1+\frac{1}{2}z^2)(1+\frac{1}{3}z^3)\ldots$. For $1 \le n \le 10$ the answers are $1, \frac{1}{2}, \frac{5}{6}, \frac{7}{12}, \frac{37}{60}, \frac{79}{120}, \frac{173}{280}, \frac{101}{168}, \frac{127}{210}, \frac{1033}{1680}$. [Let $f(y) = \ln(1+y) - y = O(y^2)$. We have

$$g(z) = \exp\Big(\sum_{n\ge1} z^n/n + \sum_{n\ge1} f(z^n/n)\Big) = h(z)/(1-z),$$

and it can be shown that the limiting probability is $h(1) = \exp\big(\sum_{n\ge1} f(1/n)\big) = e^{-\gamma} \approx .56146$ as $n \to \infty$; cf. D. H. Lehmer, *Acta Arith.* **21** (1972), 379–388. Indeed, N. G. de Bruijn has established the asymptotic formula $\lim_{p\to\infty} a_{np} = e^{-\gamma} + e^{-\gamma}/n + O(n^{-2}\log n)$.]

29. Let $q_1(x)$ and $q_2(x)$ be any two of the irreducible divisors of $g(x)$. By the Chinese remainder theorem (exercise 3), choosing a random polynomial $t(x)$ of degree $< 2d$ is equivalent to choosing two random polynomials $t_1(x)$ and $t_2(x)$ of degrees $< d$, where $t_i(x) = t(x) \bmod q_i(x)$. The gcd will be a proper factor if $t_1(x)^{(p^d-1)/2} \bmod q_1(x) = 1$ and $t_2(x)^{(p^d-1)/2} \bmod q_1(x) \neq 1$, or vice versa, and this condition holds for exactly $2((p^d-1)/2)((p^d+1)/2) = (p^{2d}-1)/2$ choices of $t_1(x)$ and $t_2(x)$.

Notes: We are considering here only the behavior with respect to two irreducible factors, but the true behavior is probably much better. Suppose that each irreducible factor $q_i(x)$ has probability $\frac{1}{2}$ of dividing $t(x)^{(p^d-1)/2} - 1$ for each $t(x)$, independent of the behavior for other $q_j(x)$ and $t(x)$; and assume that $g(x)$ has r irreducible factors in all. Then if we encode each $q_i(x)$ by a sequence of 0's and 1's according as $q_i(x)$ does or doesn't divide $t(x)^{(p^d-1)/2} - 1$ for the successive t's tried, we obtain a random binary

trie with r lieves (cf. Section 6.3). The cost associated with an internal node of this trie, having m lieves as descendants, is $O(m^2(\log p))$; and the solution to the recurrence $A_n = \binom{n}{2} + 2^{1-n}\sum\binom{n}{k}A_k$ is $A_n = 2\binom{n}{2}$, by exercise 5.2.2–36. Hence the sum of costs in the given random trie—representing the expected time to factor $g(x)$ *completely*—is $O(r^2(\log p)^3)$ under this plausible assumption. The plausible assumption becomes rigorously true if we choose $t(x)$ at random of degree $< rd$ instead of restricting it to degree $< 2d$.

30. Let $T(x) = x + x^p + \cdots + x^{p^{d-1}}$ and $v(x) = T(t(x)) \bmod q(x)$. Since $t(x)^{p^d} = t(x)$ in the field of polynomial remainders modulo $q(x)$, we have $v(x)^p = v(x)$ in that field; in other words, $v(x)$ is one of the p roots of the equation $y^p - y = 0$. Hence $v(x)$ is an integer.

It follows that $\prod_{0\le s<p}\gcd(g_d(x), T(t(x)) - s) = g_d(x)$. In particular, when $p = 2$ we can argue as in exercise 29 that $\gcd(g_d(x), T(t(x)))$ will be a proper factor of $g_d(x)$ with probability $\ge \frac{1}{2}$ when $g_d(x)$ has at least two irreducible factors and $t(x)$ is a random binary polynomial of degree $< 2d$.

[Note that $T(t(x)) \bmod g(x)$ can be computed by starting with $u(x) \leftarrow t(x)$ and setting $u(x) \leftarrow (u(x) + u(x)^p) \bmod g(x)$ repeatedly, $d - 1$ times. The method of this exercise is based on the polynomial factorization $x^{p^d} - x = \prod_{0\le s<p}(T(x) - s)$, which holds for any p, while formula (21) is based on the polynomial factorization $x^{p^d} - x = x(x^{(p^d-1)/2} + 1)(x^{(p^d-1)/2} - 1)$ for odd p.]

31. If α is an element of the field of p^d elements, let $d(\alpha)$ be the "degree" of α, namely the smallest exponent e such that $\alpha^{p^e} = \alpha$. Then

$$P_\alpha(x) = (x - \alpha)(x - \alpha^p)\ldots(x - \alpha^{p^{d-1}}) = q_\alpha(x)^{d/d(\alpha)},$$

where $q_\alpha(x)$ is an irreducible polynomial of degree $d(\alpha)$. As α runs through all elements of the field, the corresponding $q_\alpha(x)$ runs through every irreducible polynomial of degree e dividing d, where every such irreducible occurs exactly e times. We have $(x + t)^{(p^d-1)/2} \bmod q_\alpha(x) = 1$ if and only if $(\alpha + t)^{(p^d-1)/2} = 1$ in the field. If t is an integer, we have $d(\alpha + t) = d(\alpha)$, hence $n(p, d)$ is d^{-1} times the number of elements α of degree d such that $\alpha^{(p^d-1)/2} = 1$. Similarly, if $t_1 \ne t_2$ we want to count the number of elements of degree d such that $(\alpha + t_1)^{(p^d-1)/2} = (\alpha + t_2)^{(p^d-1)/2}$, i.e., $((\alpha + t_1)/(a + t_2))^{(p^d-1)/2} = 1$. As α runs through all the elements of degree d, so does the quantity $(\alpha + t_1)/(\alpha + t_2) = 1 + (t_1 - t_2)/(\alpha + t_2)$.

[We have $n(p, d) = \frac{1}{4}d^{-1}\sum_{c\setminus d}(3 + (-1)^c)\mu(c)(p^{d/c} - 1)$, which is about half the total number of irreducibles—exactly half, in fact, when d is odd. This proves that $\gcd(g_d(x), (x + t)^{(p^d-1)/2} - 1)$ has a good chance of finding factors of $g_d(x)$ when t is fixed and $g_d(x)$ is chosen at random; but a probabilistic algorithm is supposed to work with guaranteed probability for fixed $g_d(x)$ and random t, as in exercise 29.]

32. (a) Clearly $x^n - 1 = \prod_{d\setminus n}\Psi_d(x)$, since every complex nth root of unity is a primitive dth root for some unique $d \setminus n$. The second identity follows from the first; and $\Psi_n(x)$ has integer coefficients since it is expressed in terms of products and quotients of monic polynomials with integer coefficients. (b) The condition in the hint suffices to prove that $f(x) = \Psi_n(x)$, so we shall take the hint. When p does not divide n, we have $\gcd(x^n - 1, nx^{n-1}) = 1$ modulo p, hence $x^n - 1$ is squarefree modulo p. Given $f(x)$ and ζ as in the hint, let $g(x)$ be the irreducible factor of $\Psi_n(x)$ such that $g(\zeta^p) = 0$. If

$g(x) \neq f(x)$ then both $f(x)$ and $g(x)$ are distinct factors of $\Psi_n(x)$, hence they are distinct factors of $x^n - 1$, hence they have no irreducible factors in common modulo p. However, ζ^p is a root of $f(x^p)$, so $\gcd(g(x), f(x^p)) \neq 1$ over the integers, hence $g(x)$ is a divisor of $f(x^p)$. By (5), $g(x)$ is a divisor of $f(x)^p$, modulo p, contradicting the assumption that $f(x)$ and $g(x)$ have no irreducible factors in common. Therefore $f(x) = g(x)$. [The irreducibility of $\Psi_n(x)$ was first proved for prime n by K. F. Gauss in *Disquisitiones Arithmeticæ* (Leipzig, 1801), Art. 341, and for general n by L. Kronecker, *J. de Math. Pures et Appliquées* **19** (1854), 177–192.]

(c) $\Psi_1(x) = x - 1$; and when p is prime, $\Psi_p(x) = 1 + x + \cdots + x^{p-1}$. If $n > 1$ is odd, it is not difficult to prove that $\Psi_{2n}(x) = \Psi_n(-x)$. If p divides n, the second identity in (a) shows that $\Psi_{pn}(x) = \Psi_n(x^p)$. If p does not divide n, we have $\Psi_{pn}(x) = \Psi_n(x^p)/\Psi_n(x)$. For nonprime $n \leq 15$ we have $\Psi_4(x) = x^2 + 1$, $\Psi_6(x) = x^2 - x + 1$, $\Psi_8(x) = x^4 + 1$, $\Psi_9(x) = x^6 + x^3 + 1$, $\Psi_{10}(x) = x^4 - x^3 + x^2 - x + 1$, $\Psi_{12}(x) = x^4 - x^2 + 1$, $\Psi_{14}(x) = x^6 - x^5 + x^4 - x^3 + x^2 - x + 1$, $\Psi_{15}(x) = x^8 - x^7 + x^5 - x^4 + x^3 - x + 1$. [The formula $\Psi_{pq}(x) = (1 + x^p + \cdots + x^{(q-1)p})(x-1)/(x^q - 1)$ can be used to show that $\Psi_{pq}(x)$ has all coefficients ± 1 or 0 when p and q are prime; but the coefficients of $\Psi_{pqr}(x)$ can be arbitrarily large.]

33. False; we lose all p_j with e_j divisible by p. True if $p \geq \deg(u)$. [See exercise 36.]

34. [D. Y. Y. Yun, *Proc. ACM Symp. Symbolic and Algebraic Comp.* (1976), 26–35.] Set $(t(x), v_1(x), w_1(x)) \leftarrow \mathrm{GCD}(u(x), u'(x))$. If $t(x) = 1$, set $e \leftarrow 1$; otherwise set $(u_i(x), v_{i+1}(x), w_{i+1}(x)) \leftarrow \mathrm{GCD}(v_i(x), w_i(x) - v_i'(x))$ for $i = 1, 2, \ldots, e-1$, until finding $w_e(x) - v_e'(x) = 0$. Finally set $u_e(x) \leftarrow v_e(x)$.

To prove the validity of this algorithm, we observe that it computes the polynomials $t(x) = u_2(x)u_3(x)^2u_4(x)^3\ldots$, $v_i(x) = u_i(x)u_{i+1}(x)u_{i+2}(x)\ldots$, and

$$w_i(x) = u_i'(x)u_{i+1}(x)u_{i+2}(x)\ldots + 2u_i(x)u_{i+1}'(x)u_{i+2}(x)\ldots + 3u_i(x)u_{i+1}(x)u_{i+2}'(x)\ldots + \cdots.$$

We have $\gcd(t(x), w_1(x)) = 1$, since an irreducible factor of $u_i(x)$ divides all but the ith term of $w_1(x)$, and it is relatively prime to that term. Furthermore $\gcd(u_i(x), v_{i+1}(x))$ is clearly 1.

[Exercise 2(b) indicates that comparatively few polynomials are squarefree, but non-squarefree polynomials actually occur often in practice; hence this method turns out to be quite important. See Paul S. Wang and Barry M. Trager, *SIAM J. Computing* **8** (1979), 300–305, for suggestions on how to improve the efficiency when the given polynomial is already squarefree.]

35. We have $w_j(x) = \gcd(u_j(x), v_j^*(x)) \cdot \gcd(u_{j+1}^*(x), v_j(x))$, where

$$u_j^*(x) = u_j(x)u_{j+1}(x)\ldots \qquad \text{and} \qquad v_j^*(x) = v_j(x)v_{j+1}(x)\ldots.$$

[Yun notes that the running time for squarefree factorization by the method of exercise 34 is at most about twice the running time to calculate $\gcd(u(x), u'(x))$. Furthermore if we are given an arbitrary method for discovering squarefree factorization, the method of this exercise leads to a gcd procedure. (When $u(x)$ and $v(x)$ are squarefree, their gcd is simply $w_2(x)$ where $w(x) = u(x)v(x) = w_1(x)w_2(x)^2$; the polynomials $u_j(x)$, $v_j(x)$, $u_j^*(x)$, and $v_j^*(x)$ are all squarefree.) Hence the problem of converting a primitive polynomial of degree n to its squarefree representation is computationally *equivalent* to the problem of calculating the gcd of two nth degree polynomials, in the sense of asymptotic worst-case running time.]

36. Let $U_j(x)$ be the value computed for "$u_j(x)$" by the procedure of exercise 34. If $\deg(U_1)+2\deg(U_2)+\cdots=\deg(u)$, then $u_j(x)=U_j(x)$ for all j. But in general we will have $e<p$ and $U_j(x)=\prod_{k\geq 0}u_{j+pk}(x)$ for $1\leq j<p$. To separate these factors further, we can calculate $t(x)/(U_2(x)U_3(x)^2\ldots U_{p-1}(x)^{p-2})=\prod_{j\geq p}u_j(x)^{p\lfloor j/p\rfloor}=z(x^p)$. After recursively finding the squarefree representation of $z(x)=(z_1(x),z_2(x),\ldots)$, we will have $z_k(x)=\prod_{0\leq j<p}u_{j+pk}(x)$, so we can calculate the individual $u_i(x)$ by the formula $\gcd(U_j(x),z_k(x))=u_{j+pk}(x)$ for $1\leq j<p$. The polynomial $u_{pk}(x)$ will be left when the other factors of $z_k(x)$ have been removed.

Note: This procedure is fairly simple but the program is lengthy. If one's goal is to have a short program for complete factorization modulo p, rather than an extremely efficient one, it is probably easiest to modify the distinct-degree factorization routine so that it casts out $\gcd(x^{p^d}-x,u(x))$ several times for the same value of d until the gcd is 1. In this case you needn't begin by calculating $\gcd(u(x),u'(x))$ and removing multiple factors as suggested in the text, since the polynomial $x^{p^d}-x$ is squarefree.

37. The exact probability is $\prod_{j\geq 1}(a_{jp}/p^j)^{k_j}/k_j!$, where k_j is the number of d_i that are equal to j. Since $a_{jp}/p^j\approx 1/j$ by exercise 4, we get the formula of exercise 1.3.3–21.

Notes: This exercise says that if we fix the prime p and let the polynomial $u(x)$ be random, it will have certain probability of splitting in a given way modulo p. A much harder problem is to fix the polynomial $u(x)$ and to let p be "random"; it turns out that the same asymptotic result holds for almost all $u(x)$. G. Frobenius proved in 1880 that the integer polynomial $u(x)$ splits modulo p into factors of degrees $d_1,\ldots,d_r$, when p is a large prime chosen at random, with probability equal to the number of permutations in the Galois group G of $u(x)$ having cycle lengths $\{d_1,\ldots,d_r\}$ divided by the total number of permutations in G. (If $u(x)$ has rational coefficients and distinct roots $\xi_1,\ldots,\xi_n$ over the complex numbers, its Galois group is the (unique) group G of permutations such that the polynomial $\prod_{p(1)\ldots p(n)\in G}(z+\xi_{p(1)}y_1+\cdots+\xi_{p(n)}y_n)=U(z,y_1,\ldots,y_n)$ has rational coefficients and is irreducible over the rationals.) Furthermore B. L. van der Waerden proved in 1934 that almost all polynomials of degree n have the set of all $n!$ permutations as their Galois group. Therefore almost all fixed irreducible polynomials $u(x)$ will factor as we might expect them to, with respect to randomly chosen large primes p. References: *Sitzungsberichte Königl. Preuß. Akad. Wiss.* (Berlin: 1896), 689–703; *Math. Annalen* **109** (1934), 13–16. See also N. Chebotarev, *Math. Annalen* **95** (1926), for a generalization of Frobenius's theorem to conjugacy classes of the Galois group.

38. (Partial solution by Peter Weinberger.) The average number of 1-cycles in a randomly chosen element of any transitive permutation group G on n objects is 1, since the probability is $1/n$ that any given object is fixed. Since Galois groups are always transitive, the remarks in the previous answer show that a fixed irreducible polynomial has exactly one linear factor modulo p, on the average, as $p\to\infty$. Thus, *the average number of linear factors of $u(x)$ modulo p is the number of irreducible factors of $u(x)$ over the integers.*

Weinberger [*Proc. Symp. Pure Math.* **24** (Amer. Math. Soc., 1973), 321–332] has proved that if the generalized Riemann hypothesis (GRH) holds—this is a conjecture about the zeros of a generalized zeta function—then there is an absolute constant A_1 with the following property: The number of prime ideals of norm $\leq x$, in any algebraic number field of degree n, differs from $\int_2^x dt/\ln t$ by at most $A_1 n x^{1/2}\ln(x\Delta)$, where Δ is the absolute value of the discriminant of the irreducible polynomial u that defines the

field. The number of prime ideals of norm $\leq x$ is at most $nx^{1/2}$ different from the total number of linear factors of u modulo primes $\leq x$, since such linear factors correspond to ideals of norm p, while other prime ideals have norms $\geq p^2$. Consequently if we let $N(x)$ be the total number of linear factors of a given primitive polynomial u, modulo all primes $\leq x$, then the GRH implies that there is an absolute constant A_2 such that $|N(x)/\pi(x) - r| < A_2 n x^{-1/2}(\ln x)(\ln x\Delta)$. A proof of GRH would yield a "short" proof of the number of irreducible factors of any primitive polynomial u over the integers, since we could evaluate $N(x)$ for a value of x sufficiently large to make this error bound less than $\frac{1}{2}$. Unfortunately A_2 is quite large.

SECTION 4.6.3

1. x^m, where $m = 2^{\lambda(n)}$, the highest power of 2 less than or equal to n.

2. Assume that x is input in register A, and n in location NN; the output is in register X.

```
01  A1 ENTX 1      1          A1. Initialize.
02     STX  Y      1          Y ← 1.
03     STA  Z      1          Z ← x.
04     LDA  NN     1          N ← n.
05     JMP  2F     1          To A2.
06  5H SRB  1      L+1-K
07     STA  N      L+1-K      N ← ⌊N/2⌋.
08  A5 LDA  Z      L          A5. Square Z.
09     MUL  Z      L          Z × Z mod w
10     STX  Z      L              → Z.
11  A2 LDA  N      L          A2. Halve N.
12  2H JAE  5B     L+1        To A5 if N is even.
13     SRB  1      K
14  A4 JAZ  4F     K          Jump if N = 1.
15     STA  N      K-1        N ← ⌊N/2⌋.
16  A3 LDA  Z      K-1        A3. Multiply Y by Z.
17     MUL  Y      K-1        Z × Y mod w
18     STX  Y      K-1            → Y.
19     JMP  A5     K-1        To A5.
20  4H LDA  Z      1
21     MUL  Y      1          Do the final multiplication. ∎
```

[It would be better programming practice to change the instruction in line 05 to "JAP", followed by an error indication. The running time is $21L + 16K + 8$, where $L = \lambda(n)$ is one less than the number of bits in the binary representation of n, and $K = \nu(n)$ is the number of 1 bits in that representation.]

For the serial program, we may assume that n is small enough to fit in an index register; otherwise serial exponentiation is out of the question. The following program leaves the output in register A:

```
01  S1 LD1  NN     1      rI1 ← n.
02     STA  X      1      X ← x.
03     JMP  2F     1
```

```
04  1H MUL  X  N-1   rA × X mod w
05     SLAX 5  N-1        → rA.
06  2H DEC1 1    N     rI1 ← rI1 - 1.
07     J1P  1B   N     Multiply again if rI1 > 0.  ∎
```

The running time for this program is $14N - 7$; it is faster than the previous program when $n \leq 7$, slower when $n \geq 8$.

3. The sequences of exponents are: (a) 1, 2, 3, 6, 7, 14, 15, 30, 60, 120, 121, 242, 243, 486, 487, 974, 975 [16 multiplications]; (b) 1, 2, 3, 4, 8, 12, 24, 36, 72, 108, 216, 324, 325, 650, 975 [14 multiplications]; (c) 1, 2, 3, 6, 12, 15, 30, 60, 120, 240, 243, 486, 972, 975 [13 multiplications]; (d) 1, 2, 3, 6, 12, 15, 30, 60, 75, 150, 300, 600, 900, 975 [13 multiplications]. [The smallest possible number of multiplications is 12; this is obtainable by combining the factor method with the binary method, since $975 = 15 \cdot (2^6 + 1)$.]

4. $(777777)_8 = 2^{18} - 1$.

5. T1. [Initialize.] Set LINKU$[j] \leftarrow 0$ for $1 \leq j \leq 2^r$, and set $k \leftarrow 0$, LINKR$[0] \leftarrow 1$, LINKR$[1] \leftarrow 0$.

T2. [Change level.] (Now level k of the tree has been linked together from left to right, starting at LINKR[0].) If $k = r$, the algorithm terminates. Otherwise set $n \leftarrow$ LINKR$[0]$, $m \leftarrow 0$.

T3. [Prepare for n.] (Now n is a node on level k, and m points to the rightmost node currently on level $k + 1$.) Set $q \leftarrow 0$, $s \leftarrow n$.

T4. [Already in tree?] (Now s is a node in the path from the root to n.) If LINKU$[n + s] \neq 0$, go to T6 (the value $n + s$ is already in the tree).

T5. [Insert below n.] If $q = 0$, set $m' \leftarrow n + s$. Then set LINKR$[n + s] \leftarrow q$, LINKU$[n + s] \leftarrow n$, $q \leftarrow n + s$.

T6. [Move up.] Set $s \leftarrow$ LINKU$[s]$. If $s \neq 0$, return to T4.

T7. [Attach group.] If $q \neq 0$, set LINKR$[m] \leftarrow q$, $m \leftarrow m'$.

T8. [Move n.] Set $n \leftarrow$ LINKR$[n]$. If $n \neq 0$, return to T3.

T9. [End of level.] Set LINKR$[m] \leftarrow 0$, $k \leftarrow k + 1$, and return to T2. ∎

6. Prove by induction that the path to the number $2^{e_0} + 2^{e_1} + \cdots + 2^{e_t}$, if $e_0 > e_1 > \cdots > e_t \geq 0$, is $1, 2, 2^2, \ldots, 2^{e_0}, 2^{e_0} + 2^{e_1}, \ldots, 2^{e_0} + 2^{e_1} + \cdots + 2^{e_t}$; furthermore, the sequences of exponents on each level are in decreasing lexicographic order.

7. The binary and factor methods require one more step to compute x^{2n} than x^n; the power tree method requires at most one more step. Hence (a) $15 \cdot 2^k$; (b) $33 \cdot 2^k$; (c) $23 \cdot 2^k$; $k = 0, 1, 2, 3, \ldots$.

8. The power tree always includes the node $2m$ at one level below m, unless it occurs at the same level or an earlier level; and it always includes the node $2m + 1$ at one level below $2m$, unless it occurs at the same level or an earlier level. [It is not true that $2m$ is a son of m in the power tree for all m; the smallest example where this fails is $m = 2138$, which appears on level 15, while 4276 appears elsewhere on level 16. In fact, $2m$ sometimes occurs on the same level as m; the smallest example is $m = 6029$.]

9. Start with $N \leftarrow n$, $Z \leftarrow x$, and $Y_k \leftarrow 1$ for $1 \leq k < m$; in general we will have $x^n = Y_1 Y_2^2 \ldots Y_{m-1}^{m-1} Z^N$. If $N > 0$, set $k \leftarrow N \bmod m$, and if $k \neq 0$ set $Y_k \leftarrow Y_k \cdot Z$. Then set $Z \leftarrow Z^m$, $N \leftarrow \lfloor N/m \rfloor$, and repeat. Finally set $Y_k \leftarrow Y_k \cdot Y_{k+1}$ for $k = m-2$, $m - 3, \ldots, 1$; the answer is $Y_1 \ldots Y_{m-1}$.

10. By using the "FATHER" representation discussed in Section 2.3.3: Make use of a table $f[j]$, $1 \le j \le 100$, such that $f[1] = 0$ and $f[j]$ is the number of the node just above j for $j \ge 2$. (The fact that each node of this tree has degree at most two has no effect on the efficiency of this representation; it just makes the tree look prettier as an illustration.)

11. 1, 2, 3, 5, 10, 20, (23 or 40), 43; 1, 2, 4, 8, 9, 17, (26 or 34), 43; 1, 2, 4, 8, 9, 17, 34, (43 or 68), 77; 1, 2, 4, 5, 9, 18, 36, (41 or 72), 77. If either of the latter two paths were in the tree we would have no possibility for $n = 43$, since the tree must contain either 1, 2, 3, 5 or 1, 2, 4, 8, 9.

12. No such infinite tree can exist, since $l(n) \neq l^*(n)$ for some n.

13. For Case 1, use a Type-1 chain followed by $2^{A+C} + 2^{B+C} + 2^A + 2^B$; or use the factor method. For Case 2, use a Type-2 chain followed by $2^{A+C+1} + 2^{B+C} + 2^A + 2^B$. For Case 3, use a Type-5 chain followed by addition of $2^A + 2^{A-1}$, or use the factor method. For Case 4, $n = 135 \cdot 2^D$, so we may use the factor method.

14. (a) It is easy to verify that steps $r-1$ and $r-2$ are not both small, so let us assume that step $r-1$ is small and step $r-2$ is not. If $c = 1$, then $\lambda(a_{r-1}) = \lambda(a_{r-k})$, so $k = 2$; and since $4 \le \nu(a_r) = \nu(a_{r-1}) + \nu(a_{r-k}) - 1 \le \nu(a_{r-1}) + 1$, we have $\nu(a_{r-1}) \ge 3$, making $r-1$ a star step (lest $a_0, a_1, \ldots, a_{r-3}, a_{r-1}$ include only one small step). Then $a_{r-1} = a_{r-2} + a_{r-q}$ for some q, and if we replace a_{r-2}, a_{r-1}, a_r by $a_{r-2}, 2a_{r-2}, 2a_{r-2} + a_{r-q} = a_r$, we obtain another counterexample chain in which step r is small; but this is impossible. On the other hand, if $c \ge 2$, then $4 \le \nu(a_r) \le \nu(a_{r-1}) + \nu(a_{r-k}) - 2 \le \nu(a_{r-1})$; hence $\nu(a_{r-1}) = 4$, $\nu(a_{r-k}) = 2$, and $c = 2$. This leads readily to an impossible situation by a consideration of the six types in the proof of Theorem B.

(b) If $\lambda(a_{r-k}) < m-1$, we have $c \ge 3$, so $\nu(a_{r-k}) + \nu(a_{r-1}) \ge 7$ by (22); therefore both $\nu(a_{r-k})$ and $\nu(a_{r-1})$ are ≥ 3. All small steps must be $\le r-k$, and $\lambda(a_{r-k}) = m-k+1$. If $k \ge 4$, we must have $c = 4$, $k = 4$, $\nu(a_{r-1}) = \nu(a_{r-4}) = 4$; thus $a_{r-1} \ge 2^m + 2^{m-1} + 2^{m-2}$, and a_{r-1} must equal $2^m + 2^{m-1} + 2^{m-2} + 2^{m-3}$; but $a_{r-4} \ge \frac{1}{8} a_{r-1}$ now implies that $a_{r-1} = 8a_{r-4}$. Thus $k = 3$ and $a_{r-1} > 2^m + 2^{m-1}$. Since $a_{r-2} < 2^m$ and $a_{r-3} < 2^{m-1}$, step $r-1$ must be a doubling; but step $r-2$ is a nondoubling, since $a_{r-1} \neq 4a_{r-3}$. Furthermore, since $\nu(a_{r-3}) \ge 3$, $r-3$ is a star step; and $a_{r-2} = a_{r-3} + a_{r-5}$ would imply that $a_{r-5} = 2^{m-2}$, hence we must have $a_{r-2} = a_{r-3} + a_{r-4}$. As in a similar case treated in the text, the only possibility is now seen to be $a_{r-4} = 2^{m-2} + 2^{m-3}$, $a_{r-3} = 2^{m-2} + 2^{m-3} + 2^{d+1} + 2^d$, $a_{r-1} = 2^m + 2^{m-1} + 2^{d+2} + 2^{d+1}$, and even this possibility is impossible.

16. $l^B(n) = \lambda(n) + \nu(n) - 1$; so if $n = 2^k$, $l^B(n)/\lambda(n) = 1$, but if $n = 2^{k+1} - 1$, $l^B(n)/\lambda(n) = 2$.

17. Let $i_1 < \cdots < i_t$. Delete any intervals I_k that can be removed without affecting the union $I_1 \cup \cdots \cup I_t$. (The interval $(j_k, i_k]$ may be dropped out if either $j_{k+1} \le j_k$ or $j_1 < j_2 < \cdots$ and $j_{k+1} \le i_{k-1}$.) Now combine overlapping intervals $(j_1, i_1], \ldots, (j_d, i_d]$ into an interval $(j', i'] = (j_1, i_d]$ and note that

$$a_{i'} < a_{j'}(1+\delta)^{i_1 - j_1 + \cdots + i_d - j_d} \le a_{j'}(1+\delta)^{2(i'-j')},$$

since each point of $(j', i']$ is covered at most twice in $(j_i, i_1] \cup \cdots \cup (j_d, i_d]$.

18. Call $f(m)$ a "nice" function if $(\log f(m))/m \to 0$ as $m \to \infty$. A polynomial in m is nice. The product of nice functions is nice. If $g(m) \to 0$ and c is a positive constant, then $c^{mg(m)}$ is nice; also $\binom{2m}{mg(m)}$ is nice, for by Stirling's approximation this is equivalent to saying that $g(m)\log(1/g(m)) \to 0$.

Now replace each term of the summation by the maximum term that is attained for any s, t, v. The total number of terms is nice, and so are $\binom{m+s}{t+v}$, $\binom{t+v}{v} \le 2^{t+v}$, and β^{2v}, because $(t+v)/m \to 0$. Finally, $\binom{(m+s)^2}{t} \le (2m)^{2t}/t! < (4m^2/t)^t e^t$, where $(4e)^t$ is nice; setting t to its maximum value $(1-\frac{1}{2}\epsilon)m/\lambda(m)$, we have the upper bound $(m^2/t)^t = (m\lambda(m)/(1-\frac{1}{2}\epsilon))^t = 2^{m(1-\epsilon/2)} \cdot f(m)$, where $f(m)$ is nice. Hence the entire sum is less than α^m for large m, if $\alpha = 2^{1-\eta}$, $0 < \eta < \frac{1}{2}\epsilon$.

19. (a) $M \cap N$, $M \cup N$, $M \uplus N$, respectively; see Eqs. 4.5.2–6, 4.5.2–7.

(b) $f(z)g(z)$, $\operatorname{lcm}(f(z), g(z))$, $\gcd(f(z), g(z))$. (For the same reasons as (a), because the monic irreducible polynomials over the complex numbers are precisely the polynomials $z - \zeta$.)

(c) Commutative laws $A \uplus B = B \uplus A$, $A \cup B = B \cup A$, $A \cap B = B \cap A$. Associative laws $A \uplus (B \uplus C) = (A \uplus B) \uplus C$, $A \cup (B \cup C) = (A \cup B) \cup C$, $A \cap (B \cap C) = (A \cap B) \cap C$. Distributive laws $A \cup (B \cap C) = (A \cup B) \cap (A \cup C)$, $A \cap (B \cup C) = (A \cap B) \cup (A \cap C)$, $A \uplus (B \cup C) = (A \uplus B) \cup (A \uplus C)$, $A \uplus (B \cap C) = (A \uplus B) \cap (A \uplus C)$. Idempotent laws $A \cup A = A$, $A \cap A = A$. Absorption laws $A \cup (A \cap B) = A$, $A \cap (A \cup B) = A$, $A \cap (A \uplus B) = A$, $A \cup (A \uplus B) = A \uplus B$. Identity and zero laws $\emptyset \uplus A = A$, $\emptyset \cup A = A$, $\emptyset \cap A = \emptyset$, where $\emptyset$ is the empty multiset. Counting law $A \uplus B = (A \cup B) \uplus (A \cap B)$. Further properties analogous to those of sets come from the partial ordering defined by the rule $A \subseteq B$ iff $A \cap B = A$ (iff $A \cup B = B$).

Notes: Other common applications of multisets are zeros and poles of meromorphic functions, invariants of matrices in canonical form, invariants of finite Abelian groups, etc.; multisets can be useful in combinatorial counting arguments and in the development of measure theory. The terminal strings of a noncircular context-free grammar form a multiset that is a set if and only if the grammar is unambiguous. Although multisets appear frequently in mathematics, they often must be treated rather clumsily because there is currently no standard way to treat sets with repeated elements. Several mathematicians have voiced their belief that the lack of adequate terminology and notation for this common concept has been a definite handicap to the development of mathematics. (A multiset is, of course, formally equivalent to a mapping from a set into the nonnegative integers, but this formal equivalence is of little or no practical value for creative mathematical reasoning.) The author has discussed this matter with many people in an attempt to find a good remedy. Some of the names suggested for the concept were list, bunch, bag, heap, sample, weighted set, collection; but these words either conflict with present terminology, have an improper connotation, or are too much of a mouthful to say and to write conveniently. It does not seem out of place to coin a new word for such an important concept, and "multiset" has been suggested by N. G. de Bruijn. The notation "$A \uplus B$" has been selected by the author to avoid conflict with existing notations and to stress the analogy with set union. It would not be as desirable to use "$A + B$" for this purpose, since algebraists have found that $A + B$ is a good notation for $\{\alpha + \beta \mid \alpha \in A \text{ and } \beta \in B\}$. If A is a multiset of nonnegative integers, let $G(z) = \sum_{n \in A} z^n$ be a generating function corresponding to A. (Generating functions with nonnegative integer coefficients obviously correspond one-to-one with multisets of nonnegative integers.) If $G(z)$ corresponds to A and $H(z)$ to B, then $G(z) + H(z)$ corresponds to $A \uplus B$ and $G(z)H(z)$ corresponds to $A + B$.

If we form "Dirichlet" generating functions $g(z) = \sum_{n\in A} 1/n^z$, $h(z) = \sum_{n\in B} 1/n^z$, then the product $g(z)h(z)$ corresponds to the multiset product AB.

20. Type 3: $(S_0, \ldots, S_r) = (M_{00}, \ldots, M_{r0}) = (\{0\}, \ldots, \{A\}, \{A-1, A\}, \{A-1, A, A\}, \{A-1, A-1, A, A, A\}, \ldots, \{A+C-3, A+C-3, A+C-2, A+C-2, A+C-2\})$. Type 5: $(M_{00}, \ldots, M_{r0}) = (\{0\}, \ldots, \{A\}, \{A-1, A\}, \ldots, \{A+C-1, A+C\}, \{A+C-1, A+C-1, A+C\}, \ldots, \{A+C+D-1, A+C+D-1, A+C+D\})$; $(M_{01}, \ldots, M_{r1}) = (\emptyset, \ldots, \emptyset, \emptyset, \ldots, \emptyset, \{A+C-2\}, \ldots, \{A+C+D-2\})$, $S_i = M_{i0} \uplus M_{i1}$.

21. For example, let $u = 2^{8q+5}$, $x = (2^{(q+1)u} - 1)/(2^u - 1) = 2^{qu} + \cdots + 2^u + 1$, $y = 2^{(q+1)u} + 1$. Then $xy = (2^{2(q+1)u} - 1)/(2^u - 1)$. If $n = 2^{4(q+1)u} + xy$, we have $l(n) \le 4(q+1)u + q + 2$ by Theorem F, but $l^*(n) = 4(q+1)u + 2q + 2$ by Theorem H.

22. Underline everything except the $u - 1$ insertions used in the calculation of x.

23. Theorem G (everything underlined).

24. Use the numbers $(B^{a_i} - 1)/(B-1)$, $0 \le i \le r$, underlined when a_i is underlined; and $c_k B^{i-1}(B^{b_j} - 1)/(B-1)$ for $0 \le j < t$, $0 < i \le b_{j+1} - b_j$, $1 \le k \le l^0(B)$, underlined when c_k is underlined, where $c_0, c_1, \ldots$ is a minimum length l^0-chain for B. To prove the second inequality, let $B = 2^m$ and use (3). (The second inequality is rarely, if ever, an improvement on Theorem G.)

25. We may assume that $d_k = 1$. Use the rule R $A_{k-1} \ldots A_1$, where A_j = "XR" if $d_j = 1$, A_j = "R" otherwise, and where "R" means take the square root, "X" means multiply by x. For example, if $y = (.1101101)_2$, the rule is R R XR XR R XR XR. (There exist binary square-root extraction algorithms suitable for computer hardware, requiring an execution time comparable to that of division; computers with such hardware could therefore calculate more general fractional powers using the technique in this exercise.)

26. If we know the pair (F_k, F_{k-1}), then we have $(F_{k+1}, F_k) = (F_k + F_{k-1}, F_k)$ and $(F_{2k}, F_{2k-1}) = (F_k^2 + 2F_kF_{k-1}, F_k^2 + F_{k-1}^2)$; so a binary method can be used to calculate (F_n, F_{n-1}), using $O(\log n)$ arithmetic operations. Perhaps better is to use the pair of values (F_k, L_k), where $L_k = F_{k-1} + F_{k+1}$ (cf. Section 4.5.4); then we have $(F_{k+1}, L_{k+1}) = (\frac{1}{2}(F_k + L_k), \frac{1}{2}(5F_k + L_k))$, $(F_{2k}, L_{2k}) = (F_kL_k, L_k^2 - 2(-1)^k)$.

For the general linear recurrence $x_n = a_1x_{n-1} + \cdots + a_dx_{n-d}$, we can compute x_n in $O(d^3 \log n)$ arithmetic operations by computing the nth power of an appropriate $d \times d$ matrix. [This observation is due to J. C. P. Miller and D. J. S. Brown, *Comp. J.* **9** (1966), 188–190.]

27. First form the $2^m - m - 1$ products $x_1^{e_1} \ldots x_m^{e_m}$, for all sequences of exponents such that $0 \le e_j \le 1$ and $e_1 + \cdots + e_m \ge 2$. Let $n_j = (d_{j\lambda} \ldots d_{j1}d_{j0})_2$; to complete the calculation, take $x_1^{d_{1\lambda}} \ldots x_m^{d_{m\lambda}}$, then square and multiply by $x_1^{d_{1i}} \ldots x_m^{d_{mi}}$, for $i = \lambda - 1, \ldots, 1, 0$. [Straus showed in *AMM* **71** (1964), 807–808, that $2\lambda(n)$ may be replaced by $(1+\epsilon)\lambda(n)$ for any $\epsilon > 0$, by generalizing this binary method to 2^k-ary as in Theorem D. See exercise 39 for later developments.]

28. (a) $x \nabla y = x \vee y \vee (x+y)$, where "$\vee$" is logical "or", cf. exercise 4.6.2–26; clearly $\nu(x \nabla y) \le \nu(x \vee y) + \nu(x \wedge y) = \nu(x) + \nu(y)$. (b) Note first that $A_{i-1}/2^{d_i - 1} \subseteq A_i/2^{d_i}$ for $1 \le i \le r$. Secondly, note that $d_j = d_{i-1}$ in a nondoubling; for otherwise $a_{i-1} \ge 2a_j \ge a_j + a_k = a_i$. Hence $A_j \subseteq A_{i-1}$ and $A_k \subseteq A_{i-1}/2^{d_j - d_k}$. (c) An easy induction on i, except that close steps need closer attention. Let us say that m has property $P(\alpha)$ if the 1's in its binary representation all appear in consecutive

blocks of $\geq \alpha$ in a row. If m and m' have $P(\alpha)$, so does $m \nabla m'$; if m has $P(\alpha)$ then $\rho(m)$ has $P(\alpha+\delta)$. Hence B_i has $P(1+\delta c_i)$. Finally if m has $P(\alpha)$ then $\nu(\rho(m)) \leq (\alpha+\delta)\nu(m)/\alpha$; for $\nu(m) = \nu_1 + \cdots + \nu_q$, where each block size ν_j is $\geq \alpha$, hence $\nu(\rho(m)) \leq (\nu_1+\delta)+\cdots+(\nu_q+\delta) \leq (1+\delta/\alpha)\nu_1+\cdots+(1+\delta/\alpha)\nu_q$. (d) Let $f = b_r + c_r$ be the number of nondoublings and s the number of small steps. If $f \geq 3.271 \lg \nu(n)$ we have $s \geq \lg \nu(n)$ as desired, by (16). Otherwise we have $a_i \leq (1+2^{-\delta})^{b_i} 2^{c_i+d_i}$ for $0 \leq i \leq r$, hence $n \leq ((1+2^{-\delta})/2)^{b_r} 2^r$, and $r \geq \lg n + b_r - b_r \lg(1+2^{-\delta}) \geq \lg n + \lg \nu(n) - \lg(1+\delta c_r) - b_r \lg(1+2^{-\delta})$. Let $\delta = \lceil \lg(f+1) \rceil$; then $\ln(1+2^{-\delta}) \leq \ln(1+1/(f+1)) \leq 1/(f+1) \leq \delta/(1+\delta f)$, and it follows that $\lg(1+\delta x) + (f-x)\lg(1+2^{-\delta}) \leq \lg(1+\delta f)$ for $0 \leq x \leq f$. Hence finally $l(n) \geq \lg n + \lg \nu(n) - \lg(1+(3.271 \lg \nu(n))\lceil \lg(1+3.271 \lg \nu(n)) \rceil)$. [*Theoretical Comp. Sci.* **1** (1975), 1–12.]

29. In the paper just cited, Schönhage refined the method of exercise 28 to prove that $l(n) \geq \lg n + \lg \nu(n) - 2.13$ for all n. Can the remaining gap be closed?

30. $n = 31$ is the smallest example; $l(31) = 7$, but 1, 2, 4, 8, 16, 32, 31 is an addition-subtraction chain of length 6. [After proving Theorem E, Erdős stated that the same result holds also for addition-subtraction chains. Schönhage has extended the lower bound of exercise 28 to addition-subtraction chains, with $\nu(n)$ replaced by $\bar{\nu}(n)$ = minimum number of nonzero digits to represent $n = (n_q \ldots n_0)_2$ where each n_j is -1, 0, or $+1$. This quantity $\bar{\nu}(n)$ is the number of 1's, in the ordinary binary representation of n, that are immediately preceded by 0 or by the string $00(10)^k1$ for some $k \geq 0$.]

32. First compute 2^i for $1 \leq i \leq \lambda(n_m)$, then compute each $n = n_j$ by the following variant of the 2^k-ary method: For all odd $i < 2^k$, compute $f_i = \sum\{ 2^{kt+e} \mid d_t = 2^e i \}$ where $n = (\ldots d_1 d_0)_{2^k}$, in at most $\lfloor \frac{1}{k} \lg n \rfloor$ steps; then compute $n = \sum i f_i$ in at most $\sum l(i) + 2^{k-1}$ further steps. The number of steps per n_j is $\leq \lfloor \frac{1}{k} \lg n \rfloor + O(k2^k)$, and this is $\lambda(n)/\lambda\lambda(n) + O(\lambda(n)\lambda\lambda\lambda(n)/\lambda\lambda(n)^2)$ when $k = \lfloor \lg \lg n - 3 \lg \lg \lg n \rfloor$.

[A generalization of Theorem E gives the corresponding lower bound. Reference: *SIAM J. Computing* **5** (1976), 100–103. See also exercise 39.]

33. The following construction due to D. J. Newman provides the best upper bound currently known: Let $k = p_1 \ldots p_r$ be the product of the first r primes. Compute k and all quadratic residues mod k by the method of exercise 32, in $O(2^{-r} k \log k)$ steps (because there are approximately $2^{-r}k$ quadratic residues). Also compute all multiples of k that are $\leq m^2$, in about m^2/k further steps. Now m additions suffice to compute $1^2, 2^2, \ldots, m^2$. We have $k = \exp(p_r + O(p_r/(\log p_r)^{1000}))$ where p_r is given by the formula in exercise 4.5.4–35; so by choosing

$$r = \lfloor (1 + (1 + \tfrac{1}{2}\ln 2)/\lg\lg m) \ln m / \ln\ln m \rfloor$$

it follows that $l(1^2, \ldots, m^2) = m + O(m \cdot \exp(-\frac{1}{2}\ln 2 \ln m / \ln\ln m))$.

On the other hand, D. Dobkin and R. Lipton have shown that, for any $\epsilon > 0$, $l(1^2, \ldots, m^2) > m + m^{2/3-\epsilon}$ when m is sufficiently large [*SIAM J. Computing* **9** (1980), 121–125].

35. See *Discrete Math.* **23** (1978), 115–119.

36. Eight; there are four ways to compute $39 = 12+12+12+3$ and two ways to compute $79 = 39+39+1$.

37. The statement is true. The labels in the reduced graph of the binary chain are $\lfloor n/2^k \rfloor$ for $k = e_0, \ldots, 0$; they are $1, 2, \ldots, 2^{e_0}, n$ in the dual graph. [Similarly, the right-to-left m-ary method of exercise 9 is the dual of the left-to-right method.]

38. 2^t are equivalent to the binary chain; it would be 2^{t-1} if $e_0 = e_1 + 1$. The number of chains equivalent to the scheme of Algorithm A is the number of ways to compute the sum of $t+2$ numbers of which two are identical. This is $\frac{1}{2}f_{t+1} + \frac{1}{2}f_t$, where f_m is the number of ways to compute the sum of $m+1$ distinct numbers. When we take commutativity into account, we see that f_m is 2^{-m} times $(m+1)!$ times the number of binary trees on m nodes, so $f_m = (2m-1)(2m-3)\ldots 1$.

39. The quantity $l([n_1, n_2, \ldots, n_m])$ is the minimum of arcs $-$ vertices $+ m$ taken over all directed graphs having m vertices s_j whose in-degree is zero and one vertex t whose out-degree is zero, where there are exactly n_j oriented paths from s_j to t for $1 \le j \le m$. The quantity $l(n_1, n_2, \ldots, n_m)$ is the minimum of arcs $-$ vertices $+1$ taken over all directed graphs having one vertex s whose in-degree is zero and m vertices t_j whose out-degree is zero, where there are exactly n_j oriented paths from s to t_j for $1 \le j \le m$. These problems are dual to each other, if we change the direction of all the arcs.

Note: C. H. Papadimitriou points out that this is a special case of a much more general theorem. Let $N = (n_{ij})$ be an $m \times p$ matrix of nonnegative integers having no row or column entirely zero. We can define $l(N)$ to be the minimum number of multiplications needed to compute the set of monomials $\{ x_1^{n_{1j}} \ldots x_m^{n_{mj}} \mid 1 \le j \le p \}$. Now $l(N)$ is also the minimum of arcs $-$ vertices $+ m$ taken over all directed graphs having m vertices s_i whose in-degree is zero and p vertices t_j whose out-degree is zero, where there are exactly n_{ij} oriented paths from s_i to t_j for each i and j. By duality we have $l(N) = l(N^T) + m - p$.

N. Pippenger has proved a comprehensive generalization of the results of exercises 27 and 32. Let $L(m, p, n)$ be the maximum of $l(N)$ taken over all $m \times p$ matrices N of nonnegative integers $n_{ij} \le n$. Then $L(m, p, n) = \min(m, p) \lg n + H/\lg H + O(m + p + H(\log\log H)^{1/2}(\log H)^{-3/2})$, where $H = mp \lg(n+1)$. [*SIAM J. Computing* **9** (1980), 230–250.]

40. By exercise 39, it suffices to show that $l(m_1 n_1 + \cdots + m_t n_t) \le l(m_1, \ldots, m_t) + l([n_1, \ldots, n_t])$. But this is clear, since we can first form $\{x^{m_1}, \ldots, x^{m_t}\}$ and then compute the monomial $(x^{m_1})^{n_1} \ldots (x^{m_t})^{n_t}$.

Notes: Theorem F is a special case of this result, since we clearly have $l(2^m, x) \le m + \nu(x) - 1$ when $\lambda(x) \le m$. One strong way to state Olivos's theorem is that if $a_0, \ldots, a_r$ and $b_0, \ldots, b_s$ are any addition chains, then $l(\sum c_{ij} a_i b_j) \le r + s + \sum c_{ij} - 1$ for any $(r+1) \times (s+1)$ matrix of nonnegative integers c_{ij}.

41. [To appear.] The stated formula can be proved whenever $A \ge 9m^2$. Since this is a polynomial in m, and since the problem of finding a minimum vertex cover is NP hard (cf. Section 7.9), the problem of computing $l(n_1, \ldots, n_m)$ is NP complete. [It is unknown whether or not the problem of computing $l(n)$ is NP complete.]

SECTION 4.6.4

1. Set $y \leftarrow x^2$, then compute $((\ldots(u_{2n+1}y + u_{2n-1})y + \cdots)y + u_1)x$.

2. Replacing x in (2) by the polynomial $x + x_0$ leads to the following procedure:

G1. Do step G2 for $k = n, n-1, \ldots, 0$ (in this order), and stop.

G2. Set $v_k \leftarrow u_k$, and then set $v_j \leftarrow v_j + x_0 v_{j+1}$ for $j = k, k+1, \ldots, n-1$. (When $k = n$, this step simply sets $v_n \leftarrow u_n$.) ∎

The computations turn out to be identical to those in H1 and H2, but performed in a different order. (This application was, in fact, Newton's original motivation for using scheme (2).)

3. The coefficient of x^k is a polynomial in y that may be evaluated by Horner's rule: $(\ldots(u_{n,0}x+(u_{n-1,1}y+u_{n-1,0}))x+\cdots)x+((\ldots(u_{0,n}y+u_{0,n-1})y+\cdots)y+u_{0,0})$. [For a "homogeneous" polynomial, such as $u_n x^n + u_{n-1}x^{n-1}y + \cdots + u_1 xy^{n-1} + u_0 y^n$, another scheme is more efficient: if $0 < |x| \le |y|$, first divide x by y, evaluate a polynomial in x/y, then multiply by y^n.]

4. Rule (2) involves $4n$ or $3n$ real multiplications and $4n$ or $7n$ real additions; (3) is worse, it takes $4n+2$ or $4n+1$ mults, $4n+2$ or $4n+5$ adds.

5. One multiplication to compute x^2; $\lfloor n/2 \rfloor$ multiplications and $\lfloor n/2 \rfloor$ additions to evaluate the first line; $\lceil n/2 \rceil$ multiplications and $\lceil n/2 \rceil - 1$ additions to evaluate the second line; and one addition to add the two lines together. Total: $n+1$ multiplications and n additions.

6. **J1.** Compute and store the values $x_0^2, \ldots, x_0^{\lceil n/2 \rceil}$.

J2. Set $v_j \leftarrow u_j x_0^{j-\lfloor n/2 \rfloor}$ for $0 \le j \le n$.

J3. For $k = 0, 1, \ldots, n-1$, set $v_j \leftarrow v_j + v_{j+1}$ for $j = n-1, \ldots, k+1, k$.

J4. Set $v_j \leftarrow v_j x_0^{\lfloor n/2 \rfloor - j}$ for $0 \le j \le n$. ∎

There are $(n^2+n)/2$ additions, $n+\lceil n/2 \rceil - 1$ multiplications, n divisions. Another multiplication and division can be saved by treating v_n and v_0 as special cases. *Reference: SIGACT News* **7**, 3 (Summer 1975), 32–34.

7. Let $x_j = x_0 + jh$, and consider (42), (44). Set $y_j \leftarrow u(x_j)$ for $0 \le j \le n$. For $k = 1, 2, \ldots, n$ (in this order), set $y_j \leftarrow y_j - y_{j-1}$ for $j = k, k+1, \ldots, n$ (in this order). Now $\beta_j = y_j$ for all j.

8. See (43).

9. [*Combinatorial Mathematics* (Buffalo: Math. Assoc. of America, 1963), 26–28.] This formula can be regarded as an application of the principle of inclusion and exclusion (Section 1.3.3), since the sum of the terms for $n - \epsilon_1 - \cdots - \epsilon_n = k$ is the sum of all $x_{1j_1}x_{2j_2}\ldots x_{nj_n}$ for which k values of the j_i do not appear. A direct proof can be given by observing that the coefficient of $x_{1j_1}\ldots x_{nj_n}$ is

$$\sum (-1)^{n-\epsilon_1-\cdots-\epsilon_n} \epsilon_{j_1} \ldots \epsilon_{j_n};$$

if the j's are distinct, this equals unity, but if $j_1, \ldots, j_n \neq k$ then it is zero, since the terms for $\epsilon_k = 0$ cancel the terms for $\epsilon_k = 1$.

To evaluate the sum efficiently, we can start with $\epsilon_1 = 1$, $\epsilon_2 = \cdots = \epsilon_n = 0$, and we can then proceed through all combinations of the ϵ's in such a way that only one ϵ changes from one term to the next. (See "Gray code" in Chapter 7.) The work to compute the first term is $n-1$ multiplications; the subsequent $2^n - 2$ terms each involve n additions, then $n-1$ multiplications, then one more addition. Total: $(2^n-1)(n-1)$ multiplications, and $(2^n-2)(n+1)$ additions. Only $n+1$ temp storage locations are needed, one for the main partial sum and one for each factor of the current product.

10. $\sum_{1\le k<n}(k+1)\binom{n}{k+1} = n(2^{n-1}-1)$ multiplications and $\sum_{1\le k<n} k\binom{n}{k+1} = n2^{n-1}-2^n+1$ additions. This is approximately half as many arithmetic operations as the method of exercise 9, although it requires a more complicated program to control the sequence. Approximately $\binom{n}{\lceil n/2\rceil}+\binom{n}{\lceil n/2\rceil-1}$ temporary storage locations must be used, and this grows exponentially large (on the order of $2^n/\sqrt{n}$).

The method in this exercise is equivalent to the unusual matrix factorization of the permanent function given by Jurkat and Ryser in *J. Algebra* **5** (1967), 342–357. It may also be regarded as an application of (39) and (40), in an appropriate sense.

12. Here is a brief summary of progress on this famous research problem: J. Hopcroft and L. R. Kerr proved, among other things, that seven multiplications are necessary in 2×2 matrix multiplication [*SIAM J. Appl. Math.* **20** (1971), 30–36]. R. L. Probert showed that all 7-multiplication schemes, in which each multiplication takes a linear combination of elements from one matrix and multiplies by a linear combination of elements from the other, must have at least 15 additions [*SIAM J. Computing* **5** (1976), 187–203]. For $n=3$, the best method known is due to J. D. Laderman [*Bull. Amer. Math. Soc.* **82** (1976), 126–128], who showed that 23 noncommutative multiplications suffice. His construction has been generalized by Ondrej Sýkora, who exhibited a method requiring $n^3-(n-1)^2$ noncommutative multiplications and $n^3-n^2+11(n-1)^2$ additions, a result that also reduces to (36) when $n=2$ [*Lecture Notes in Comp. Sci.* **53** (1977), 504–512]. The best lower bound known to hold for all n is the fact that $2n^2-1$ nonscalar multiplications are necessary [Jean-Claude Lafon and S. Winograd, *Theoretical Comp. Sci.*, to appear]. Pan has generalized this to a lower bound of $mn+ns+m-n-1$ in the $m\times n\times s$ case [see *SIAM J. Computing* **9** (1980), 341]. The best upper bounds known for large n were changing rapidly as this book was being prepared for publication; see exercises 60–64.

13. By summing geometric series, we find that $F(t_1,\ldots,t_n)$ equals

$$\sum_{0\le s_1<m_1,\ldots,0\le s_n<m_n} \exp(-2\pi i(s_1t_1/m_1+\cdots+s_nt_n/m_n)f(s_1,\ldots,s_n))/m_1\ldots m_n.$$

The inverse transform times $m_1\ldots m_n$ can be found by doing a regular transform and interchanging t_j with m_j-t_j when $t_j\neq 0$; cf. exercise 4.3.3–9.

[If we regard $F(t_1,\ldots,t_n)$ as the coefficient of $x_1^{t_1}\ldots x_n^{t_n}$ in a multivariate polynomial, the finite Fourier transform amounts to evaluation of this polynomial at roots of unity, and the inverse transform amounts to finding the interpolating polynomial.]

14. Let $m_1=\cdots=m_n=2$, $F(t_1,t_2,\ldots,t_n)=F(2^{n-1}t_n+\cdots+2t_2+t_1)$, and $f(s_1,s_2,\ldots,s_n)=f(2^{n-1}s_1+2^{n-2}s_2+\cdots+s_n)$; note the reversed treatment between t's and s's. Also let $g_k(s_k,\ldots,s_n,t_k)$ be ω raised to the $2^{k-1}t_k(s_n+2s_{n-1}+\cdots+2^{n-k}s_k)$ power.

At each iteration we essentially take 2^{n-1} pairs of complex numbers (α,β) and replace them by $(\alpha+\zeta\beta,\alpha-\zeta\beta)$, where ζ is a suitable power of ω, hence $\zeta=\cos\theta+i\sin\theta$ for some θ. If we take advantage of simplifications when $\zeta=\pm 1$ or $\pm i$, the total work comes to $((n-3)\cdot 2^{n-1}+2)$ complex multiplications and $n\cdot 2^n$ complex additions; the techniques of exercise 41 can be used to reduce the real multiplications and additions used to implement these complex operations.

The number of complex multiplications can be reduced about 25 per cent without changing the number of additions by combining passes k and $k+1$ for $k=1,3,\ldots$; this means that 2^{n-2} quadruples $(\alpha,\beta,\gamma,\delta)$ are being replaced by $(\alpha+\zeta\beta+\zeta^2\gamma+\zeta^3\delta,\ \alpha+i\zeta\beta-\zeta^2\gamma-i\zeta^3\delta,\ \alpha-\zeta\beta+\zeta^2\gamma-\zeta^3\delta,\ \alpha-i\zeta\beta-\zeta^2\gamma+i\zeta^3\delta)$. The number of complex multiplications when n is even is thereby reduced to $(3n-2)2^{n-3}-5\lfloor 2^{n-1}/3\rfloor$.

These calculations assume that the given numbers $F(t)$ are complex. If the $F(t)$ are real, then $f(s)$ is the complex conjugate of $f(2^n - s)$, so we can avoid the redundancy by computing only the 2^n independent real numbers $f(0)$, $\Re f(1)$, ..., $\Re f(2^{n-1} - 1)$, $f(2^{n-1})$, $\Im f(1)$, ..., $\Im f(2^{n-1} - 1)$. The entire calculation in this case can be done by working with 2^n real values, using the fact that $f^{[k]}(s_{n-k+1}, \ldots, s_n, t_1, \ldots, t_{n-k})$ will be the complex conjugate of $f^{[k]}(s'_{n-k+1}, \ldots, s'_n, t_1, \ldots, t_{n-k})$ when $(s_1 \ldots s_n)_2 + (s'_1 \ldots s'_n)_2 \equiv 0$ (modulo 2^n). About half as many multiplications and additions are needed as in the complex case.

[The fast Fourier transform algorithm is essentially due to C. Runge and H. König in 1924, and it was generalized by J. W. Cooley and J. W. Tukey, ***Math. Comp.* 19 (1965), 297–301**. Its interesting history has been traced by J. W. Cooley, P. A. W. Lewis, and P. D. Welch, *Proc. IEEE* **55** (1967), 1675–1677. Details concerning its use have been discussed by R. C. Singleton, *CACM* **10** (1967), 647–654; M. C. Pease, *JACM* **15** (1968), 252–264; **G. D. Berglund, *Math. Comp.* 22 (1968), 275–279**, *CACM* **11** (1968), 703–710; A. M. Macnaghten and C. A. R. Hoare, *Comp. J.* **20** (1977), 78–83. See also exercises 53, 57, and 59.]

15. (a) The hint follows by integration and induction. Let $f^{(n)}(\theta)$ take on all values between A and B inclusive, as θ varies from $\min(x_0, \ldots, x_n)$ to $\max(x_0, \ldots, x_n)$. Replacing $f^{(n)}$ by each of these bounds, in the stated integral, yields $A/n! \le f(x_0, \ldots, x_n) \le B/n!$. (b) It suffices to prove this for $j = n$. Let f be Newton's interpolation polynomial, then $f^{(n)}$ is the constant $n!\alpha_n$.

16. Carry out the multiplications and additions of (43) as operations on polynomials. (The special case $x_0 = x_1 = \cdots = x_n$ is considered in exercise 2. We have used this method in step C8 of Algorithm 4.3.3C.)

17. T. M. Vari has shown that $n - 1$ multiplications are necessary, by proving that n multiplications are necessary to compute $x_1^2 + \cdots + x_n^2$ [Cornell Computer Science Report 120 (Jan. 1972)].

18. $\alpha_0 = \frac{1}{2}(u_3/u_4 + 1)$, $\beta = u_2/u_4 - \alpha_0(\alpha_0 - 1)$, $\alpha_1 = \alpha_0\beta - u_1/u_4$, $\alpha_2 = \beta - 2\alpha_1$, $\alpha_3 = u_0/u_4 - \alpha_1(\alpha_1 + \alpha_2)$, $\alpha_4 = u_4$.

19. Since α_5 is the leading coefficient, we may assume without loss of generality that $u(x)$ is monic (i.e., $u_5 = 1$). Then α_0 is a root of the cubic equation $40z^3 - 24u_4z^2 + (4u_4^2 + 2u_3)z + (u_2 - u_3u_4) = 0$; this equation always has at least one real root, and it may have three. Once α_0 is determined, we have $\alpha_3 = u_4 - 4\alpha_0$, $\alpha_1 = u_3 - 4\alpha_0\alpha_3 - 6\alpha_0^2$, $\alpha_2 = u_1 - \alpha_0(\alpha_0\alpha_1 + 4\alpha_0^2\alpha_3 + 2\alpha_1\alpha_3 + \alpha_0^3)$, $\alpha_4 = u_0 - \alpha_3(\alpha_0^4 + \alpha_1\alpha_0^2 + \alpha_2)$.

For the given polynomial we are to solve the cubic equation $40z^3 - 120z^2 + 80z = 0$; this leads to three solutions $(\alpha_0, \alpha_1, \alpha_2, \alpha_3, \alpha_4, \alpha_5) = (0, -10, 13, 5, -5, 1)$, $(1, -20, 68, 1, 11, 1)$, $(2, -10, 13, -3, 27, 1)$.

21. $z = (x+1)x-2$, $w = (x+5)z+9$, $u(x) = (w+z-8)w-8$; or $z = (x+9)x+26$, $w = (x-3)z + 73$, $u(x) = (w + z - 24)w - 12$.

22. $\alpha_6 = 1$, $\alpha_0 = -1$, $\alpha_1 = 1$, $\beta_1 = -2$, $\beta_2 = -2$, $\beta_3 = -2$, $\beta_4 = 1$, $\alpha_3 = -4$, $\alpha_2 = 0$, $\alpha_4 = 4$, $\alpha_5 = -2$. We form $z = (x-1)x + 1$, $w = z + x$, and $u(x) = ((z - x - 4)w + 4)z - 2$. In this special case we see that one of the seven additions can be saved if we compute $w = x^2 + 1$, $z = w - x$.

23. (a) We may use induction on n; the result is trivial if $n < 2$. If $f(0) = 0$, then the result is true for the polynomial $f(z)/z$, so it holds for $f(z)$. If $f(iy) = 0$ for some real $y \neq 0$, then $g(+iy) = h(+iy) = 0$; since the result is true for $f(z)/(z^2 + y^2)$, it holds

[redacted]

of $f(z)$ inside the region, which is at most 1. When R is large, the path $f(Re^{it})$ for $\pi/2 \leq t \leq 3\pi/2$ will circle the origin clockwise approximately $n/2$ times; so the path $f(it)$ for $-R \leq t \leq R$ must go counterclockwise around the origin at least $n/2 - 1$ times. For n even, this implies that $f(it)$ crosses the imaginary axis at least $n-2$ times, and the real axis at least $n - 3$ times; for n odd, $f(it)$ crosses the real axis at least $n - 2$ times and the imaginary axis at least $n - 3$ times. These are roots respectively of $g(it) = 0$, $h(it) = 0$.

(b) If not, g or h would have a root of the form $a + bi$ with $a \neq 0$ and $b \neq 0$. But this would imply the existence of at least three other such roots, namely $a - bi$ and $-a \pm bi$, while $g(z)$ and $h(z)$ have at most n roots.

24. The roots of u are -7, $-3 \pm i$, $-2 \pm i$, and -1; permissible values of c are 2 and 4 (but *not* 3, since $c = 3$ makes the sum of the roots equal to zero). Case 1, $c = 2$: $p(x) = (x+5)(x^2+2x+2)(x^2+1)(x-1) = x^6 + 6x^5 + 6x^4 + 4x^3 - 5x^2 - 2x - 10$; $q(x) = 6x^2 + 4x - 2 = 6(x+1)(x - \frac{1}{3})$. Let $\alpha_2 = -1$, $\alpha_1 = \frac{1}{3}$; $p_1(x) = x^4 + 6x^3 + 5x^2 - 2x - 10 = (x^2 + 6x + \frac{16}{3})(x^2 - \frac{1}{3}) - \frac{74}{9}$; $\alpha_0 = 6$, $\beta_0 = \frac{16}{3}$, $\beta_1 = -\frac{74}{9}$. Case 2, $c = 4$: A similar analysis gives $\alpha_2 = 9$, $\alpha_1 = -3$, $\alpha_0 = -6$, $\beta_0 = 12$, $\beta_1 = -26$.

25. $\beta_1 = \alpha_2$, $\beta_2 = 2\alpha_1$, $\beta_3 = \alpha_7$, $\beta_4 = \alpha_6$, $\beta_5 = \beta_6 = 0$, $\beta_7 = \alpha_1$, $\beta_8 = 0$, $\beta_9 = 2\alpha_1 - \alpha_8$.

26. (a) $\lambda_1 = \alpha_1 \times \lambda_0$, $\lambda_2 = \alpha_2 + \lambda_1$, $\lambda_3 = \lambda_2 \times \lambda_0$, $\lambda_4 = \alpha_3 + \lambda_3$, $\lambda_5 = \lambda_4 \times \lambda_0$, $\lambda_6 = \alpha_4 + \lambda_5$. (b) $\kappa_1 = 1 + \beta_1 x$, $\kappa_2 = 1 + \beta_2\kappa_1 x$, $\kappa_3 = 1 + \beta_3\kappa_2 x$, $u(x) = \beta_4\kappa_3 = \beta_1\beta_2\beta_3\beta_4 x^3 + \beta_2\beta_3\beta_4 x^2 + \beta_3\beta_4 x + \beta_4$. (c) If any coefficient is zero, the coefficient of x^3 must also be zero in (b), while (a) yields an arbitrary polynomial $\alpha_1 x^3 + \alpha_2 x^2 + \alpha_3 x + \alpha_4$ of degree ≤ 3.

27. Otherwise there would be a nonzero polynomial $f(q_n, \ldots, q_1, q_0)$ with integer coefficients such that $q_n \cdot f(q_n, \ldots, q_1, q_0) = 0$ for all sets $(q_n, \ldots, q_0)$ of real numbers. This cannot happen, since it is easy to prove by induction on n that a nonzero polynomial always takes on some nonzero value. (Cf. exercise 4.6.1–16. However, this result is false for *finite* fields in place of the real numbers.)

28. The indeterminate quantities $\alpha_1, \ldots, \alpha_s$ form an algebraic basis for the polynomial domain $Q[\alpha_1, \ldots, \alpha_s]$, where Q is the field of rational numbers. Since $s + 1$ is greater than the number of elements in a basis, the polynomials $f_j(\alpha_1, \ldots, \alpha_s)$ are algebraically dependent; this means that there is a nonzero polynomial g with rational coefficients such that $g(f_0(\alpha_1, \ldots, \alpha_s), \ldots, f_s(\alpha_1, \ldots, \alpha_s))$ is identically zero.

29. Given $j_0, \ldots, j_t \in \{0, 1, \ldots, n\}$, there are nonzero polynomials with integer coefficients such that $g_j(q_{j_0}, \ldots, q_{j_t}) = 0$ for all $(q_n, \ldots, q_0)$ in R_j, $1 \leq j \leq m$. The product $g_1 g_2 \ldots g_m$ is therefore zero for all $(q_n, \ldots, q_0)$ in $R_1 \cup \cdots \cup R_m$.

30. Starting with the construction in Theorem M, we will prove that $m_p+(1-\delta_{0m_c})$ of the β's may effectively be eliminated: If μ_i corresponds to a parameter multiplication, we have $\mu_i = \beta_{2i-1} \times (T_{2i} + \beta_{2i})$; add $c\beta_{2i-1}\beta_{2i}$ to each β_j for which $c\mu_i$ occurs in T_j, and replace β_{2i} by zero. This removes one parameter for each parameter multiplication. If μ_i is the first chain multiplication, then μ_i is the first chain multiplication, then $\mu_i = (\gamma_1 x + \theta_1 + \beta_{2i-1}) \times (\gamma_{2x} + \theta_2 + \beta_{2i})$, where γ_1, γ_2, θ_1, θ_2 are polynomials in β_1, $\ldots$, β_{2i-2} with integer coefficients. Here θ_1 and θ_2 can be "absorbed" into β_{2i-1} and β_{2i}, respectively, so we may assume that $\theta_1 = \theta_2 = 0$. Now add $c\beta_{2i-1}\beta_{2i}$ to each β_j for which $c\mu_i$ occurs in T_j; add $\beta_{2i-1}\gamma_2/\gamma_1$ to β_{2i}; and set β_{2i-1} to zero. The result set is unchanged by this elimination of β_{2i-1}, except for the values of $\alpha_1, \ldots, \alpha_s$ such that γ_1 is zero. [This proof is essentially due to V. Îa. Pan, *Russian Mathematical Surveys* **21**,1 (1966), 105–136.] The latter case can be handled as in the proof of Theorem A, since the polynomials with $\gamma_1 = 0$ can be evaluated by eliminating β_{2i} (as in the first construction, where μ_i corresponds to a parameter multiplication).

31. Otherwise we could add one parameter multiplication as a final step, and violate Theorem C. (The exercise is an improvement over Theorem A, in this special case, since there are only n degrees of freedom in the coefficients of a monic polynomial of degree n.)

32. $\lambda_1 = \lambda_0 \times \lambda_0$, $\lambda_2 = \alpha_1 \times \lambda_1$, $\lambda_3 = \alpha_2 + \lambda_2$, $\lambda_4 = \lambda_3 \times \lambda_1$, $\lambda_5 = \alpha_3 + \lambda_4$. We need at least three multiplications to compute u_4x^4 (see Section 4.6.3), and at least two additions by Theorem A.

33. We must have $n+1 \le 2m_c+m_p+\delta_{0m_c}$, and $m_c+m_p = (n+1)/2$; so there are no parameter multiplications. Now the first λ_i whose leading coefficient (as a polynomial in x) is not an integer must be obtained by a chain addition; and there must be at least $n+1$ parameters, so there are at least $n+1$ parameter additions.

34. Transform the given chain step by step, and also define the "content" c_i of λ_i, as follows: (Intuitively, c_i is the leading coefficient of λ_i.) Define $c_0 = 1$. (a) If the step has the form $\lambda_i = \alpha_j + \lambda_k$, replace it by $\lambda_i = \beta_j + \lambda_k$, where $\beta_j = \alpha_j/c_k$; and define $c_i = c_k$. (b) If the step has the form $\lambda_i = \alpha_j - \lambda_k$, replace it by $\lambda_i = \beta_j + \lambda_k$, where $\beta_j = -\alpha_j/c_k$; and define $c_i = -c_k$. (c) If the step has the form $\lambda_i = \alpha_j \times \lambda_k$, replace it by $\lambda_i = \lambda_k$ (the step will be deleted later); and define $c_i = \alpha_j c_k$. (d) If the step has the form $\lambda_i = \lambda_j \times \lambda_k$, leave it unchanged; and define $c_i = c_j c_k$.

After this process is finished, delete all steps of the form $\lambda_i = \lambda_k$, replacing λ_i by λ_k in each future step that uses λ_j. Then add a final step $\lambda_{r+1} = \beta \times \lambda_r$, where $\beta = c_r$. This is the desired scheme, since it is easy to verify that the new λ_i are just the old ones divided by the factor c_i. The β's are given functions of the α's; division by zero is no problem, because if any $c_k = 0$ we must have $c_r = 0$ (hence the coefficient of x^n is zero), or else λ_k never contributes to the final result.

35. Since there are at least five parameter steps, the result is trivial unless there is at least one parameter multiplication; considering the ways in which three multiplications can form u_4x^4, we see that there must be one parameter multiplication and two chain multiplications. Therefore the four addition-subtractions must each be parameter steps, and exercise 34 applies. We can now assume that only additions are used, and that we have a chain to compute a general *monic* fourth-degree polynomial with *two* chain multiplications and four parameter additions. The only possible scheme of this type

that calculates a fourth-degree polynomial has the form

$$\begin{aligned}\lambda_1 &= \alpha_1 + \lambda_0\\ \lambda_2 &= \alpha_2 + \lambda_0\\ \lambda_3 &= \lambda_1 \times \lambda_2\\ \lambda_4 &= \alpha_3 + \lambda_3\\ \lambda_5 &= \alpha_4 + \lambda_3\\ \lambda_6 &= \lambda_4 \times \lambda_5\\ \lambda_7 &= \alpha_5 + \lambda_6\end{aligned}$$

Actually this chain has one addition too many, but any correct scheme can be put into this form if we restrict some of the α's to be functions of the others. Now λ_7 has the form $(x^2+Ax+B)(x^2+Ax+C)+D = x^4+2Ax^3+(E+A^2)x^2+EAx+F$, where $A=\alpha_1+\alpha_2$, $B=\alpha_1\alpha_2+\alpha_3$, $C=\alpha_1\alpha_2+\alpha_4$, $D=\alpha_6$, $E=B+C$, $F=BC+D$; and since this involves only three independent parameters it cannot represent a general monic fourth-degree polynomial.

36. As in the solution to exercise 35, we may assume that the chain computes a general monic polynomial of degree six, using only three chain multiplications and six parameter additions. The computation must take one of two general forms

$$\begin{aligned}\lambda_1 &= \alpha_1 + \lambda_0\\ \lambda_2 &= \alpha_2 + \lambda_0\\ \lambda_3 &= \lambda_1 \times \lambda_2\\ \lambda_4 &= \alpha_3 + \lambda_0\\ \lambda_5 &= \alpha_4 + \lambda_3\\ \lambda_6 &= \lambda_4 \times \lambda_5\\ \lambda_7 &= \alpha_5 + \lambda_6\\ \lambda_8 &= \alpha_6 + \lambda_6\\ \lambda_9 &= \lambda_7 \times \lambda_8\\ \lambda_{10} &= \alpha_7 + \lambda_9\end{aligned}\qquad\qquad\begin{aligned}\lambda_1 &= \alpha_1 + \lambda_0\\ \lambda_2 &= \alpha_2 + \lambda_0\\ \lambda_3 &= \lambda_1 \times \lambda_2\\ \lambda_4 &= \alpha_3 + \lambda_3\\ \lambda_5 &= \alpha_4 + \lambda_3\\ \lambda_6 &= \lambda_4 \times \lambda_5\\ \lambda_7 &= \alpha_5 + \lambda_3\\ \lambda_8 &= \alpha_6 + \lambda_6\\ \lambda_9 &= \lambda_7 \times \lambda_8\\ \lambda_{10} &= \alpha_7 + \lambda_9\end{aligned}$$

where, as in exercise 35, an extra addition has been inserted to cover a more general case. Neither of these schemes can calculate a general sixth-degree monic polynomial, since the first case is a polynomial of the form

$$(x^3+Ax^2+Bx+C)(x^3+Ax^2+Bx+D)+E,$$

and the second case (cf. exercise 35) is a polynomial of the form

$$(x^4+2Ax^3+(E+A^2)x^2+EAx+F)(x^2+Ax+G)+H;$$

both of these involve only five independent parameters.

37. Let $u^{[0]}(x) = u_n x^n + u_{n-1}x^{n-1} + \cdots + u_0$, $v^{[0]}(x) = x^n + v_{n-1}x^{n-1} + \cdots + v_0$. For $1 \le j \le n$, divide $u^{[j-1]}(x)$ by the monic polynomial $v^{[j-1]}(x)$, obtaining $u^{[j-1]}(x) = \alpha_j v^{[j-1]}(x) + \beta_j v^{[j]}(x)$. Assume that a monic polynomial $v^{[j]}(x)$ of degree $n-j$ exists satisfying this relation; this will be true for almost all rational functions. Let $u^{[j]}(x) = v^{[j-1]}(x) - xv^{[j]}(x)$. These definitions imply that $\deg(u^{[n]}) < 1$, so we may let $\alpha_{n+1} = u^{[n]}(x)$.

For the given rational function we have

α_j	β_j	$v^{[j]}(x)$	$u^{[j]}(x)$
1	2	$x+5$	$3x+19$
3	4	1	5

so $u^{[0]}(x)/v^{[0]}(x) = 1 + 2/(x + 3 + 4/(x + 5))$.

Notes: A general rational function of the stated form has $2n + 1$ "degrees of freedom," in the sense that it can be shown to have $2n + 1$ essentially independent parameters. If we generalize polynomial chains to "arithmetic chains," which allow division operations as well as addition, subtraction, and multiplication, we can obtain the following results with slight modifications to the proofs of Theorems A and M: *An arithmetic chain with q addition-subtraction steps has at most $q+1$ degrees of freedom. An arithmetic chain with m multiplication-division steps has at most $2m + 1$ degrees of freedom.* Therefore an arithmetic chain that computes almost all rational functions of the stated form must have at least $2n$ addition-subtractions, and n multiplication-divisions; the method in this exercise is "optimal."

38. The theorem is certainly true if $n = 0$. Assume that n is positive, and that a polynomial chain computing $P(x; u_0, \ldots, u_n)$ is given, where each of the parameters α_j has been replaced by a real number. Let $\lambda_i = \lambda_j \times \lambda_k$ be the first chain multiplication step that involves one of $u_0, \ldots, u_n$; such a step must exist because of the rank of A. Without loss of generality, we may assume that λ_j involves u_n; thus, λ_j has the form $h_0u_0 + \cdots + h_nu_n + f(x)$, where $h_0, \ldots, h_n$ are real, $h_n \neq 0$, and $f(x)$ is a polynomial with real coefficients. (The h's and the coefficients of $f(x)$ are derived from the values assigned to the α's.)

Now change step i to $\lambda_i = \alpha \times \lambda_k$, where α is an arbitrary real number. (We could take $\alpha = 0$; general α is used here merely to show that there is a certain amount of flexibility available in the proof.) Add further steps to calculate

$$\lambda = (\alpha - f(x) - h_0u_0 - \cdots - h_{n-1}u_{n-1})/h_n;$$

these new steps involve only additions and parameter multiplications (by suitable new parameters). Finally, replace $\lambda_{-n-1} = u_n$ everywhere in the chain by this new element λ. The result is a chain that calculates

$$Q(x; u_0, \ldots, u_{n-1}) = P(x; u_0, \ldots, u_{n-1}, (\alpha - f(x) - h_0u_0 - \cdots - h_{n-1}u_{n-1})/h_n);$$

and this chain has one less chain multiplication. The proof will be complete if we can show that Q satisfies the hypotheses. The quantity $(\alpha - f(x))/h_n$ leads to a possibly increased value of m, and a new vector B'. If the columns of A are A_0, A_1, $\ldots$, A_n (these vectors being linearly independent over the reals), the new matrix A' corresponding to Q has the column vectors

$$A_0 - (h_0/h_n)A_n, \qquad \ldots, \qquad A_{n-1} - (h_{n-1}/h_n)A_n,$$

plus perhaps a few rows of zeros to account for an increased value of m, and these columns are clearly also linearly independent. By induction, the chain that computes Q has at least $n - 1$ chain multiplications, so the original chain has at least n.

[Pan showed also that the use of division would give no improvement; cf. *Problemy Kibernetiki* **7** (1962), 21–30. Generalizations to the computation of several polynomials in several variables, with and without various kinds of preconditioning, have been given by S. Winograd, *Comm. Pure and Applied Math.* **23** (1970), 165–179.]

39. By induction on m. Let $w_m(x) = x^{2m} + u_{2m-1}x^{2m-1} + \cdots + u_0$, $w_{m-1}(x) = x^{2m-2} + v_{2m-3}x^{2m-3} + \cdots + v_0$, $a = \alpha_1 + \gamma_m$, $b = \alpha_m$, and let

$$f(r) = \textstyle\sum_{i,j\geq 0}(-1)^{i+j}\binom{i+j}{j}u_{r+i+2j}\,a^i b^j.$$

It follows that $v_r = f(r+2)$ for $r \geq 0$, and $\delta_m = f(1)$. If $\delta_m = 0$ and a is given, we have a polynomial of degree $m-1$ in b, with leading coefficient $\pm(u_{2m-1} - ma) = \pm(\gamma_2 + \cdots + \gamma_m - m\gamma_m)$.

In Motzkin's unpublished notes he arranged to make $\delta_k = 0$ almost always, by choosing γ's so that this leading coefficient is $\neq 0$ when m is even and $= 0$ when m is odd; then we almost always can let b be a (real) root of an odd-degree polynomial.

40. No; S. Winograd found a way to compute all polynomials of degree 13 with only 7 (possibly complex) multiplications [*Comm. Pure and Applied Math.* **25** (1972), 455–457]. L. Revah found schemes that evaluate almost all polynomials of degree $n \geq 9$ with $\lfloor n/2 \rfloor + 1$ (possibly complex) multiplications [*SIAM J. Computing* **4** (1975), 381–392]; she also showed that when $n = 9$ it is possible to achieve $\lfloor n/2 \rfloor + 1$ multiplications only with at least $n+3$ additions. By appending sufficiently many additions (cf. exercise 39), the "almost all" and "possibly complex" provisos disappear. V. Ia. Pan [*Proc. ACM Symp. Theory Comp.* **10** (1978), 162–172; IBM Research Report RC7754 (1979)] found schemes with $\lfloor n/2 \rfloor + 1$ (complex) multiplications and the minimum number $n+2+\delta_{n9}$ of (complex) additions, for all odd $n \geq 9$; his method for $n = 9$ is

$$\begin{aligned} v(x) &= ((x+\alpha)^2 + \beta)(x+\gamma), \qquad w(x) = v(x) + x, \\ t(x) &= (v(x)+\delta)(w(x)+\epsilon) - (v(x)+\delta')(w(x)+\epsilon'), \\ u(x) &= (v(x)+\varsigma)(t(x)+\eta) + \kappa. \end{aligned}$$

The minimum number of *real* additions necessary, when the minimum number of (real) multiplications is achieved, remains unknown for $n \geq 9$.

41. $a(c+d) - (a+b)d + i(a(c+d) + (b-a)c)$. [Beware numerical instability. Three multiplications are necessary, since complex multiplication is a special case of (69) with $p(u) = u^2 + 1$. Without the restriction on additions there are other possibilities. For example, the symmetric formula $ac - bd + i((a+b)(c+d) - ac - bd)$ was suggested by Peter Ungar in 1963; cf. Eq. 4.3.3–2 with 2^n replaced by i. See I. Munro, *Proc. ACM Symp. Theory Comp.* **3** (1960), 40–44; S. Winograd, *Linear Alg. Appl.* **4** (1971), 381–388.]

Alternatively, if $a^2 + b^2 = 1$ and $t = (1-a)/b = b/(1+a)$, the algorithm "$w = c - td$, $v = d + bw$, $u = w - tv$" for calculating the product $(a+bi)(c+di) = u+iv$ has been suggested by Oscar Buneman [*J. Comp. Phys.* **12** (1973), 127–128]. In this method if $a = \cos\theta$ and $b = \sin\theta$, we have $t = \tan(\theta/2)$.

[Helmut Alt and Jan van Leeuwen have shown that four real multiplications or divisions are necessary for computing $1/(a+bi)$, and four are sufficient for computing $a/(b+ci)$. It is unknown whether $(a+bi)/(c+di)$ can be computed with only five multiplications or divisions.]

42. (a) Let $\pi_1, \ldots, \pi_m$ be the λ_i's that correspond to chain multiplications; then $\pi_i = P_{2i-1} \times P_{2i}$ and $u(x) = P_{2m+1}$, where each P_j has the form $\beta_j + \beta_{j0}x + \beta_{j1}\pi_1 + \cdots + \beta_{jr(j)}\pi_{r(j)}$, where $r(j) \leq \lceil j/2 \rceil - 1$ and each of the β_j and β_{jk} is a polynomial in the α's with integer coefficients. We can systematically modify the chain (cf. exercise 30) so that $\beta_j = 0$ and $\beta_{jr(j)} = 1$, for $1 \leq j \leq 2m$; furthermore we can assume that

$\beta_{30} = 0$. The result set now has at most $m + 1 + \sum_{1 \le j \le 2m}(\lceil j/2 \rceil - 1) = m^2 + 1$ degrees of freedom.

(b) Any such polynomial chain with at most m chain multiplications can be simulated by one with the form considered in (a), except that now we let $r(j) = \lceil j/2 \rceil - 1$ for $1 \le j \le 2m + 1$, and we do not assume that $\beta_{30} = 0$ or that $\beta_{jr(j)} = 1$ for $j \ge 3$. This single canonical form involves $m^2 + 2m$ parameters. As the α's run through all integers and as we run through all chains, the β's run through at most 2^{m^2+2m} sets of values mod 2, hence the result set does also. In order to obtain all 2^n polynomials of degree n with 0–1 coefficients, we need $m^2 + 2m \ge n$.

(c) Set $m \leftarrow \lfloor \sqrt{n} \rfloor$ and compute $x^2, x^3, \ldots, x^m$. Let $u(x) = u_{m+1}(x)x^{(m+1)m} + \cdots + u_1(x)x^m + u_0(x)$, where each $u_j(x)$ is a polynomial of degree $\le m$ with integer coefficients (hence it can be evaluated without any more multiplications). Now evaluate $u(x)$ by rule (2) as a polynomial in x^m with known coefficients. (The number of additions used is approximately the sum of the absolute values of the coefficients, so this algorithm is efficient on 0–1 polynomials. Paterson and Stockmeyer also gave another algorithm that uses about $\sqrt{2n}$ multiplications.)

Reference: *SIAM J. Computing* **2** (1973), 60–66; see also J. E. Savage, *SIAM J. Computing* **3** (1974), 150–158. For analogous results about additions, see Borodin and Cook, *SIAM J. Computing* **5** (1976), 146–157; Rivest and Van de Wiele, *Inf. Proc. Letters* **8** (1979), 178–180.]

43. When $a_i = a_j + a_k$ is a step in some optimal addition chain for $n + 1$, compute $x^i = x^j x^k$ and $p_i = p_k x^j + p_j$, where $p_i = x^{i-1} + \cdots + x + 1$; omit the final calculation of x^{n+1}. We save one multiplication whenever $a_k = 1$, in particular when $i = 1$. (Cf. exercise 4.6.3–31 with $\epsilon = \frac{1}{2}$.)

44. It suffices to show that (T_{ijk})'s rank is *at most* that of (t_{ijk}), since we can obtain (t_{ijk}) back from (T_{ijk}) by transforming it in the same way with F^{-1}, G^{-1}, H^{-1}. If $t_{ijk} = \sum_{1 \le l \le r} a_{il} b_{jl} c_{kl}$ then it follows immediately that

$$T_{ijk} = \sum_{1 \le l \le r}(\sum_{1 \le p \le m} F_{ip} a_{pl})(\sum_{1 \le q \le n} G_{jq} b_{ql})(\sum_{1 \le r \le s} H_{kr} c_{rl}).$$

[H. F. de Groote has proved that all normal schemes that yield 2×2 matrix products with seven chain multiplications are equivalent, in the sense that they can be obtained from each other by nonsingular matrix multiplication as in this exercise. In this sense Strassen's algorithm is unique.]

45. By exercise 44 we can add any multiple of a row, column, or plane to another one without changing the rank; we can also multiply a row, column, or plane by a nonzero constant, or transpose the tensor. A sequence of such operations can always be found to reduce a give $2 \times 2 \times 2$ tensor to one of the forms $\binom{0\,0}{0\,0}\binom{0\,0}{0\,0}$, $\binom{1\,0}{0\,0}\binom{0\,0}{0\,0}$, $\binom{1\,0}{0\,1}\binom{0\,0}{0\,0}$, $\binom{1\,0}{0\,0}\binom{0\,0}{0\,1}$, $\binom{1\,0}{0\,1}\binom{0\,1}{q\,r}$. The last tensor has rank 3 or 2 according as the polynomial $u^2 - ru - q$ has one or two irreducible factors in the field of interest, by Theorem W (cf. (72)).

46. A general $m \times n \times s$ tensor has mns degrees of freedom. By exercise 28 it is impossible to express all $m \times n \times s$ tensors in terms of the $(m + n + s)r$ elements of a realization A, B, C unless $(m + n + s)r \ge mns$. On the other hand, assume that $m \ge n \ge s$. The rank of an $m \times n$ matrix is at most n, so we can realize any tensor in ns chain multiplications by realizing each matrix plane separately. [Exercise 45 shows that this lower bound on the maximum tensor rank is not best possible, nor is the upper bound. Thomas D. Howell (Ph. D. thesis, Cornell Univ., 1976) has shown that there are tensors of rank $\ge \lceil mns/(m + n + s - 2) \rceil$ over the complex numbers.]

48. If A, B, C and A', B', C' are realizations of (t_{ijk}) and (t'_{ijk}) of respective lengths r and r', then $A'' = A \oplus A'$, $B'' = B \oplus B'$, $C'' = C \oplus C'$, and $A''' = A \otimes A'$, $B''' = B \otimes B'$, $C''' = C \otimes C'$, are realizations of (t''_{ijk}) and (t'''_{ijk}) of respective lengths $r + r'$ and $r \cdot r'$.

Note: Many people have made the natural conjecture that $\operatorname{rank}((t_{ijk}) \oplus (t'_{ijk})) = \operatorname{rank}(t_{ijk}) + \operatorname{rank}(t'_{ijk})$, but the construction in exercise 60(b) makes this seem much less plausible than it once was.

49. By Lemma T, $\operatorname{rank}(t_{ijk}) \geq \operatorname{rank}(t_{i(jk)})$. Conversely if M is a matrix of rank r we can transform it by row and column operations, finding nonsingular matrices F and G such that FMG has all entries 0 except for r diagonal elements that are 1; cf. Algorithm 4.6.2N. The tensor rank of FMG is therefore $\leq r$; and it is the same as the tensor rank of M, by exercise 44.

50. Let $i = \langle i', i'' \rangle$ where $1 \leq i' \leq m$ and $1 \leq i'' \leq n$; then $t_{\langle i',i'' \rangle jk} = \delta_{i''j}\delta_{i'k}$, and it is clear that $\operatorname{rank}(t_{i(jk)}) = mn$ since $(t_{i(jk)})$ is a permutation matrix. By Lemma L, $\operatorname{rank}(t_{ijk}) \geq mn$. Conversely, since (t_{ijk}) has only mn nonzero entries, its rank is clearly $\leq mn$. (There is consequently no normal scheme requiring fewer than the mn obvious multiplications. There is no such abnormal scheme either [*Comm. Pure and Appl. Math.* **3** (1970), 165–179]. But some savings can be achieved if the same matrix is used with $s > 1$ different column vectors, since this is equivalent to $(m \times n)$ times $(n \times s)$ matrix multiplication.)

51. (a) $s_1 = y_0 + y_1$, $s_2 = y_0 - y_1$; $m_1 = \frac{1}{2}(x_0 + x_1)s_1$, $m_2 = \frac{1}{2}(x_0 - x_1)s_2$; $w_0 = m_1 + m_2$, $w_1 = m_1 - m_2$. (b) Here are some intermediate steps, using the methodology in the text: $((x_0 - x_2) + (x_1 - x_2)u)((y_0 - y_2) + (y_1 - y_2)u) \bmod (u^2 + u + 1) = ((x_0 - x_2)(y_0 - y_2) - (x_1 - x_2)(y_1 - y_2)) + ((x_0 - x_2)(y_0 - y_2) - (x_1 - x_0)(y_1 - y_0))u$. The first realization is

$$\begin{pmatrix} 1 & 1 & \bar{1} & 0 \\ 1 & 0 & 1 & 1 \\ 1 & \bar{1} & 0 & \bar{1} \end{pmatrix}, \quad \begin{pmatrix} 1 & 1 & \bar{1} & 0 \\ 1 & 0 & 1 & 1 \\ 1 & \bar{1} & 0 & \bar{1} \end{pmatrix}, \quad \begin{pmatrix} 1 & 1 & 1 & \bar{2} \\ 1 & 1 & \bar{2} & 1 \\ 1 & \bar{2} & 1 & 1 \end{pmatrix} \times \frac{1}{3}.$$

The second realization is

$$\begin{pmatrix} 1 & 1 & 1 & \bar{2} \\ 1 & 1 & \bar{2} & 1 \\ 1 & \bar{2} & 1 & 1 \end{pmatrix} \times \frac{1}{3}, \quad \begin{pmatrix} 1 & 1 & \bar{1} & 0 \\ 1 & \bar{1} & 0 & \bar{1} \\ 1 & 0 & 1 & 1 \end{pmatrix}, \quad \begin{pmatrix} 1 & 1 & \bar{1} & 0 \\ 1 & 0 & 1 & 1 \\ 1 & \bar{1} & 0 & \bar{1} \end{pmatrix}.$$

The resulting algorithm computes $s_1 = y_0 + y_1$, $s_2 = y_0 - y_1$, $s_3 = y_2 - y_0$, $s_4 = y_2 - y_1$, $s_5 = s_1 + y_2$; $m_1 = \frac{1}{3}(x_0 + x_1 + x_2)s_5$, $m_2 = \frac{1}{3}(x_0 + x_1 - 2x_2)s_2$, $m_3 = \frac{1}{3}(x_0 - 2x_1 + x_2)s_3$, $m_4 = \frac{1}{3}(-2x_0 + x_1 + x_2)s_4$; $t_1 = m_1 + m_2$, $t_2 = m_1 - m_2$, $t_3 = m_1 + m_3$, $w_0 = t_1 - m_3$, $w_1 = t_3 + m_4$, $w_2 = t_2 - m_4$.

52. Let $i = \langle i', i'' \rangle$ when $i \bmod n' = i'$ and $i \bmod n'' = i''$. Then we wish to compute $w_{\langle k',k'' \rangle} = \sum x_{\langle i',i'' \rangle} y_{\langle j',j'' \rangle}$ summed for $i' + j' \equiv k'$ (modulo n') and $i'' + j'' \equiv k''$ (modulo n''). This can be done by applying the n' algorithm to the $2n'$ vectors $X_{i'}$ and $Y_{j'}$ of length n'', obtaining the n' vectors $W_{k'}$. Each vector addition becomes n'' additions, each parameter multiplication becomes n'' parameter multiplications, and each chain multiplication of vectors is replaced by a cyclic convolution of degree n''. [If the subalgorithms use the minimum number of chain multiplications, this algorithm uses $2(n' - d(n'))(n'' - d(n''))$ more than the minimum, where $d(n)$ is the number of divisors of n.]

53. (a) Let $n(k) = (p-1)p^{e-k-1} = \varphi(p^{e-k})$ for $0 \le k < e$, and $n(k) = 1$ for $k \ge e$. Represent the numbers $\{1, \ldots, m\}$ in the form $a^i p^k$ (modulo m), where $0 \le k \le e$ and $0 \le i < n(k)$, and a is a fixed primitive element modulo p^e. For example, when $m = 9$ we can let $a = 2$; the values are $\{2^0 3^0, 2^1 3^0, 2^0 3^1, 2^2 3^0, 2^5 3^0, 2^1 3^1, 2^4 3^0, 2^3 3^0, 2^0 3^2\}$. Then $f(a^i p^k) = \sum_{0 \le l \le e} \sum_{0 \le j < n(l)} \omega^{g(i,j,k,l)} F(a^j p^l)$ where $g(i,j,k,l) = a^{i+j} p^{k+l}$.

We shall compute $f_{ikl} = \sum_{0 \le j < n(l)} \omega^{g(i,j,k,l)} F(a^j p^l)$ for $0 \le i < n(k)$ and for each k, l. This is a cyclic convolution of degree $n(k+l)$ on the values $x_i = \omega^{a^i p^{k+l}}$ and $y_s = \sum_{0 \le j < n(l),\, s+j \equiv 0 \,(\text{modulo } n(k+l))} F(a^j p^l)$, since $f_{ikl} = \sum x_r y_s$ summed over $r+s \equiv i \,(\text{modulo } n(k+l))$. The Fourier transform is obtained by summing appropriate f_{ikl}'s. [*Note:* When linear combinations of the x_i are formed, e.g., as in (67), the result will be purely real or purely imaginary, when the cyclic convolution algorithm has been constructed by using rule (57) with $u^{n(k)} - 1 = (u^{n(k)/2} - 1)(u^{n(k)/2} + 1)$. The reason is that reduction mod $(u^{n(k)/2} - 1)$ produces a polynomial with real coefficients $\omega^j + \omega^{-j}$ while reduction mod $(u^{n(k)/2} + 1)$ produces a polynomial with imaginary coefficients $\omega^j - \omega^{-j}$.]

When $p = 2$ an analogous construction applies, using the representation $(-1)^i a^j 2^k$ (modulo m), where $0 \le k \le e$ and $0 \le i \le \min(e-k, 1)$ and $0 \le j < 2^{e-k-2}$. In this case we use the construction of exercise 52 with $n' = 2$ and $n'' = 2^{e-k-2}$; although these numbers are not relatively prime, the construction does yield the desired direct product of cyclic convolutions.

(b) Let $a'm' + a''m'' = 1$; and let $\omega' = \omega^{a''m''}$, $\omega'' = \omega^{a'm'}$. Define $s' = s \bmod m'$, $s'' = s \bmod m''$, $t' = t \bmod m'$, $t'' = t \bmod m''$, so that $\omega^{st} = (\omega')^{s't'} (\omega'')^{s''t''}$. It follows that $f(s', s'') = \sum_{0 \le t' < m',\, 0 \le t'' < m''} (\omega')^{s't'} (\omega'')^{s''t''} F(t', t'')$; in other words, the one-dimensional Fourier transform on m elements is actually a two-dimensional Fourier transform on $m' \times m''$ elements, in slight disguise.

We shall deal with "normal" algorithms consisting of (i) a number of sums s_i of the F's and s's; followed by (ii) a number of products m_j, each of which is obtained by multiplying one of the F's or S's by a real or imaginary number α_j; followed by (iii) a number of further sums t_k, each of which is formed from m's or t's (not F's or s's). The final values must be m's or t's. For example, the "normal" Fourier transform scheme for $m = 5$ constructed from (67) and the method of part (a) is as follows: $s_1 = F(1) + F(4)$, $s_2 = F(3) + F(2)$, $s_3 = s_1 + s_2$, $s_4 = s_1 - s_2$, $s_5 = F(1) - F(4)$, $s_6 = F(2) - F(3)$, $s_7 = s_5 - s_6$; $m_1 = \frac{1}{4}(\omega + \omega^2 + \omega^4 + \omega^3)s_3$, $m_2 = \frac{1}{4}(\omega - \omega^2 + \omega^4 - \omega^3)s_4$, $m_3 = \frac{1}{2}(\omega + \omega^2 - \omega^4 - \omega^3)s_5$, $m_4 = \frac{1}{2}(-\omega + \omega^2 + \omega^4 - \omega^3)s_6$, $m_5 = \frac{1}{2}(\omega^3 - \omega^2)s_7$, $m_6 = 1 \cdot F(5)$, $m_7 = 1 \cdot s_3$; $t_0 = m_1 + m_6$, $t_1 = t_0 + m_2$, $t_2 = m_3 + m_5$, $t_3 = t_0 - m_2$, $t_4 = m_4 - m_5$, $t_5 = t_1 + t_2$, $t_6 = t_3 + t_4$, $t_7 = t_1 - t_2$, $t_8 = t_3 - t_4$, $t_9 = m_6 + m_7$. Note the multiplication by 1 shown in m_6 and m_7; this is required by our conventions, and it is important to include such cases for use in recursive constructions (although the multiplications need not really be done). Here $m_6 = f_{001}$, $m_7 = f_{010}$, $t_5 = f_{000} + f_{001} = f(2^0)$, $t_6 = f_{100} + f_{101} = f(2^1)$, etc. We can improve the scheme by introducing $s_8 = s_3 + F(5)$, replacing m_1 by $(\frac{1}{4}(\omega + \omega^2 + \omega^4 + \omega^3) - 1)s_3$ [this is $-\frac{5}{4}s_3$], replacing m_6 by $1 \cdot s_8$, and deleting m_7 and t_9; this saves one of the trivial multiplications by 1, and it will be advantageous when the scheme is used to build larger ones. In the improved scheme, $f(5) = m_6$, $f(1) = t_5$, $f(2) = t_6$, $f(3) = t_8$, $f(4) = t_7$.

Now suppose we have normal one-dimensional schemes for m' and m'', using respectively (a', a'') complex additions, (t', t'') trivial multiplications by ± 1 or $\pm i$, and a total of (c', c'') complex multiplications including the trivial ones. (The nontrivial

complex multiplications are all "simple" since they involve only two real multiplications and no real additions.) We can construct a normal scheme for the two-dimensional $m' \times m''$ case by applying the m' scheme to vectors $F(t', *)$ of length m''. Each s_i step becomes m'' additions; each m_j becomes a Fourier transform on m'' elements, but with all of the α's in this algorithm multiplied by α_j; and each t_k becomes m'' additions. Thus the new algorithm has $(a'm'' + c'a'')$ complex additions, $t't''$ trivial multiplications, and a total of $c'c''$ complex multiplications.

Using these techniques, Winograd has found normal one-dimensional schemes for the following small values of m with the following costs (a, t, c):

$m = 2$	$(2, 2, 2)$	$m = 7$	$(36, 1, 9)$
$m = 3$	$(6, 1, 3)$	$m = 8$	$(26, 6, 8)$
$m = 4$	$(8, 4, 4)$	$m = 9$	$(46, 1, 12)$
$m = 5$	$(17, 1, 6)$	$m = 16$	$(74, 8, 18)$

By combining these schemes as described above, we obtain methods that use fewer arithmetic operations than the "fast Fourier transform" (FFT) discussed in exercise 14. For example, when $m = 1008 = 7 \cdot 9 \cdot 16$, the costs come to $(17946, 8, 1944)$, so we can do a Fourier transform on 1008 complex numbers with 3872 real multiplications and 35892 real additions. It is possible to improve on Winograd's method for combining relatively prime moduli by using multidimensional convolutions, as shown by Nussbaumer and Quandalle in *IBM J. Res. and Devel.* **22** (1978), 134–144; their ingenious approach reduces the amount of computation needed for 1008-point complex Fourier transforms to 3084 real multiplications and 34668 real additions. By contrast, the FFT on 1024 complex numbers involves 14344 real multiplications and 27652 real additions. If the two-passes-at-once improvement in the answer to exercise 14 is used, however, the FFT on 1024 complex numbers needs only 10936 real multiplications and 25948 additions, and it is not difficult to implement. Therefore the subtler methods are faster only on machines that take significantly longer to multiply than to add.

[References: *Proc. Nat. Acad. Sci. USA* **73** (1976), 1005–1006; ***Math. Comp.* 32 (1978), 175–199; *Advances in Math.* 32 (1979), 83–117.**]

54. $\max(2e_1\deg(p_1) - 1, \ldots, 2e_q\deg(p_q) - 1, q + 1)$.

55. $2n' - q'$, where n' is the degree of the minimum polynomial of P (i.e., the monic polynomial μ of least degree such that $\mu(P)$ is the zero matrix) and r' is the number of distinct irreducible factors it has. (Reduce P by similarity transformations.)

56. Let $t_{ijk} + t_{jik} = \tau_{ijk} + \tau_{jik}$, for all i, j, k. If A, B, C is a realization of (t_{ijk}) of rank r, then $\sum_{1 \le l \le r} c_{kl} (\sum a_{il} x_i)(\sum b_{jl} x_j) = \sum_{i,j} t_{ijk} x_i x_j = \sum_{i,j} \tau_{ijk} x_i x_j$ for all k. Conversely, let the lth chain multiplication of a polynomial chain, for $1 \le l \le r$, be the product $(\alpha_l + \sum \alpha_{il} x_i)(\beta_l + \sum \beta_{jl} x_j)$, where α_l and β_l denote possible constant terms and/or nonlinear terms. All terms of degree 2 appearing at any step of the chain can be expressed as a linear combination $\sum_{1 \le l \le r} c_l (\sum a_{il} x_i)(\sum b_{jl} x_j)$; hence the chain defines a tensor (t_{ijk}) of rank $\le r$ such that $t_{ijk} + t_{jik} = \tau_{ijk} + \tau_{jik}$. This establishes the hint. Now $\operatorname{rank}(\tau_{ijk} + \tau_{jik}) = \operatorname{rank}(t_{ijk} + t_{jik}) \le \operatorname{rank}(t_{ijk}) + \operatorname{rank}(t_{jik}) = 2 \operatorname{rank}(t_{ijk})$.

A bilinear form in $x_1, \ldots, x_m, y_1, \ldots, y_n$ is a quadratic form in $m + n$ variables, where $\tau_{ijk} = t_{i,j-m,k}$ for $i \le m$ and $j > m$, otherwise $\tau_{ijk} = 0$. Now $\operatorname{rank}(\tau_{ijk}) + \operatorname{rank}(\tau_{jik}) \ge \operatorname{rank}(t_{ijk})$, since we obtain a realization of (t_{ijk}) by suppressing the last n rows of A and the first m rows of B in a realization A, B, C of $(\tau_{ijk} + \tau_{jik})$.

57. Let N be the smallest power of 2 that exceeds $2n$, and let $u_{n+1} = \cdots = u_{N-1} = v_{n+1} = \cdots = v_{N-1} = 0$. If $U_s = \sum_{0\le t<N} \omega^{st} u_t$, $V_s = \sum_{0\le t<N} \omega^{st} v_t$, $0 \le s < N$, $\omega = e^{2\pi i/N}$, then $\sum_{0\le s<N} \omega^{-st} U_s V_s = N \sum u_{t_1} v_{t_2}$, where the latter sum is taken over all t_1 and t_2 with $0 \le t_1, t_2 < N$, $t_1 + t_2 \equiv t$ (modulo N). The terms vanish unless $t_1 \le n$ and $t_2 \le n$, so $t_1 + t_2 < N$; thus the sum is the coefficient of z^t in the product $u(z)v(z)$. If we use the method of exercise 14 to compute the Fourier transforms and the inverse transforms, the number of complex operations is $O(N \log N) + O(N \log N) + O(N) + O(N \log N)$; and $N < 4n$. [Cf. Section 4.3.3 and the paper by J. M. Pollard, *Math. Comp.* **25** (1971), 365–374.]

When multiplying integer polynomials, it is possible to use an *integer* number ω that is of order 2^t modulo a prime p, and to determine the results modulo sufficiently many primes. Useful primes in this regard, together with their least primitive roots r (from which we take $\omega = r^{(p-1)/2^t} \bmod p$ when $p \bmod 2^t = 1$), can be found as described in Section 4.5.4. For $t = 9$, the ten largest cases $< 2^{35}$ are $p = 2^{35} - 512a + 1$, where $(a, r) = (28, 7), (31, 10), (34, 13), (56, 3), (58, 10), (76, 5), (80, 3), (85, 11), (91, 5), (101, 3)$; the ten largest cases $< 2^{31}$ are $p = 2^{31} - 512a + 1$, where $(a, r) = (1, 10), (11, 3), (19, 11), (20, 3), (29, 3), (35, 3), (55, 19), (65, 6), (95, 3), (121, 10)$. For larger t, all primes p of the form $2^t q + 1$ where $q < 32$ is odd and $2^{24} < p < 2^{36}$ are given by $(p - 1, r) = (11 \cdot 2^{21}, 3), (25 \cdot 2^{20}, 3), (27 \cdot 2^{20}, 5), (25 \cdot 2^{22}, 3), (27 \cdot 2^{22}, 7), (5 \cdot 2^{25}, 3), (7 \cdot 2^{26}, 3), (27 \cdot 2^{26}, 13), (15 \cdot 2^{27}, 31), (17 \cdot 2^{27}, 3), (3 \cdot 2^{30}, 5), (13 \cdot 2^{28}, 3), (29 \cdot 2^{27}, 3), (23 \cdot 2^{29}, 5)$. Some of the latter primes can be used with $\omega = 2^e$ for appropriate small e. For a discussion of such primes, see R. M. Robinson, *Proc. Amer. Math. Soc.* **9** (1958), 673–681; S. W. Golomb, *Math. Comp.* **30** (1976), 657–663.

However, the method of exercise 59 will almost always be preferable in practice.

58. (a) In general if A, B, C realizes (t_{ijk}), then $(x_1, \ldots, x_m)A$, B, C is a realization of the $1 \times n \times s$ matrix whose entry in row j, column k is $\sum x_i t_{ijk}$. So there must be at least as many nonzero elements in $(x_1, \ldots, x_m)A$ as the rank of this matrix. In the case of the $m \times n \times (m + n - 1)$ tensor corresponding to polynomial multiplication of degree $m - 1$ by degree $n - 1$, the corresponding matrix has rank n whenever $(x_1, \ldots, x_m) \ne (0, \ldots, 0)$. A similar statement holds with $A \leftrightarrow B$ and $m \leftrightarrow n$. [In particular, if we work over the field of 2 elements, this says that the rows of A modulo 2 form a "linear code" of m vectors having distance at least n, whenever A, B, C is a realization consisting entirely of integers. This observation, due to R. W. Brockett and D. Dobkin [*Linear Algebra and its Applic.* **19** (1978), 207–235, Theorem 14], can be used to obtain nontrivial lower bounds on the rank over the integers. For example, M. R. Brown and D. Dobkin have used it to show that realizations of $n \times n$ polynomial multiplication over the integers must have $t \ge 3.52n$, for all sufficiently large n; see *IEEE Trans.* **C–29** (1980), 337–340.]

(b) $\begin{pmatrix} 1&0&0&0&0&1&1&1 \\ 0&1&0&0&1&1&0&1 \\ 0&0&1&1&0&0&1&1 \end{pmatrix}$, $\begin{pmatrix} 1&0&0&0&0&1&1&1 \\ 0&1&0&0&0&1&0&1 \\ 0&0&1&0&0&0&1&1 \\ 0&0&0&1&1&0&0&1 \end{pmatrix}$, $\begin{pmatrix} 1&0&0&0&0&0&0&0 \\ \bar{1}&\bar{1}&0&0&0&1&0&0 \\ \bar{1}&1&\bar{1}&0&0&0&1&0 \\ 1&0&0&\bar{1}&\bar{1}&\bar{1}&\bar{1}&1 \\ 0&0&1&0&1&0&0&0 \\ 0&0&0&1&0&0&0&0 \end{pmatrix}$.

59. [*IEEE Trans.* **ASSP–28** (1980), 205–215.] Note that cyclic convolution is polynomial multiplication mod $u^n - 1$, and negacyclic convolution is polynomial multiplication mod $u^n + 1$. Let us now change notation, replacing n by 2^n; we shall consider recursive algorithms for cyclic and negacyclic convolution $(z_0, \ldots, z_{2^n-1})$ of $(x_0, \ldots, x_{2^n-1})$ with

$(y_0, \ldots, y_{2^n-1})$. The algorithms are presented in unoptimized form, for brevity and ease in exposition; the reader who implements them will notice that many things can be streamlined.

C1. [Test for simple case.] If $n = 1$, set $z_0 \leftarrow x_0y_0 + x_1y_1$, $z_1 \leftarrow (x_0 + x_1)(y_0 + y_1) - z_0$, and terminate. Otherwise set $m \leftarrow 2^{n-1}$.

C2. [Remainderize.] For $0 \le k < m$, set $(x_k, x_{m+k}) \leftarrow (x_k + x_{m+k}, x_k - x_{m+k})$ and $(y_k, y_{m+k}) \leftarrow (y_k + y_{m+k}, y_k - y_{m+k})$. (Now we have $x(u) \bmod (u^m - 1) = x_0 + \cdots + x_{m-1}u^{m-1}$ and $x(u) \bmod (u^m + 1) = x_m + \cdots + x_{2m-1}$; we will compute $x(u)y(u) \bmod (u^m - 1)$ and $x(u)y(u) \bmod (u^m + 1)$, then we will combine the results by (57).)

C3. [Recurse.] Set $(z_0, \ldots, z_{m-1})$ to the cyclic convolution of $(x_0, \ldots, x_{m-1})$ with $(y_0, \ldots, y_{m-1})$. Also set $(z_m, \ldots, z_{2m-1})$ to the negacyclic convolution of $(x_m, \ldots, x_{2m-1})$ with $(y_m, \ldots, y_{2m-1})$.

C4. [Unremainderize.] For $0 \le k < m$, set $(z_k, z_{m+k}) \leftarrow \frac{1}{2}(z_k + z_{m+k}, z_k - z_{m+k})$. Now $(z_0, \ldots, z_{m-1})$ is the desired answer. ∎

N1. [Test for simple case.] If $n = 1$, set $t \leftarrow x_0(y_0 + y_1)$, $z_0 \leftarrow t - (x_0 + x_1)y_1$, $z_1 \leftarrow t + (x_1 - x_0)y_0$, and terminate. Otherwise set $m \leftarrow 2^{\lfloor n/2 \rfloor}$ and $r \leftarrow 2^{\lceil n/2 \rceil}$. (The following steps use 2^{n+1} auxiliary variables X_{ij} for $0 \le i < 2m$ and $0 \le j < r$, to represent $2m$ polynomials $X_i(w) = X_{i0} + X_{i1}w + \cdots + X_{i(r-1)}w^{r-1}$; similarly, there are 2^{n+1} auxiliary variables Y_{ij}.)

N2. [Initialize auxiliary polynomials.] Set $X_{ij} \leftarrow X_{(i+m)j} \leftarrow x_{mj+i}$ $Y_{ij} \leftarrow Y_{(i+m)j} \leftarrow y_{mj+i}$, for $0 \le i < m$ and $0 \le j < r$. (At this point we have $x(u) = X_0(u^m) + uX_1(u^m) + \cdots + u^{m-1}X_{m-1}(u^m)$, and a similar formula holds for $y(u)$. Our strategy will be to multiply these polynomials modulo $(u^{mr} + 1) = (u^n + 1)$, by operating modulo $(w^r + 1)$ on the polynomials $X(w)$ and $Y(w)$, finding their cyclic correlation of length $2m$ and thereby obtaining $x(u)y(u) = Z_0(u^m) + uZ_1(u^m) + \cdots + u^{2m-1}Z_{2m-1}(u^m)$.)

N3. [Transform.] (Now we will essentially do a fast Fourier transform on the polynomials $(X_0, \ldots, X_{m-1}, 0, \ldots, 0)$ and $(Y_0, \ldots, Y_{m-1}, 0, \ldots, 0)$, using $w^{r/m}$ as a $(2m)$th root of unity. This is efficient, because multiplication by a power of w is not really a multiplication at all.) For $j = \lfloor n/2 \rfloor - 1, \ldots, 1, 0$ (in this order), do the following for all m binary numbers $s + t = (s_{\lfloor n/2 \rfloor} \ldots s_{j+1}0 \ldots 0)_2 + (0 \ldots 0t_{j-1} \ldots t_0)_2$: Replace $(X_{s+t}(w), X_{s+t+2^j}(w))$ by the pair of polynomials $(X_{s+t}(w) + w^{(r/m)(s/2)}X_{s+t+2^j}(w), X_{s+t}(w) - w^{(r/m)(s/2)}X_{s+t+2^j}(w))$. (See Section 4.3.3 and Eq. 4.3.3–33. The operation $X_i(w) \leftarrow X_i(w) + w^kX_l(w)$ means, more precisely, that we set $X_{ij} \leftarrow X_{ij} + X_{l(j+k)}$ if $j + k < r$, otherwise $X_{ij} \leftarrow X_{ij} - X_{l(j+k-r)}$, for $0 \le j < r$.) Do the same transformation on the Y's.

N4. [Recurse.] For $0 \le i < 2m$, set $(Z_{i0}, \ldots, Z_{i(r-1)})$ to the negacyclic convolution of $(X_{i0}, \ldots, X_{i(r-1)})$ and $(Y_{i0}, \ldots, Y_{i(r-1)})$.

N5. [Untransform.] For $j = 0, 1, \ldots, \lfloor n/2 \rfloor$ (in this order), set $(Z_{s+t}(w), Z_{s+t+2^j}(w)) \leftarrow \frac{1}{2}(Z_{s+t}(w) + Z_{s+t+2^j}(w), w^{-(r/m)(s/2)}(Z_{s+t}(w) - Z_{s+t+2^j}(w)))$, for all m choices of s and t as in step N3.

N6. [Repack.] (Now we have accomplished the goal stated at the end of step N2, since it is easy to show that the transform of the Z's is the product of the transforms of the X's and the Y's.) Set $z_i \leftarrow Z_{i0} - Z_{(m+i)(r-1)}$ and $z_{mj+i} \leftarrow Z_{ij} + Z_{(m+i)(j-1)}$ for $0 < j < r$, for $0 \le i < m$. ∎

It is easy to verify that at most n extra bits of precision are needed for the intermediate variables in this calculation; i.e., if $|x_i| \le M$ for $0 \le i < 2^n$ at the beginning of the algorithm, then all of the x and X variables will be bounded by $2^n M$ throughout.

Algorithm N performs A_n addition-subtractions, D_n halvings, and M_n multiplications, where $A_1 = 5$, $D_1 = 0$, $M_1 = 3$; for $n > 1$ we have $A_n = \lfloor n/2 \rfloor 2^{n+2} + 2^{\lfloor n/2 \rfloor + 1} A_{\lfloor n/2 \rfloor} + (\lfloor n/2 \rfloor + 1)2^{n+1} + 2^n$, $D_n = 2^{\lfloor n/2 \rfloor + 1} D_{\lfloor n/2 \rfloor} + (\lfloor n/2 \rfloor + 1)2^{n+1}$, and $M_n = 2^{\lfloor n/2 \rfloor + 1} M_{\lfloor n/2 \rfloor}$. The solutions are $A_n = 11 \cdot 2^{n-1+\lceil \lg n \rceil} - 3 \cdot 2^n + 6 \cdot 2^n S_n$, $D_n = 4 \cdot 2^{n-1+\lceil \lg n \rceil} - 2 \cdot 2^n + 2 \cdot 2^n S_n$, $M_n = 3 \cdot 2^{n-1+\lceil \lg n \rceil}$; here S_n satisfies the recurrence $S_1 = 0$, $S_n = 2S_{\lceil n/2 \rceil} + \lfloor n/2 \rfloor$, and it is not difficult to prove the inequalities $\frac{1}{2} n \lceil \lg n \rceil \le S_n \le \frac{1}{2} n \lg n + n$. Algorithm C does approximately the same amount of work as Algorithm N.

It would be interesting to find a simpler way to carry out the additions and subtractions in step N3 (and the reverse operations in N5), perhaps analogous to Yates's method. The operation $X_i \leftarrow X_i + w^k X_l$ sketched above can be done with a procedure that generalizes the data-rotation algorithm of Fletcher and Silver in *CACM* **9** (1966), 326, but there might be a better way.

60. (a) In Σ_1, for example, we can group all terms having a common value of j and k into a single trilinear term; this gives ν^2 trilinear terms when $(j,k) \in E \times E$, plus ν^2 when $(j,k) \in E \times O$ and ν^2 when $(j,k) \in O \times E$. When $\tilde{j} = k$ we can also include $-x_{jj}\, y_{j\tilde{j}}\, z_{\tilde{j}j}$ in Σ_1, free of charge. [In the case $n = 10$, the method multiplies 10 by 10 matrices with 710 noncommutative multiplications; this is fewer than required by any other known method, although Winograd's scheme (35) uses only 600 when commutativity is allowed.]

(b) Here we simply let S be all the indices (i,j,k) of one problem, $\tilde{S}$ the indices of the other. [When $m = n = s = 10$, the result is quite surprising: We can multiply two separate 10×10 matrices with 1300 noncommutative multiplications, while no scheme is known that would multiply each of them with 650.]

(c) Corresponding to the left-hand side of the stated identity we get the terms

$$x_{i+\epsilon,j+\zeta}\, y_{j+\zeta,k+\eta}\, z_{k+\eta,i+\epsilon} + x_{j+\eta,k+\epsilon}\, y_{k+\epsilon,i+\zeta}\, z_{i+\zeta,j+\eta} + x_{k+\zeta,i+\eta}\, y_{i+\eta,j+\epsilon}\, z_{j+\epsilon,k+\zeta}$$

summed over $(i,j,k) \in S$ and $0 \le \epsilon, \zeta, \eta \le 1$, so we get all the trilinear terms of the form $x_{ij}\, y_{jk}\, z_{ki}$ except when $\lceil i/2 \rceil = \lceil j/2 \rceil = \lceil k/2 \rceil$; however, these missing terms can all be included in Σ_1, Σ_2, or Σ_3. The sum Σ_1 turns out to include terms of the form $x_{i+\epsilon,j+\zeta}\, y_{i+\eta,j+\epsilon}$ times some sum of z's, so it contributes $8\nu^2$ terms to the trilinear realization; and Σ_2, Σ_3 are similar. To verify that the aBC terms cancel out, note that they are $\sum (-1)^{\zeta+\eta} x_{i+\epsilon,j+\zeta}\, y_{k+\epsilon,i+\zeta}\, z_{j+\epsilon,k+\zeta}$, so $\eta = 1$ cancels with $\eta = 0$. [This technique leads to asymptotic improvements over Strassen's method whenever $\frac{1}{3} n^3 + 6n^2 - \frac{4}{3} n < n^{\lg 7}$, namely when $36 \le n \le 184$, and it was the first construction known to break the $\lg 7$ barrier. Reference: *SIAM J. Computing* **9** (1980), 321–342.]

61. (a) Replace $a_{ij}(u)$ by $u a_{il}(u)$. (b) Let $a_{il}(u) = a_{il\mu} u^\mu$, etc., in a polynomial realization of length $r = \operatorname{rank}_d(t_{ijk})$. Then $t_{ijk} = \sum_{\mu+\nu+\sigma=d} \sum_{1 \le l \le r} a_{il\mu} b_{jl\nu} c_{kl\sigma}$. [This result can be improved to $\operatorname{rank}(t_{ijk}) \le (2d+1) \operatorname{rank}_d(t_{ijk})$ in an infinite field, because the trilinear form $\sum_{\mu+\nu+\sigma} a_\mu b_\nu c_\sigma$ corresponds to multiplication of polynomials modulo u^{d+1}, as pointed out by Bini and Pan.] (c,d) This is clear from the realizations in exercise 48.

62. The rank is 3, by the method of proof in Theorem W with $P = \left(\begin{smallmatrix} 0 & 1 \\ 0 & 0 \end{smallmatrix}\right)$. The border rank cannot be 1, since we cannot have $a_1(u)b_1(u)c_1(u) \equiv a_1(u)b_2(u)c_2(u) \equiv u^d$ and $a_1(u)b_2(u)c_1(u) \equiv a_1(u)b_1(u)c_2(u) \equiv 0$ (modulo u^{d+1}). The border rank is 2 because of the realization $\left(\begin{smallmatrix} 1 & 1 \\ u & 0 \end{smallmatrix}\right)$, $\left(\begin{smallmatrix} u & 0 \\ 1 & 1 \end{smallmatrix}\right)$, $\left(\begin{smallmatrix} 1 & -1 \\ 0 & u \end{smallmatrix}\right)$.

63. (a) Let the elements of $T(m, n, s)$ and $T(M, N, S)$ be denoted by $t_{\langle i,j'\rangle\langle j,k'\rangle\langle k,i'\rangle}$ and $T_{\langle I,J'\rangle\langle J,K'\rangle\langle K,I'\rangle}$, respectively. Each element $\mathcal{T}_{\langle I,J'\rangle\langle J,K'\rangle\langle K,I'\rangle}$ of the direct product, where $I = \langle i, I\rangle$, $J = \langle j, J\rangle$, and $K = \langle k, K\rangle$, is equal to $t_{\langle i,j'\rangle\langle j,k'\rangle\langle k,i'\rangle}T_{\langle I,J'\rangle\langle J,K'\rangle\langle K,I'\rangle}$ by definition, so it is 1 iff $I' = I$ and $J' = J$ and $K' = K$.

(b) We have $M(mns) \le r^3$, since $T(mns, mns, mns) = T(m, n, s) \otimes T(n, s, m) \otimes T(s, m, n)$. If $M(P) \le R$ we have $M(P^h) \le R^h$ for all h, and it follows that $M(N) \le M(P^{\lceil \log_P N\rceil}) \le R^{\lceil \log_P N\rceil} \le RN^{\log R/\log P}$. [This result appears in Pan's 1972 paper.]

(c) We have $M_d(mns) \le r^3$ for some d, where $M_d(n) = \operatorname{rank}_d(T(n, n, n))$. If $M_d(P) \le R$ we have $M_{hd}(P^h) \le R^h$ for all h, and the stated formula follows since $M(P^h) \le \binom{hd+2}{2}R^h$ by exercise 61. In an infinite field we save a factor of $\log N$. [This result is due to Bini and Schönhage, 1979.]

(d) Let $P = mns$; we can perform p^{3h} independent $P^h \times P^h$ matrix multiplications with at most $\binom{hd+2}{2}p^{3h}r^{3h}$ noncommutative scalar multiplications. Reduce $M(P^{2h})$ to $M(P^h)$ matrix multiplications of size $P^h \times P^h$; thus we have $M(P^{2h}) \le \binom{hd+2}{2}r^{3h}M(P^h)(1 + O(p/r)^{3h})$. Iterating this recurrence gives

$$M(N) = O(N^{\beta(m,n,s,r)}) \cdot \exp(O(\log\log n)^2).$$

64. (a) Let $a = x_{ij}$, $A = uX_{ki}$, $b = y_{jk}$, $B = Y_{ij}$, $c = uz_{ki}$, $C = Z_{jk}$, so that $\Sigma_2 = O(u^2)$ can be eliminated. [When $m = s = 7$ and $n = 1$, this gives $M(N) = O(N^{2.66})$.] (b) Take $\alpha_1 = s - 1$, $\alpha_2 = -\alpha_1^{-2}$, $\alpha_3 = \alpha_4 = -1$, $\alpha_5 = 1$, $\alpha_6 = s - 1$, and $d \ge 4$. [We assume that α^{-1} exists in the field.] (c) Taking the direct product of $T(m, n, 2s) \oplus T(2n, s, m) \oplus T(s, 2m, n)$ with itself $3h$ times gives a tensor whose border rank is at most $\big(2(m+1)n(s+2)\big)^{3h}$. This tensor is the direct sum of 3^{3h} terms of the form $T(m^i(2n)^j s^k, n^i s^j (2m)^k, (2s)^i m^j n^k)$ where $i + j + k = 3h$, and $(3h)!/h!^3$ of these have $i = j = k = h$. Thus if we let $P = (2mns)^h$ and $p = (3h)!/h!^3$, the border rank of $pT(P, P, P)$ is at most pr, where

$$r = \big(2(m + 1)n(s + 2)\big)^{3h}/p.$$

Exercise 63(d) now implies that $M(N) = O(N^{\beta(P,P,P,r)+\epsilon})$ for all $\epsilon > 0$; here P and r are functions of h. We complete the proof by letting h be large in $\beta(P, P, P, r) = \log r/\log P = (3h\log 2(m + 1)n(s + 2) - 3h\log 3 + O(\log h))/(3h\log 2mns)$, which equals $\beta(m, n, 2s, \frac{2}{3}(m + 1)n(s + 2)) + O((\log h)/h)$. [The best value is obtained for $m = 5$, $n = 1$, $s = 11$, $\beta = 3\log_{110} 52 < 2.522$.]

SECTION 4.7

1. Find the first nonzero coefficient V_m, as in (4), and divide both $U(z)$ and $V(z)$ by z^m (shifting the coefficients m places to the left). The quotient will be a power series iff $U_0 = \cdots = U_{m-1} = 0$.

2. We have $V_0^{n+1}W_n = V_0^nU_n - (V_0^1W_0)(V_0^{n-1}V_n) - (V_0^2W_1)(V_0^{n-2}V_{n-1}) - \cdots - (V_0^nW_{n-1})(V_0^0V_1)$. Thus, we can start by replacing (U_j, V_j) by $(V_0^jU_j, V_0^{j-1}V_j)$ for $j \geq 1$, then set $W_n \leftarrow U_n - \sum_{0\leq k<n} W_kV_{n-k}$ for $n \geq 0$, finally replace W_j by W_j/V_0^{j+1} for $j \geq 0$. Similar techniques are possible in connection with other algorithms in this section.

3. Yes. When $\alpha = 0$, it is easy to prove by induction that $W_1 = W_2 = \cdots = 0$. When $\alpha = 1$, we find $W_n = V_n$, by the "cute" identity

$$\sum_{1\leq k\leq n} \left(\frac{k-(n-k)}{n}\right) V_kV_{n-k} = V_0V_n.$$

4. If $W(z) = e^{V(z)}$, then $W'(z) = V'(z)W(z)$; we find $W_0 = 1$, and

$$W_n = \sum_{1\leq k\leq n} \frac{k}{n} V_kW_{n-k}, \qquad \text{for } n \geq 1.$$

If $W(z) = \ln(1 + V(z))$, then $W'(z) + W'(z)V(z) = V'(z)$; the rule is $W_0 = 0$, and $W_1 + 2W_2z + \cdots = V'(z)/(1 + V(z))$.

[By exercise 6, the logarithm can be obtained to order n in $O(n \log n)$ operations. R. P. Brent observes that $\exp(V(z))$ can also be calculated with this asymptotic speed by applying Newton's method to $f(x) = \ln x - V(z)$; therefore general exponentiation $(1+V(z))^\alpha = \exp(\alpha \ln(1+V(z)))$ is $O(n \log n)$ too. Reference: *Analytic Computational Complexity*, ed. by J. F. Traub (New York: Academic Press, 1975), 172–176.]

5. We get the original series back again. This can be used to test a reversion algorithm.

6. $\varphi(x) = x + x(1 - xV(z))$, cf. Algorithm 4.3.3R. Thus after $W_0, \ldots, W_{N-1}$ are known, the idea is to input $V_N, \ldots, V_{2N-1}$, compute $(W_0 + \cdots + W_{N-1}z^{N-1}) \times (V_0 + \cdots + V_{2N-1}z^{2N-1}) = 1 + R_0z^N + \cdots + R_{N-1}z^{2N-1} + O(z^{2N})$, and let $W_N + \cdots + W_{2N-1}z^{N-1} = -(W_0 + \cdots + W_{N-1}z^{N-1})(R_0 + \cdots + R_{N-1}z^{N-1}) + O(z^N)$. [*Numer. Math.* **22** (1974), 341–348; this algorithm was, in essence, first published by M. Sieveking, *Computing* **10** (1972), 153–156.] Note that the total time for N coefficients is $O(N \log N)$ if we use "fast" polynomial multiplication (exercise 4.6.4–57).

7. $W_n = \binom{mk}{k}/n$ when $n = (m-1)k + 1$, otherwise 0. (Cf. exercise 2.3.4.4–11.)

8. Input G_1 in step L1, and G_n in step L2. In step L4, the output should be $(U_{n-1}G_1 + 2U_{n-2}G_2 + \cdots + nU_0G_n)/n$. (The running time of the order N^3 algorithm is hereby increased by only order N^2. The value $W_1 = G_1$ might be output in step L1.)

Note: Algorithms T and N determine $V^{-1}(U(z))$; the algorithm in this exercise determines $G(V^{-1}(z))$, which is somewhat different. Of course, the results can all be obtained by a sequence of operations of reversion and composition (exercise 11), but it is helpful to have more direct algorithms for each case.

9.

	$n=1$	$n=2$	$n=3$	$n=4$	$n=5$
T_{1n}	1	1	2	5	14
T_{2n}		1	2	5	14
T_{3n}			1	3	9
T_{4n}				1	4
T_{5n}					1

10. Form $y^{1/\alpha} = x(1 + a_1x + a_2x^2 + \cdots)^{1/\alpha} = x(1 + c_1x + c_2x^2 + \cdots)$ by means of Eq. (9); then revert the latter series. (See the remarks following Eq. 1.2.11.3–11.)

11. Set $W_0 \leftarrow U_0$, and set $(T_k, W_k) \leftarrow (V_k, 0)$ for $1 \le k \le N$. Then for $n = 1$, 2, ..., N, do the following: Set $W_j \leftarrow W_j + U_nT_j$ for $n \le j \le N$; and then set $T_j \leftarrow T_{j-1}V_1 + \cdots + T_nV_{j-n}$ for $j = N, N-1, \ldots, n+1$.

Here $T(z)$ represents $V(z)^n$. An *on-line* power series algorithm for this problem, analogous to Algorithm T, could be constructed, but it would require about $N^2/2$ storage locations. There is also an on-line algorithm that solves this exercise and needs only $O(N)$ storage locations: We may assume that $V_1 = 1$, if U_k is replaced by $U_kV_1^k$ and V_k is replaced by V_k/V_1 for all k. Then we may revert $V(z)$ by Algorithm L, using its output as input to the algorithm of exercise 8 with $G_1 = U_1$, $G_2 = U_2$, etc., thus computing $U((V^{-1})^{-1}(z)) - U_0$.

Brent and Kung have constructed several algorithms that are asymptotically faster. For example, we can evaluate $U(x)$ for $x = V(z)$ by a slight variant of exercise 4.6.4–42(c), doing about $2\sqrt{n}$ chain multiplications of cost $M(n)$ and about n parameter multiplications of cost n, where $M(n)$ is the number of operations needed to multiply power series to order n; the total time is therefore $O(\sqrt{n}M(n) + n^2) = O(n^2)$. A still faster method can be based on the identity $U(V_0(z) + z^mV_1(z)) = U(V_0(z)) + z^mU'(V_0(z))V_1(z) + z^{2m}U''(V_0(z))V_1(z)^2/2! + \cdots$, extending to about n/m terms, where we choose $m \approx \sqrt{n/\log n}$; the first term $U(V_0(z))$ is evaluated in $O(mn(\log n)^2)$ operations using a method somewhat like that in exercise 4.6.4–43. Since we can go from $U^{(k)}(V_0(z))$ to $U^{(k+1)}(V_0(z))$ in $O(n \log n)$ operations by differentiating and dividing by $V_0'(z)$, the entire procedure takes $O(mn(\log n)^2 + (n/m)n \log n) = O(n \log n)^{3/2}$ operations. [*JACM* **25** (1978), 581–595.]

12. Polynomial division is trivial unless $m \ge n \ge 1$. Assuming the latter, the equation $u(x) = q(x)v(x) + r(x)$ is equivalent to $U(z) = Q(z)V(z) + z^{m-n+1}R(z)$ where $U(x) = x^mu(x^{-1})$, $V(x) = x^nv(x^{-1})$, $Q(x) = x^{m-n}q(x^{-1})$, and $R(x) = x^{n-1}r(x^{-1})$ are the "reverse" polynomials of u, v, q, and r.

To find $q(x)$ and $r(x)$, compute the first $m - n + 1$ coefficients of the power series $U(z)/V(z) = W(z) + O(z^{m-n+1})$; then compute the power series $U(z) - V(z)W(z)$, which has the form $z^{m-n+1}T(z)$ where $T(z) = T_0 + T_1z + \cdots$. Note that $T_j = 0$ for all $j \ge n$; hence $Q(z) = W(z)$ and $R(z) = T(z)$ satisfy the requirements.

13. Apply exercise 4.6.1–3 with $u(z) = z^N$ and $v(z) = W_0 + \cdots + W_{N-1}z^{N-1}$; the desired approximations are the values of $v_3(z)/v_2(z)$ obtained during the course of the algorithm. Exercise 4.6.1–26 tells us that there are no further possibilities with relatively prime numerator and denominator. If each W_i is an integer, an all-integer extension of Algorithm 4.6.1C will have the desired properties.

Notes: The case $N = 2n+1$ and $\deg(w_1) = \deg(w_2) = n$ is of particular interest, since it is equivalent to a so-called Toeplitz system. The method of this exercise can be generalized to arbitrary rational interpolation of the form $W(z) \equiv p(z)/q(z)$ (modulo $(z - z_1)\ldots(z - z_N)$), where the z_i's need not be distinct; thus, we can specify the value of $W(z)$ and some of its derivatives at several points. See Fred G. Gustavson and David Y. Y. Yun, IBM Research Report RC7551 (1979).

14. If $U(z) = z + U_kz^k + \cdots$ and $V(z) = z^k + V_{k+1}z^{k+1} + \cdots$, we find that the difference $V(U(z)) - U'(z)V(z)$ is $\sum_{j\ge1} z^{2k+j-1}j(U_kV_{k+j} - U_{k+j} +$ (polynomial involving only $U_k, \ldots, U_{k+j-1}, V_{k+1}, \ldots, V_{k+j-1}$)); hence $V(z)$ is unique if $U(z)$ is given and $U(z)$ is unique if $V(z)$ and U_k are given.

The solution depends on two auxiliary algorithms, the first of which solves the equation $V(z+z^kU(z)) = (1+z^{k-1}W(z))V(z)+z^{k-1}S(z)+O(z^{k-1+n})$ for $V(z) = V_0 + V_1z + \cdots + V_{n-1}z^{n-1}$, given $U(z)$, $W(z)$, $S(z)$, and n. If $n = 1$, let $V_0 = -S(0)/W(0)$; or let $V_0 = 1$ when $S(0) = W(0) = 0$. To go from n to $2n$, let

$$V(z+z^kU(z)) = (1+z^{k-1}W(z))V(z)+z^{k-1}S(z)-z^{k-1+n}R(z)+O(z^{k-1+2n}),$$
$$1+z^{k-1}\hat{W}(z) = (z/(z+z^kU(z)))^n(1+z^{k-1}W(z)),$$
$$\hat{S}(z) = (z/(z+z^kU(z)))^nR(z),$$

and let $\hat{V}(z) = V_n + V_{n+1}z + \cdots + V_{2n-1}z^{n-1}$ satisfy

$$\hat{V}(z+z^kU(z)) = (1+z^{k-1}\hat{W}(z))\hat{V}(z)+z^{k-1}\hat{S}(z)+O(z^{k-1+n}).$$

The second algorithm solves $W(z)U(z)+zU'(z) = V(z)+O(z^n)$ for $U(z) = U_0+U_1z+\cdots+U_{n-1}z^{n-1}$, given $V(z)$, $W(z)$, and n. If $n = 1$, let $U_0 = V(0)/W(0)$, or let $U_0 = 1$ in case $V(0) = W(0) = 0$. To go from n to $2n$, let $W(z)U(z)+zU'(z) = V(z)-z^nR(z)+O(z^{2n})$, and let $\hat{U}(z) = U_n+\cdots+U_{2n-1}z^{n-1}$ be the solution to the equation $(n+W(z))\hat{U}(z)+z\hat{U}'(z) = R(z)+O(z^n)$.

Resuming the notation of (27), the first algorithm can be used to solve $\hat{V}(U(z)) = U'(z)(z/U(z))^k\hat{V}(z)$ to any desired accuracy, and we set $V(z) = z^k\hat{V}(z)$. To find $P(z)$, suppose we have $V(P(z)) = P'(z)V(z)+O(z^{2k-1+n})$, an equation that holds for $n = 1$ when $P(z) = z+\alpha z^k$ and α is arbitrary. We can go from n to $2n$ by letting $V(P(z)) = P'(z)V(z)+z^{2k-1+n}R(z)+O(z^{2k-1+2n})$ and replacing $P(z)$ by $P(z)+z^{k+n}\hat{P}(z)$, where the second algorithm is used to find the polynomial $\hat{P}(z)$ such that $(k+n-zV'(z)/V(z))\hat{P}(z)+z\hat{P}'(z) = (z^k/V(z))R(z)+O(z^n)$.

Several of the values in Tables 1 and 2 were computed by John W. Wrench, Jr. For high-precision values of constants not found in this list, see J. Peters, *Ten Place Logarithms of the Numbers from 1 to 100000*, Appendix to Volume 1 (New York: F. Ungar Publ. Co., 1957); and *Handbook of Mathematical Functions*, ed. by M. Abramowitz and I. A. Stegun (Washington, D.C.: U.S. Gov't Printing Office, 1964), Chapter 1.

A table of Bernoulli numbers through B_{250} appears in a paper by D. E. Knuth and T. J. Buckholtz, *Math. Comp.* **21** (1967), 663–688.

Table 3

VALUES OF HARMONIC NUMBERS, BERNOULLI NUMBERS, AND FIBONACCI NUMBERS, FOR SMALL VALUES OF n

n	H_n	B_n	F_n	n
0	0	1	0	0
1	1	−1/2	1	1
2	3/2	1/6	1	2
3	11/6	0	2	3

For any x, let $H_x = \sum_{n\geq 1}\left(\frac{1}{n} - \frac{1}{n+x}\right)$. Then

$$\begin{aligned}
H_{1/2} &= 2 - 2\ln 2,\\
H_{1/3} &= 3 - \tfrac{1}{2}\pi/\sqrt{3} - \tfrac{3}{2}\ln 3,\\
H_{2/3} &= \tfrac{3}{2} + \tfrac{1}{2}\pi/\sqrt{3} - \tfrac{3}{2}\ln 3,\\
H_{1/4} &= 4 - \tfrac{1}{2}\pi - 3\ln 2,\\
H_{3/4} &= \tfrac{4}{3} + \tfrac{1}{2}\pi - 3\ln 2,\\
H_{1/5} &= 5 - \tfrac{1}{2}\pi\phi\sqrt{(2+\phi)/5} - \tfrac{1}{2}(3-\phi)\ln 5 - (\phi - \tfrac{1}{2})\ln(2+\phi),\\
H_{2/5} &= \tfrac{5}{2} - \tfrac{1}{2}\pi/\phi\sqrt{2+\phi} - \tfrac{1}{2}(2+\phi)\ln 5 + (\phi - \tfrac{1}{2})\ln(2+\phi),\\
H_{3/5} &= \tfrac{5}{3} + \tfrac{1}{2}\pi/\phi\sqrt{2+\phi} - \tfrac{1}{2}(2+\phi)\ln 5 + (\phi - \tfrac{1}{2})\ln(2+\phi),\\
H_{4/5} &= \tfrac{5}{4} + \tfrac{1}{2}\pi\phi\sqrt{(2+\phi)/5} - \tfrac{1}{2}(3-\phi)\ln 5 - (\phi - \tfrac{1}{2}\ln(2+\phi),\\
H_{1/6} &= 6 - \tfrac{1}{2}\pi\sqrt{3} - 2\ln 2 - \tfrac{3}{2}\ln 3,\\
H_{5/6} &= \tfrac{6}{5} + \tfrac{1}{2}\pi\sqrt{3} - 2\ln 2 - \tfrac{3}{2}\ln 3,
\end{aligned}$$

and, in general, when $0 < p < q$ (cf. exercise 1.2.9–19),

$$H_{p/q} = \frac{q}{p} - \frac{1}{2}\pi\cot\frac{p}{q}\pi - \ln 2q + 2\sum_{1\leq n<q/2}\cos\frac{2\pi np}{q}\ln\sin\frac{n}{q}\pi.$$

APPENDIX B

INDEX TO NOTATIONS

In the following formulas, letters that are not further qualified have the following significance:

j, k	integer-valued arithmetic expression
m, n	nonnegative integer-valued arithmetic expression
x, y, z	real-valued arithmetic expression
f	real-valued function

Formal symbolism	Meaning	Section reference
∎	end of algorithm, program, or proof	1.1
A_n	the nth element of linear array A	
A_{mn}	the element in row m and column n of rectangular array A	
$A[n]$	equivalent to A_n	1.1
$A[m, n]$	equivalent to A_{mn}	1.1
$V \leftarrow E$	give variable V the value of expression E	1.1
$U \leftrightarrow V$	interchange the values of variables U and V	1.1
$(B \Rightarrow E;\ E')$	conditional expression: denotes E if B is true, E' if B is false	8.1
δ_{kj}	Kronecker delta: $(j = k \Rightarrow 1;\ 0)$	1.2.6
$\sum_{R(k)} f(k)$	sum of all $f(k)$ such that the variable k is an integer and relation $R(k)$ is true	1.2.3
$\prod_{R(k)} f(k)$	product of all $f(k)$ such that the variable k is an integer and relation $R(k)$ is true	1.2.3
$\min_{R(k)} f(k)$	minimum value of all $f(k)$ such that the variable k is an integer and relation $R(k)$ is true	1.2.3
$\max_{R(k)} f(k)$	maximum value of all $f(k)$ such that the variable k is an integer and relation $R(k)$ is true	1.2.3

Formal symbolism	Meaning	Section reference
A^T	transpose of rectangular array A: $A^T[j,k] = A[k,j]$	1.2.3
x^y	x to the y power (when x is positive)	1.2.2
x^k	x to the kth power: $\left(k \geq 0 \Rightarrow \prod_{0 \leq j < k} x;\quad 1/x^{-k}\right)$	1.2.2
$x^{\overline{k}}$	x upper k: $\left(k \geq 0 \Rightarrow \prod_{0 \leq j < k} (x+j);\quad 1/(x+k)^{\overline{-k}}\right)$	1.2.6
$x^{\underline{k}}$	x lower k: $\left(k \geq 0 \Rightarrow \prod_{0 \leq j < k} (x-j);\quad 1/(x-k)^{\underline{-k}}\right)$	1.2.6
$n!$	n factorial: $n^{\underline{n}}$	1.2.5
$f'(x)$	derivative of f at x	1.2.9
$f''(x)$	second derivative of f at x	1.2.10
$f^{(n)}(x)$	nth derivative: $(n = 0 \Rightarrow f(x);\ g'(x))$, where $g(x) = f^{(n-1)}(x)$	1.2.11.2
$H_n^{(x)}$	harmonic number of order x: $\sum_{1 \leq k \leq n} 1/k^x$	1.2.7
H_n	harmonic number: $H_n^{(1)}$	1.2.7
F_n	Fibonacci number: $(n \leq 1 \Rightarrow n;\ F_{n-1} + F_{n-2})$	1.2.8
B_n	Bernoulli number	1.2.11.2
$X \cdot Y$	dot product of vectors $X = (x_1, \ldots, x_n)$ and $Y = (y_1, \ldots, y_n)$: $x_1y_1 + \cdots + x_ny_n$	
$(\ldots a_1 a_0 . a_{-1} \ldots)_b$	radix-b positional notation: $\sum_k a_k b^k$	4.1
(min x_1, ave x_2, max x_3, dev x_4)	a random variable having minimum value x_1, average ("expected") value x_2, maximum value x_3, standard deviation x_4	1.2.10

Formal symbolism	Meaning	Section reference
$\binom{x}{k}$	binomial coefficient: $(k < 0 \Rightarrow 0;\ x^{\underline{k}}/k!)$	1.2.6
$\binom{n}{n_1, n_2, \ldots, n_m}$	multinomial coefficient (defined only when $n = n_1 + n_2 + \cdots + n_m$)	1.2.6
$\begin{bmatrix} n \\ m \end{bmatrix}$	Stirling number of the first kind: $\sum_{0<k_1<k_2<\cdots<k_{n-m}<n} k_1 k_2 \ldots k_{n-m}$	1.2.6
$\begin{Bmatrix} n \\ m \end{Bmatrix}$	Stirling number of the second kind: $\sum_{1\le k_1\le k_2\le\cdots\le k_{n-m}\le m} k_1 k_2 \ldots k_{n-m}$	1.2.6
$/x_1, x_2, \ldots, x_n/$	continued fraction: $1/(x_1 + 1/(x_2 + 1/(\cdots + 1/(x_n)\ldots)))$	4.5.3
$((x))$	sawtooth function	3.3.3
$\lvert x\rvert$	absolute value of x: $(x \ge 0 \Rightarrow x;\ -x)$	
$\lVert S\rVert$	cardinal: the number of elements in set S	
$\lfloor x\rfloor$	floor of x, greatest integer function: $\max_{k\le x} k$	1.2.4
$\lceil x\rceil$	ceiling of x, least integer function: $\min_{k\ge x} k$	1.2.4
$\{\, a \mid R(a) \,\}$	set of all a such that the relation $R(a)$ is true	
$\{a_1, \ldots, a_n\}$	the set $\{\, a_k \mid 1 \le k \le n \,\}$	
$\{x\}$	fractional part (used in contexts where a real value, not a set, is implied): $x - \lfloor x\rfloor$	3.3.3
$[y, z)$	half-open interval: $\{\, x \mid y \le x < z \,\}$	
$\langle X_n\rangle$	the infinite sequence $X_0, X_1, X_2, \ldots$ (here the letter n is part of the symbolism)	1.2.9
$\log_b x$	logarithm, base b, of x (real positive x and b, where $b \ne 1$): the y such that $x = b^y$	1.2.2
$\lg x$	binary logarithm: $\log_2 x$	1.2.2
$\ln x$	natural logarithm: $\log_e x$	1.2.2

Formal symbolism	Meaning	Section reference
$\exp x$	exponential of x: e^x	1.2.2
$x \bmod y$	mod function: $\big(y = 0 \Rightarrow x;\ x - y\lfloor x/y \rfloor\big)$	1.2.4
$u(x) \bmod v(x)$	remainder of polynomial u after division by polynomial v	4.6.1
$x \equiv y \ (\text{modulo } z)$	relation of congruence: $x \bmod z = y \bmod z$	1.2.4
$j \setminus k$	j divides k: $k \bmod j = 0$	1.2.4
$\mathrm{B}(x, y)$	beta function	1.2.6
γ	Euler's constant: $\lim_{n\to\infty}(H_n - \ln n)$	1.2.7
$\gamma(x, y)$	incomplete gamma function	1.2.11.3
$\Gamma(x)$	gamma function: $\lim_{y\to\infty} \gamma(x, y)$	1.2.5
$\delta(x)$	characteristic function of the integers	3.3.3
e	base of natural logarithms: $\sum_{n\geq 0} 1/n!$	1.2.2
$\zeta(x)$	zeta function: $\lim_{n\to\infty} H_n^{(x)}$ (when $x > 1$)	1.2.7
$\ell(u)$	leading coefficient of polynomial u	4.6
$l(n)$	length of shortest addition chain for n	4.6.3
$\Lambda(n)$	von Mangoldt's function	4.5.3
$\mu(n)$	Möbius function	4.5.2
$O\big(f(n)\big)$	big-oh of $f(n)$, as the variable $n \to \infty$	1.2.11.1
$O\big(f(x)\big)$	big-oh of $f(x)$, for small values of the variable x (or for x in some specified range)	1.2.11.1
$\varphi(n)$	Euler's totient function: $\sum_{\substack{0\leq k<n \\ \gcd(k,n)=1}} 1$	1.2.4
π	circle ratio: $\sum_{n\geq 0} (-1)^n/(2n+1)$	
ϕ	golden ratio: $\frac{1}{2}\big(1 + \sqrt{5}\big)$	1.2.8
$\emptyset$	empty set: $\{\, x \mid 0 = 1 \,\}$	
∞	infinity: larger than any number	

Formal symbolism	Meaning	Section reference
$\det(A)$	determinant of square matrix A	1.2.3
$\gcd(j,k)$	greatest common divisor of j and k: $\left(j = k = 0 \Rightarrow 0;\ \max_{d\backslash j,\, d\backslash k} d\right)$	4.5.2
$\operatorname{lcm}(j,k)$	least common multiple of j and k: $\left(j = k = 0 \Rightarrow 0;\ \min_{d>0,\, j\backslash d,\, k\backslash d} d\right)$	4.5.2
$\operatorname{sign}(x)$	sign of x: $(x = 0 \Rightarrow 0;\ x/\lvert x\rvert)$	
$\Pr(S(n))$	probability that statement $S(n)$ is true, for "random" integers n (here the letter n is part of the symbolism)	3.5, 4.2.4
$\operatorname{mean}(g)$	mean value of the probability distribution represented by generating function g: $g'(1)$	1.2.10
$\operatorname{var}(g)$	variance of the probability distribution represented by generating function g: $g''(1) + g'(1) - g'(1)^2$	1.2.10
$\deg(u)$	degree of polynomial u	4.6
$\operatorname{cont}(u)$	content of polynomial u	4.6.1
$\operatorname{pp}(u(x))$	primitive part of polynomial u	4.6.1
$\Re(w)$	real part of complex number w	
$\Im(w)$	imaginary part of complex number w	
$\overline{w}$	complex conjugate: $\Re(w) - \Im(w)\,i$	
$\sqcup$	one blank space	1.3.1
rA	register A (accumulator) of MIX	1.3.1
rX	register X (extension) of MIX	1.3.1
rI1, ..., rI6	(index) registers I1, ..., I6 of MIX	1.3.1
rJ	(jump) register J of MIX	1.3.1
(L:R)	partial field of MIX word, $0 \le L \le R \le 5$	1.3.1
OP ADDRESS,I(F)	notation for MIX instruction	1.3.1, 1.3.2
u	unit of time in MIX	1.3.1
*	"self" in MIXAL	1.3.2
0F, 1F, 2F, ..., 9F	"forward" local symbol in MIXAL	1.3.2
0B, 1B, 2B, ..., 9B	"backward" local symbol in MIXAL	1.3.2
0H, 1H, 2H, ..., 9H	"here" local symbol in MIXAL	1.3.2
$\oplus\ominus\otimes\oslash$	rounded or special operations	4.2.1

INDEX AND GLOSSARY

Seek and ye shall find.

—Matthew 7:7

When an index entry refers to a page containing a relevant exercise, see also the *answer* to that exercise for further information; an answer page is not indexed here unless it refers to a topic not included in the statement of the exercise.

Any accuracies or inaccuracies in this index may be explained by the fact that it was prepared with the help of a computer, but not blindly. For additional definitions of computer terminology, see Volume 1 and the *IFIP–ICC Vocabulary of Information Processing* (Amsterdam: North-Holland Publishing Co., 1966).

THIS BOOK was composed at the Stanford Artificial Intelligence Laboratory using the TEX system for technical text developed by the author. The letters and symbols belong to the Computer Modern family of typefaces developed by the author using the METAFONT system for alphabet design. The Chinese characters in the index were designed by Tung Yun Mei using his LCCD system. The paper is S. D. Warren Text, basis 50 lb. (pH 7.8), which has a life expectancy of several hundred years. The offset printing and sewn binding were done at the Maple Press in Manchester, Pennsylvania.

PREFACE

Cookery is become an art,
a noble science;
cooks are gentlemen.
—TITUS LIVIUS, *Ab Urbe Condita* XXXIX.vi
(Robert Burton, *Anatomy of Melancholy* 1.2.2.2)

This book forms a natural sequel to the material on Information Structures in Chapter 2, because it adds the concept of linearly-ordered data to the other basic structural ideas. The title "Sorting and Searching" may sound as if this book is only for those system programmers who are concerned with the preparation of general-purpose sorting routines or applications to information retrieval. But in fact the area of sorting and searching provides an ideal framework for discussing a wide variety of important general issues:

How are good algorithms discovered?
How can given algorithms and programs be improved?
How can the efficiency of algorithms be analyzed mathematically?
How can a person choose rationally between different algorithms for the same application?
In what senses can algorithms be proved "best possible"?
How does the theory of computing interact with practical considerations?
How can external memories like tapes, drums, or disks be used efficiently with large data bases?

Indeed, I believe that virtually *every* important aspect of programming arises somewhere in the context of sorting or searching!

This volume comprises Chapters 5 and 6 of the complete series. Chapter 5 is concerned with sorting into order; this is a rather large subject which has been divided chiefly into two parts, internal sorting and external sorting. There also are supplementary sections which develop auxiliary theories about permutations (Section 5.1) and about optimum sorting algorithms (Section 5.3). Chapter 6 deals with the problem of searching for specified items in tables or files; this is subdivided into methods which search sequentially, or by comparison of keys, or by digital properties, or by "hashing," and then the more difficult problem of secondary key retrieval is considered. There is a surprising amount

of interplay between both chapters, with strong analogies tying the topics together. Two important varieties of information structures are also discussed, in addition to those considered in Chapter 2, namely priority queues (Section 5.2.3) and linear lists represented as balanced trees (Section 6.2.3).

A reader who is unfamiliar with Volume 1 of this series is urged to consult the Index to Notations (Appendix B), since some of the notational conventions found here are not in general use.

I have been using this book as a text for a student's second course in Data Structures, at the junior-to-graduate level, omitting most of the mathematical material. The mathematical portions of this book would make an appropriate text for a senior or graduate-level course in Analysis of Algorithms, emphasizing especially Sections 5.1, 5.2.2, 6.3, and 6.4. A graduate-level course on Computational Complexity could also be based on Sections 4.3.3, 4.6.3, 4.6.4, 5.3, and 5.4.4.

The rapid rise of Computer Science has delayed the publication of this book by almost three years, since so many aspects of sorting and searching have become so highly developed. I am very grateful for the continuing research support that has been granted to me by the National Science Foundation, the Office of Naval Research, the Institute for Defense Analyses, the International Business Machines Corporation, and Norges Almenvitenskapelige Forskningsrad.

Many people helped me prepare this volume for publication, especially Edward A. Bender, Clark A. Crane, David E. Ferguson, Robert W. Floyd, Ronald L. Graham, Leonidas Guibas, John Hopcroft, Richard M. Karp, Gary D. Knott, Rudolph A. Krutar, Shen Lin, Vaughan R. Pratt, Stephan O. Rice, Richard P. Stanley, J. A. van der Pool, and John W. Wrench, Jr., in addition to the students at Stanford and Berkeley who had to debug the manuscript.

Oslo, Norway
September 1972

D. E. K.

There are certain common Privileges of a Writer,
the Benefit whereof, I hope, there will be no Reason to doubt;
Particularly, that where I am not understood, it shall be concluded,
that something very useful and profound is coucht underneath.
—JONATHAN SWIFT (*Tale of a Tub*, Preface, 1704)

Notes on the Exercises

The exercises in this set of books have been designed for self-study as well as classroom study. It is difficult, if not impossible, for anyone to learn a subject purely by reading about it, without applying the information to specific problems and thereby forcing himself to think about what has been read. Furthermore, we all learn best the things that we have discovered for ourselves. Therefore the exercises form a major part of this work; a definite attempt has been made to keep them as informative as possible and to select problems that are enjoyable to solve.

In many books, easy exercises are found mixed randomly among extremely difficult ones. This is sometimes unfortunate because the reader should have some idea about how much time it ought to take him to do a problem before he tackles it (otherwise he may just skip over all the problems). A classic example of this situation is the book *Dynamic Programming* by Richard Bellman; this is an important, pioneering book in which a group of problems is collected together at the end of some chapters under the heading "Exercises and Research Problems," with extremely trivial questions appearing in the midst of deep, unsolved problems. It is rumored that someone once asked Dr. Bellman how to tell the exercises apart from the research problems, and he replied, "If you can solve it, it is an exercise; otherwise it's a research problem."

Good arguments can be made for including both research problems and very easy exercises in a book of this kind; therefore, to save the reader from the possible dilemma of determining which are which, *rating numbers* have been provided to indicate the level of difficulty. These numbers have the following general significance:

Rating	*Interpretation*
00	An extremely easy exercise which can be answered immediately if the material of the text has been understood, and which can almost always be worked "in your head."
10	A simple problem, which makes a person think over the material just read, but which is by no means difficult. It should be possible to do this in one minute at most; pencil and paper may be useful in obtaining the solution.
20	An average problem which tests basic understanding of the text material but which may take about fifteen to twenty minutes to answer completely.

30 A problem of moderate difficulty and/or complexity which may involve over two hours' work to solve satisfactorily.

40 Quite a difficult or lengthy problem which is perhaps suitable for a term project in classroom situations. It is expected that a student will be able to solve the problem in a reasonable amount of time, but the solution is not trivial.

50 A research problem which (to the author's knowledge at the time of writing) has not yet been solved satisfactorily. If the reader has found an answer to this problem, he is urged to write it up for publication; furthermore, the author of this book would appreciate hearing about the solution as soon as possible (provided it is correct)!

By interpolation in this "logarithmic" scale, the significance of other rating numbers becomes clear. For example, a rating of *17* would indicate an exercise that is a bit simpler than average. Problems with a rating of *50* which are subsequently solved by some reader may appear with a *45* rating in later editions of the book.

The author has earnestly tried to assign accurate rating numbers, but it is difficult for the person who makes up a problem to know just how formidable it will be for someone else; and everyone has more aptitude for certain types of problems than for others. It is hoped that the rating numbers represent a good guess as to the level of difficulty, but they should be taken as general guidelines, not as absolute indicators.

This book has been written for readers with varying degrees of mathematical training and sophistication; and, as a result, some of the exercises are intended only for the use of more mathematically inclined readers. Therefore the rating is preceded by an *M* if the exercise involves mathematical concepts or motivation to a greater extent than necessary for someone who is primarily interested in only the programming algorithms themselves. An exercise is marked with the letters "*HM*" if its solution necessarily involves a knowledge of calculus or other higher mathematics not developed in this book. An "*HM*" designation does *not* necessarily imply difficulty.

Some exercises are preceded by an arrowhead, "▸"; this designates problems which are especially instructive and which are especially recommended. Of course, no reader/student is expected to work *all* of the exercises, and so those which are perhaps the most valuable have been singled out. This is not meant to detract from the other exercises! Each reader should at least make an attempt to solve all of the problems whose rating is *10* or less; and the arrows may help in deciding which of the problems with a higher rating should be given priority.

Solutions to most of the exercises appear in the answer section. Please use them wisely; do not turn to the answer until you have made a genuine effort to solve the problem by yourself, or unless you do not have time to work this particular problem. *After* getting your own solution or giving the problem a

decent try, you may find the answer instructive and helpful. The solution given will often be quite short, and it will sketch the details under the assumption that you have earnestly tried to solve it by your own means first. Sometimes the solution gives less information than was asked; often it gives more. It is quite possible that you may have a better answer than the one published here, or you may have found an error in the published solution; in such a case, the author will be pleased to know the details as soon as possible. Later editions of this book will give the improved solutions together with the solver's name where appropriate.

When working an exercise you may generally use the answer to previous exercises, unless this is specifically forbidden. The rating numbers have been assigned with this in mind; thus it is possible for exercise $n + 1$ to have a lower rating than exercise n, even though it includes the result of exercise n as a special case.

Summary of codes:

▸	Recommended	*00*	Immediate
M	Mathematically oriented	*10*	Simple (one minute)
HM	Requiring "higher math"	*20*	Medium (quarter hour)
		30	Moderately hard
		40	Term project
		50	Research problem

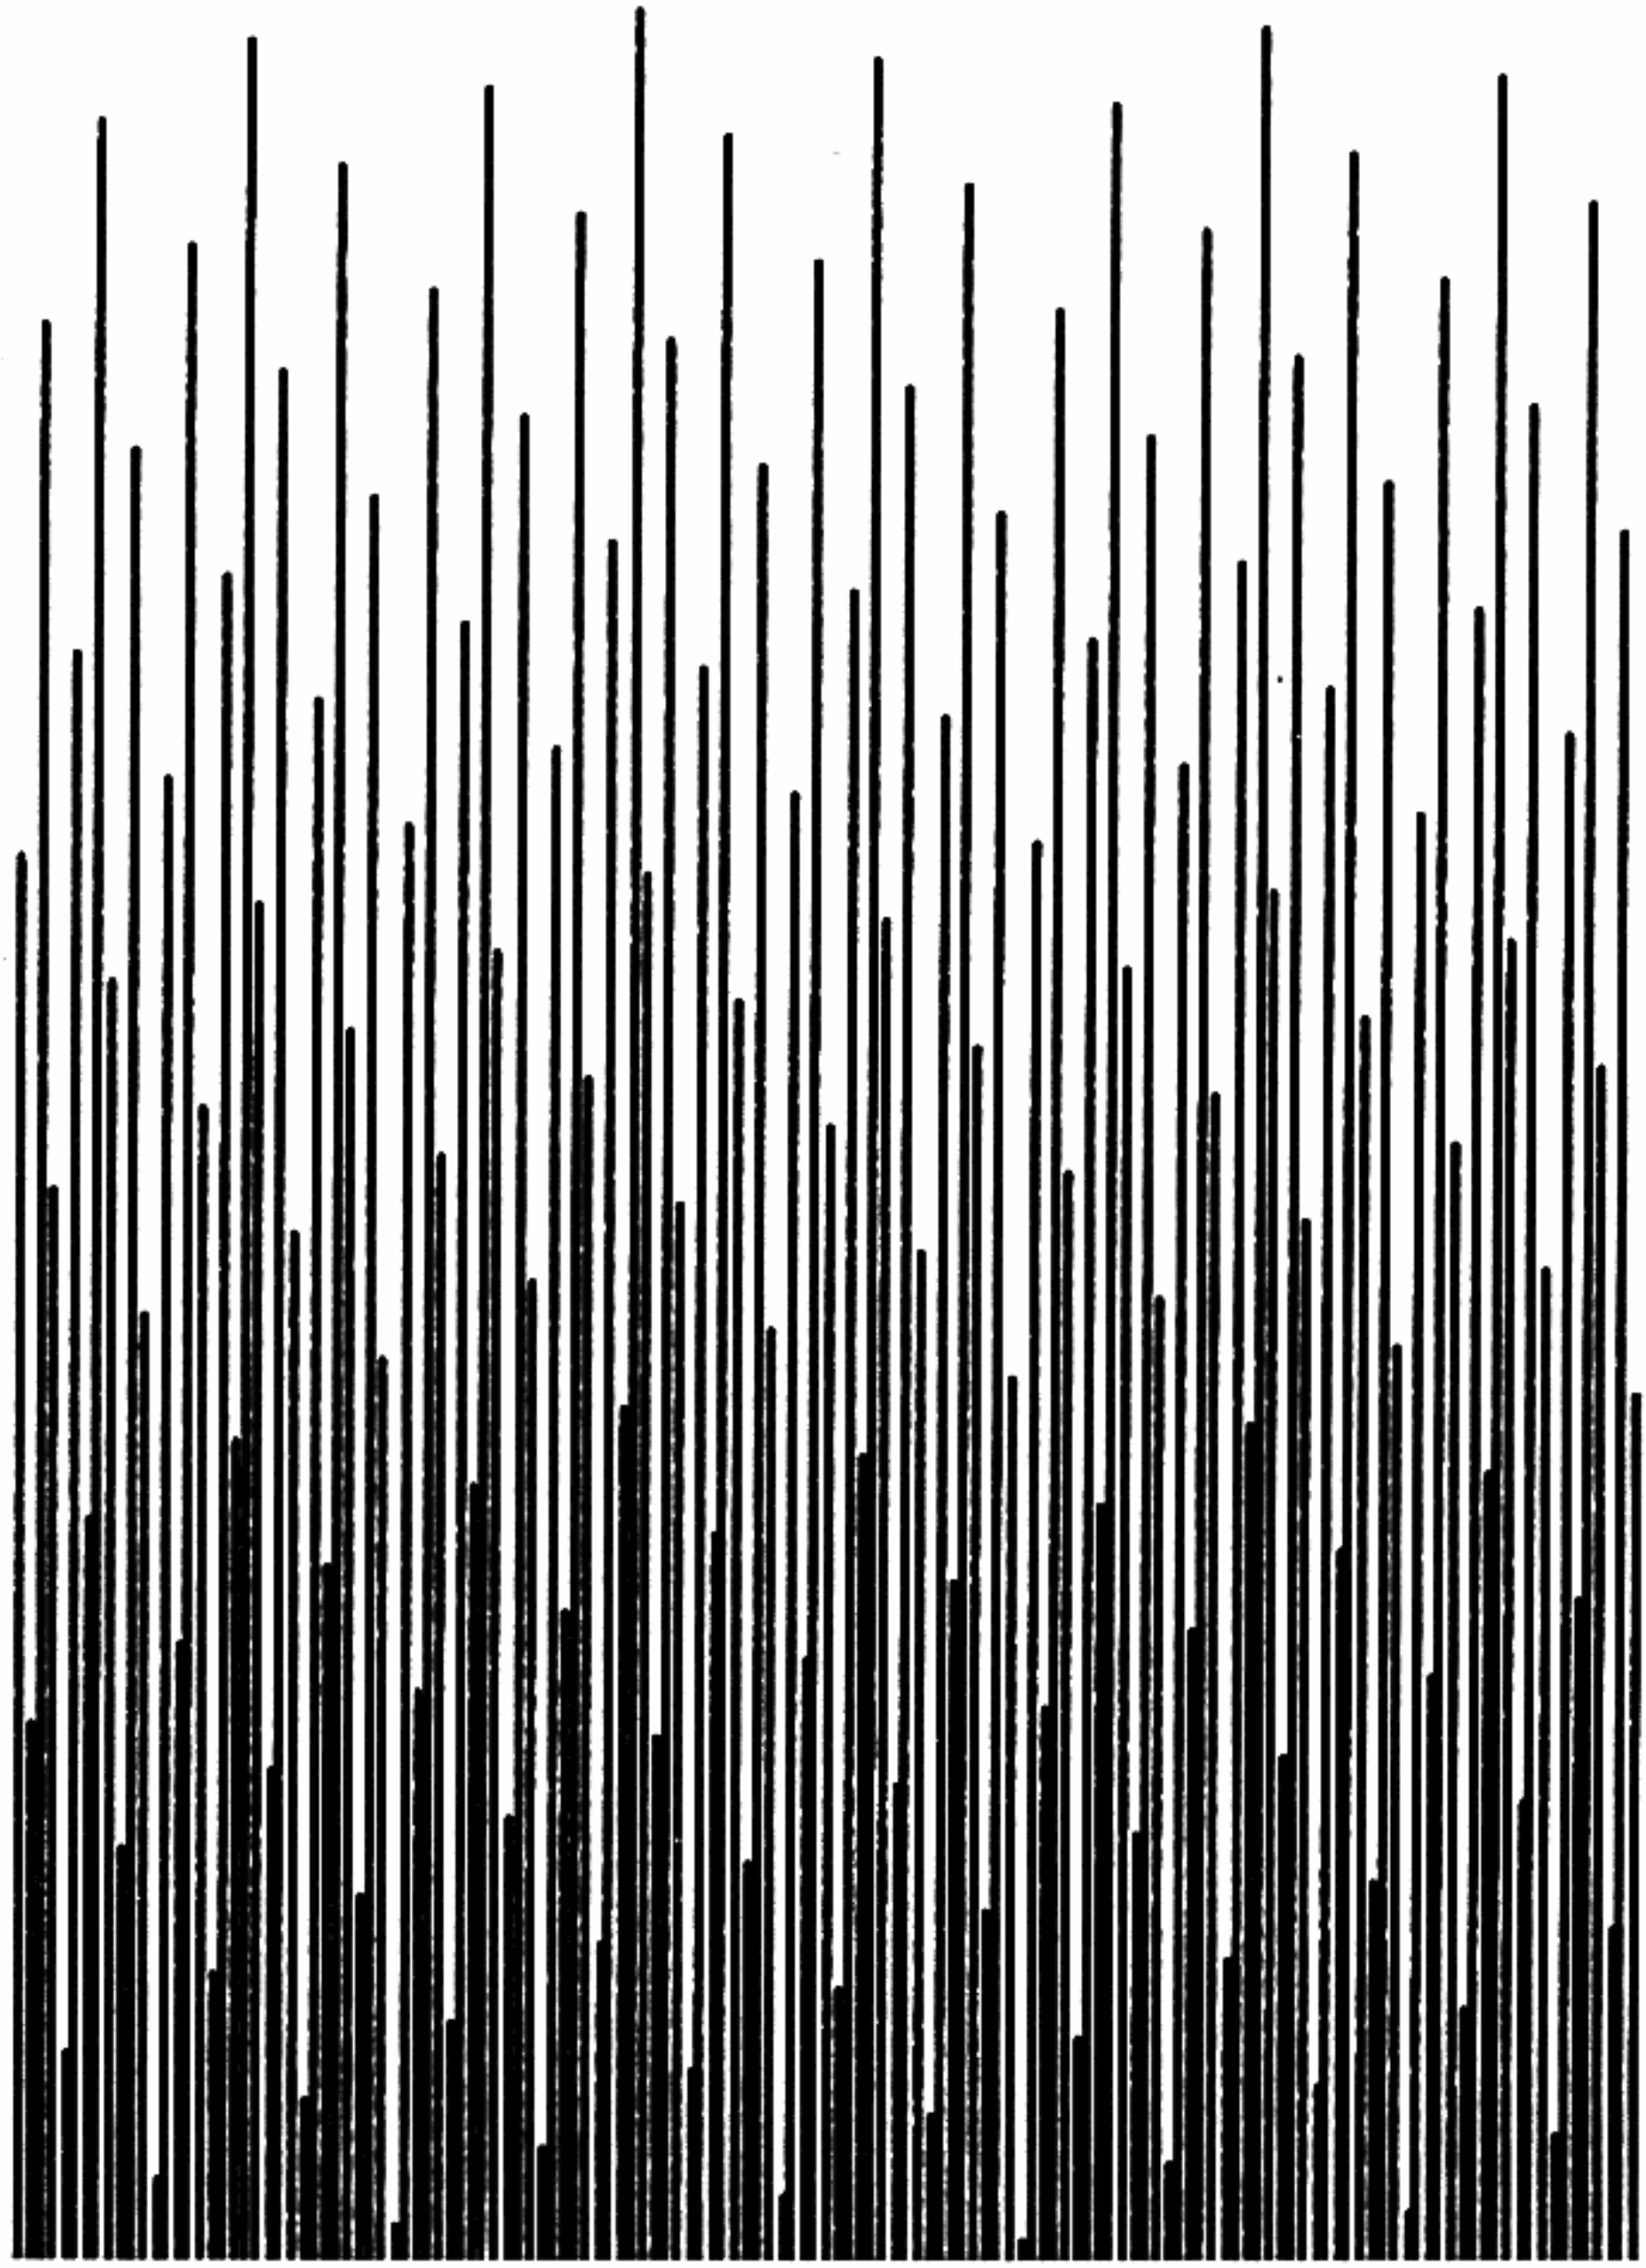
EXERCISES

▸ **1.** [*00*] What does the rating "*M20*" mean?

2. [*10*] Of what value can the exercises in a textbook be to the reader?

3. [*M50*] Prove that when n is an integer, $n > 2$, the equation $x^n + y^n = z^n$ has no solution in positive integers x, y, z.

CONTENTS



CHAPTER FIVE

SORTING

There is nothing more difficult to take in hand,
more perilous to conduct, or more uncertain in its success,
than to take the lead in the introduction of
a new order of things.

— NICCOLÒ MACHIAVELLI (The Prince, 1513)

"But you can't look up all those license
numbers in time," Drake objected.
"We don't have to, Paul. We merely arrange a list
and look for duplications."

— PERRY MASON (The Case of the Angry Mourner, 1951)

"Treesort" Computer — With this new 'computer-approach'
to nature study you can quickly identify over 260
different trees of U.S., Alaska, and Canada,
even palms, desert trees, and other exotics.
To sort, you simply insert the needle.

— Catalog of Edmund Scientific Company (1964)

In this chapter we shall study a topic which arises frequently in programming: the rearrangement of items into ascending or descending order. Imagine how hard it would be to use a dictionary if its words were not listed in alphabetical order; in a similar way, the order in which items are stored in computer memory often has a profound influence on the speed and simplicity of algorithms which manipulate them.

Although dictionaries of the English language define "sorting" as the process of separating or arranging things according to class or kind, it is traditional for computer programmers to use the word in the much more special sense of sorting things into ascending or descending order. The process should perhaps be called *ordering*, not sorting; but anyone who tries to call it "ordering" is soon led into confusion because of the many different meanings attached to this word. Consider the following sentence, for example: "Since only two of our tape drives were in working order, I was ordered to order more tape units in short order, in order to order the data several orders of magnitude faster." Mathematical terminology abounds with still more senses of order (the order

of a group, the order of a permutation, the order of a branch point, relations of order, etc., etc.). So we find that the word "order" can lead to chaos.

Some people have suggested the word "sequencing" as an appropriate name for an ordering process; but this word often seems to lack the right connotation, especially when equal elements are present, and it occasionally conflicts with other terminology. It is quite true that "sorting" is itself an overused word ("He was sort of out of sorts after sorting that sort of data."), but it has become firmly established in computing parlance. Therefore we shall use the word "sorting" chiefly in the strict sense of "sorting into order," without further apologies.

Some of the most important applications of sorting are

a) Solving the "togetherness" problem, in which all items with the same identification are brought together. Suppose that we have 10,000 items in random order, many of which have equal values; and suppose that we want to rearrange this file so that all items with equal values appear in consecutive positions. This is essentially the problem of "sorting" in the older sense of the word; and it can be solved easily by sorting the file in the new sense of the word, so that the values are in ascending order, $v_1 \le v_2 \le \cdots \le v_{10,000}$. (The efficiency which is possible in this procedure explains why the original meaning of "sorting" has changed.)

b) If two or more files have been sorted into the same order, it is possible to find all of the matching entries in one sequential pass through them, without backing up. This is the principle which Perry Mason used to help solve a murder case (see the quotation at the beginning of this chapter). It is usually much more economical to access a list of information in sequence from beginning to end, instead of skipping around at random in the list, unless the list is small enough to be stored in a high-speed random-access memory. Sorting makes it possible to use sequential accessing on large files, as a feasible substitute for direct addressing.

c) Sorting also is an aid to searching, as we shall see in Chapter 6, and therefore it helps to make computer output more suitable for human consumption. In fact, a listing that has been sorted into alphabetic order often looks quite authoritative even when the associated numerical information has been incorrectly computed.

Although sorting has traditionally been used mostly for business data processing, it is actually a basic tool which a programmer should keep in mind for use in a wide variety of situations. We have discussed its use in simplifying algebraic formulas, in exercise 2.3.2–17. The exercises below illustrate the diversity of typical applications.

One of the first large-scale software systems to demonstrate the versatility of sorting was the Larc Scientific Compiler developed by Computer Sciences Corporation in 1960. This optimizing compiler for an extended FORTRAN

language made heavy use of sorting so that the various compilation algorithms were presented with relevant parts of the source program in a convenient sequence. The first pass was a lexical scan which divided the FORTRAN source code into individual tokens, each representing an identifier (e.g., the name of a variable), or a constant, or an operator, etc. Each token was assigned several sequence numbers; when sorted on the name and an appropriate sequence number, all the uses of a given identifier were brought together. The "defining entries," which specify for example whether the identifier is a function name, parameter, or a dimensioned variable, were given a low sequence number, so that they would appear first among the tokens having a given identifier; this made it easy to check for conflicting usage of an identifier, and to allocate storage with respect to `EQUIVALENCE` declarations, etc. The information thus gathered about each identifier was now attached to each token; in this way no "symbol table" of identifiers needed to be maintained in the high-speed memory. The updated tokens were then sorted on another sequence number, which essentially brought the source program back into its original order except that the sequence was specially designed to put arithmetic expressions into a more convenient "Polish prefix" form. Sorting was also used in later phases of compilation, to facilitate loop optimization, to merge error messages into the listing, etc. In short, the compiler was designed so that virtually all the processing could be done sequentially from files that were stored in an auxiliary drum memory, since appropriate sequence numbers were attached to the data in such a way that it could be sorted into various convenient arrangements.

Another, more obvious, application of sorting occurs in file editing routines, where each line is identified by a key number. While a user is typing additions and changes, it is not necessary to have the entire file in memory. The change lines can subsequently be sorted (they are usually pretty much in order anyway), then merged with the original file. This leads to a reasonably efficient way to use memory in a multiprogramming situation. [Cf. C. C. Foster, *Comp. J.* **11** (1968), 134–137.]

Computer manufacturers estimate that over 25 percent of the running time on their computers is currently being spent on sorting, when all their customers are taken into account. There are many installations in which sorting uses more than half of the computing time. From these statistics we may conclude either that (i) there are many important applications of sorting, or (ii) many people sort when they shouldn't, or (iii) inefficient sorting algorithms are in common use. The real truth probably involves some of all three alternatives. In any event we can see that sorting is worthy of serious study, as a practical matter.

But even if sorting were almost useless, there would be plenty of rewarding reasons for studying it anyway! The ingenious algorithms which have been discovered show that sorting is an interesting topic to explore in its own right. There are many fascinating unsolved problems in this area (as well as quite a few solved ones).

From a broader perspective we will find also that sorting algorithms make an interesting *case study* of how to attack computer programming problems in general. Many important principles of data structure manipulation will be illustrated. We will be examining the evolution of various sorting techniques in an attempt to indicate how the reader might have discovered the same ideas for himself (if he had been confronted with the problem before anyone else). By extrapolation of this case study we may learn a good deal about that state of mind which helps to design good algorithms for other computer problems.

Sorting techniques also provide excellent illustrations of the general ideas involved in the *analysis of algorithms*, i.e., the ideas used to determine performance characteristics of algorithms so that an intelligent choice can be made between competing methods. Readers who are mathematically inclined will find quite a few instructive techniques in this chapter for estimating the speed of computer algorithms and for solving complicated recurrence relations. On the other hand, the material has been arranged so that readers without a mathematical bent can safely skip over these calculations.

Before going on, we ought to define our problem a little more clearly, and introduce some terminology. We are given N items

$$R_1, R_2, \ldots, R_N$$

to be sorted; we shall call them *records*, and the entire collection of N records will be called a *file*. Each record R_j has a *key*, K_j, which governs the sorting process. There may be additional information, besides the key, in a record; this extra "satellite information" has no effect on the sorting process except that it remains with the same record.

An ordering relation "$<$" is specified on the keys so that, for any three key values a, b, c, the following conditions are satisfied:

i) Exactly one of the possibilities $a < b$, $a = b$, $b < a$ is true. (This is the law of trichotomy.)

ii) If $a < b$ and $b < c$, then $a < c$. (The law of transitivity.)

These two properties characterize the mathematical concept of *linear ordering*, also called *total ordering*. Any relationship "$<$" satisfying (i) and (ii) can be sorted by most of the methods to be mentioned in this chapter, although some sorting techniques require numerical or alphabetic keys with the usual ordering.

The goal of sorting is to determine a permutation $p(1)p(2) \ldots p(N)$ of the records, which puts the keys in nondecreasing order:

$$K_{p(1)} \le K_{p(2)} \le \cdots \le K_{p(N)}. \tag{1}$$

The sorting is called *stable* if we make the further requirement that records with equal keys retain their original relative order, i.e., if

$$p(i) < p(j) \quad \text{whenever} \quad K_{p(i)} = K_{p(j)} \quad \text{and} \quad i < j. \tag{2}$$

In some cases we will want the records to be physically rearranged in storage so that their keys are in order, while in other cases it will be sufficient merely to have an auxiliary table which specifies the permutation in some way, so that the records can be accessed in order of their keys.

A few of the sorting methods assume the existence of either or both of the values "∞" and "$-\infty$" which are defined to be greater than or less than all keys, respectively:

$$-\infty < K_j < \infty, \qquad 1 \le j \le N. \tag{3}$$

These values are substituted for artificial keys and they also are used as sentinel indicators. The case of equality is excluded in (3); if equality can occur, the algorithms can be modified so that they will still work, but usually at the expense of some elegance and efficiency.

Sorting can be classified generally into *internal sorting*, in which the records are kept in the computer's high-speed random-access memory; and *external sorting*, when there are more records than can be held in memory at once. Internal sorting allows more flexibility in the structuring and accessing of the data, while external sorting shows us how to live with rather stringent accessing constraints.

The time required to sort N records, using a decent general-purpose sorting algorithm, is roughly proportional to $N \log N$; we make about $\log N$ "passes" over the data. This is the minimum possible time, as we shall see in Section 5.3.1. Thus if we double the number of records, it will take a little more than twice as long to sort them, all other things being equal. (Actually, as N approaches infinity, a better indication of the time needed to sort is $N(\log N)^2$, if the keys are distinct, since the size of the keys grows with N; but for practical purposes, N never really approaches infinity.)

EXERCISES—First Set

1. [*M20*] Prove, from the laws of trichotomy and transitivity, that the permutation $p(1)\ p(2)\ \ldots\ p(N)$ is *uniquely* determined when the sorting is assumed to be stable.

2. [*21*] Assume that each record R_j in a certain file contains *two* keys, a "major key" K_j and a "minor key" k_j, with a linear ordering $<$ defined on each of the sets of keys. Then we can define "lexicographic order" between pairs of keys (K, k) in the usual way:

$$(K_i, k_i) < (K_j, k_j) \quad \text{if} \quad K_i < K_j \quad \text{or if} \quad K_i = K_j \quad \text{and} \quad k_i < k_j.$$

A man named Mr. *A* took this file and sorted it first on the major keys, obtaining n groups of records with equal major keys in each group,

$$K_{p(1)} = \cdots = K_{p(i_1)} < K_{p(i_1+1)} = \cdots = K_{p(i_2)} < \cdots < K_{p(i_{n-1}+1)} = \cdots = K_{p(i_n)},$$

where $i_n = N$. Then he sorted each of the n groups $R_{p(i_{j-1})+1}, \ldots, R_{p(i_j)}$ on their minor keys.

Mr. B took the same original file and sorted it first on the minor keys; then he took the resulting file, and sorted it on the major keys.

Mr. C took the same original file and did a single sorting operation on it, using lexicographic order on the major and minor keys (K_j, k_j).

Did all three men obtain the same result?

3. [*M25*] Let $<$ be a relation on $K_1, \ldots, K_N$ which satisfies the law of trichotomy but *not* the transitive law. Prove that even without the transitive law it is possible to sort the records in a stable manner, meeting conditions (1) and (2); in fact, there are at least three arrangements which satisfy the conditions!

4. [*15*] Mr. B. C. Dull (a MIX programmer) wanted to know if the number stored in location A is greater than, less than, or equal to the number stored in location B. So he wrote

```
LDA  A
SUB  B
```

and tested whether register A was positive, negative, or zero. What serious mistake did he make, and what should he have done?

5. [*17*] Write a MIX subroutine for multiprecision comparison of keys, having the following specifications:

Calling sequence: `JMP COMPARE`

Entry conditions: rI1 $= n$; CONTENTS(A $+ k$) $= a_k$, CONTENTS(B $+ k$) $= b_k$, for $1 \leq k \leq n$; assume that $n \geq 1$.

Exit conditions:
CI $= +1$, if $(a_n, \ldots, a_1) > (b_n, \ldots, b_1)$;
CI $= 0$, if $(a_n, \ldots, a_1) = (b_n, \ldots, b_1)$;
CI $= -1$, if $(a_n, \ldots, a_1) < (b_n, \ldots, b_1)$;
rX and rI1 possibly affected.

Here the relation $(a_n, \ldots, a_1) < (b_n, \ldots, b_1)$ denotes lexicographic ordering from left to right; i.e., there is an index j such that $a_k = b_k$ for $n \geq k > j$, but $a_j < b_j$.

▸ **6.** [*30*] Locations A and B contain two numbers a and b, respectively. Show that it is possible to write a MIX program which computes and stores min (a, b) in location C, *without using any jump operators.* (*Caution:* Since you will not be able to test whether or not arithmetic overflow has occurred, it is wise to guarantee that overflow is impossible regardless of the values of a and b.)

7. [*M27*] After N independent, uniformly distributed random variables between 0 and 1 have been sorted into nondecreasing order, what is the probability that the rth smallest of these is $\leq x$?

EXERCISES—Second Set

Each of the following exercises states a problem which a computer programmer might face. Suggest a "good" way to solve the problem, assuming that only a relatively

small amount of internal memory is available, supplemented by about half a dozen tape units (enough tape units for sorting).

8. [*15*] You are given a tape containing one million words of data. How do you determine how many distinct words are present on the tape?

9. [*18*] You are the U. S. Internal Revenue Service; you receive millions of "information" forms from organizations telling how much income they have paid to people, and millions of "tax" forms from people telling how much income they have been paid. How do you catch people who don't report all of their income?

10. [*M25*] (*Transposing a matrix.*) You are given a magnetic tape containing one million words, representing the elements of a 1000×1000 matrix stored in order by rows: $a_{1,1}\ a_{1,2} \ldots a_{1,1000}\ a_{2,1} \ldots a_{2,1000} \ldots a_{1000,1000}$. How do you create a tape in which the elements are stored by columns $a_{1,1}\ a_{2,1} \ldots a_{1000,1}\ a_{1,2} \ldots a_{1000,2} \ldots a_{1000,1000}$ instead? (Try to make at most ten passes over the data.)

11. [*M26*] Given a large file of N words, how would you "shuffle" it into a random rearrangement?

▶ **12.** [*24*] A certain university has about 1000 faculty members and 500 committees; every faculty member is expected to be a member of at least two committees. Your job is to prepare a nicely-printed master list of all committees. For this purpose you are given a deck of about 1500 cards, in random order, punched as follows:

Faculty cards. Column 1, blank; columns 2–18, last name followed by blanks; columns 19–20, initials; columns 21–23, first committee number; columns 24–26, second committee number; . . . ; columns 78–80, twentieth committee number (if necessary), or blank.

Committee cards. Column 1, "*"; columns 2–77, name of committee; columns 78–80, number of committee.

How should you proceed? (Spell out your method in some detail.)

13. [*20*] You are working with two computer systems which have different conventions for the "collating sequence" (i.e., ordering relation) of alphameric characters. How do you make one computer sort alphameric files in the order used by the other computer?

14. [*18*] You are given a list of the names of a fairly large number of people born in the U.S.A., together with the name of the state where they were born. How do you count the number of people born in each state? (Assume that nobody appears in the list more than once.)

15. [*20*] In order to make it easier to make changes to large FORTRAN programs, you want to design a "cross-reference" routine; such a routine takes FORTRAN programs as input and prints them together with an index which shows each use of each identifier (i.e., each name) in the program. How should such a routine be designed?

16. [*33*] (*Library card sorting.*) The manner of alphabetizing catalog cards varies somewhat from one library to another; the following "alphabetical" listing indicates many of the procedures recommended in the *American Library Association Rules for Filing Catalog Cards* (Chicago, 1942):

Text of card	*Remarks*
R. Accademia nazionale dei Lincei, Rome	Ignore foreign royalty (except British)
1812; ein historischer roman.	Achtzehnhundert zwölf
Bibliothèque d'histoire révolutionnaire.	Treat apostrophe as space in French
Bibliothèque des curiosités.	Ignore accents on letters
Brown, Mrs. J. Crosby	Ignore designation of rank
Brown, John	Names with dates follow those without
Brown, John, mathematician	. . . the latter are subarranged by descriptive words
Brown, John, of Boston	
Brown, John, 1715–1766	Arrange identical names by birthdate
BROWN, JOHN, 1715–1766	Works "about" follow works "by"
Brown, John, d. 1811	Sometimes birthdate must be estimated
Brown, Dr. John, 1810–1882	Ignore designation of rank
Brown-Williams, Reginald Makepeace	Hyphen treated as space
Brown America.	Book titles follow compound names
Brown & Dallison's Nevada directory.	& in English becomes "and"
Brownjohn, Alan	
Den', Vladimir Éduardovich, 1867–	Ignore apostrophe in names
The den.	Ignore an initial article
Den lieben süssen mädeln.	. . . provided it's in nominative case
Dix, Morgan, 1827–1908	Names before words
1812 ouverture.	Dix-huit cent douze
Le XIXe sicèle français.	Dix-neuvième
The 1847 issue of U. S. stamps.	Eighteen forty-seven
1812 overture.	Eighteen twelve
I am a mathematician.	(by Norbert Weiner)
IBM journal of research and development.	Initials are like one-letter words
ha-I ha-eḥad.	Ignore initial article
Ia; a love story.	Ignore punctuation in titles
International Business Machines Corporation	
al-Khuwārizmī, Muḥammad ibn Mūsā, *fl.* 813–846	Ignore initial "al-" in Arabic names
Labour; a magazine for all workers.	Respell it "Labor"
Labor research association	
Labour, *see* Labor	Cross-reference card
McCall's cookbook	Ignore apostrophe in English
McCarthy, John, 1927–	Mc = Mac
Machine-independent computer programming.	Treat hyphen as space
MacMahon, Maj. Percy Alexander, 1854–1929	Ignore designation of rank
Mrs. Dalloway.	"Mrs." = "Mistress"
Mistress of mistresses.	
Royal society of London	
St. Petersburger Zeitung.	"St." = "Saint", even in German
Saint-Saëns, Camille, 1835–1921	Hyphen treated as space
Ste. Anne des Monts, Quebec	Sainte
Seminumerical algorithms.	

Text of card	*Remarks*
Uncle Tom's cabin.	
U. S. Bureau of the census.	"U. S." = "United States"
Vandermonde, Alexander Théophile, 1735–1796	
Van Valkenburg, Mac Elwyn, 1921–	Ignore space after prefix in surnames
Von Neumann, John, 1903–1957	
The whole art of legerdemain.	
Who's afraid of Virginia Woolf?	Ignore apostrophe in English
Wijngaarden, Adriaan van, 1916–	Surname doesn't begin with lower case letter

(Most of these rules are subject to certain exceptions, and there are many other rules not illustrated here.)

If you were given the job of sorting large numbers of library cards by computer, and eventually maintaining a very large file of such cards, and if you had no chance to change these long-standing policies of card filing, how would you arrange the data in such a way that the sorting and merging operations are facilitated?

17. [*M21*] (*Discrete logarithms.*) You know that p is a (rather large) prime number, and that a is a primitive root modulo p. Therefore, for all b in the range $1 \le b < p$, there is a unique n such that $a^n \bmod p = b$, $1 \le n < p$. How do you find n, given b, in less than $O(n)$ steps?

[*Hint:* Let $m = \lceil \sqrt{p} \rceil$ and try to solve $a^{mn_1} \equiv ba^{-n_2}$ (modulo p) for $0 \le n_1, n_2 < m$.]

18. [*M25*] (E. T. Parker.) Euler conjectured that there are no solutions to the equation

$$u^6 + v^6 + w^6 + x^6 + y^6 = z^6$$

in nonnegative integers u, v, w, x, y, z, except for the trivial solutions when at least four of the variables are zero. At the same time he conjectured that

$$x_1^n + \cdots + x_{n-1}^n = x_n^n$$

had no nontrivial solutions, for all $n \ge 3$, but this conjecture has been disproved by the computer-discovered identity $27^5 + 84^5 + 110^5 + 133^5 = 144^5$; see L. J. Lander, T. R. Parkin, and J. L. Selfridge, *Math. Comp.* **21** (1967), 446–459. Can you think of a way in which sorting would help in the search for counterexamples to Euler's conjecture when $n = 6$?

▸ **19.** [*24*] Given a file containing a large number of distinct 30-bit binary words $x_1, \ldots, x_N$, what is a good way to find all *complementary* pairs (x_i, x_j) that are present? (Two words are complementary when one has 0 wherever the other has 1, and conversely; thus they are complementary if and only if their sum is $(11\ldots1)_2$, when they are treated as binary numbers.)

▸ **20.** [*25*] Given a file containing 1000 30-bit binary words $x_1, \ldots, x_{1000}$, how would you prepare a list of all pairs (x_i, x_j) such that $x_i = x_j$ except in at most two bit positions?

▶ **21.** [*22*] How would you go about looking for five-letter anagrams such as CARET, CARTE, CATER, CRATE, REACT, TRACE; CRUEL, LUCRE, ULCER; DOWRY, ROWDY, WORDY? [One might wish to know whether there are any sets of ten or more five-letter English anagrams besides the remarkable set

APERS, ASPER, PARES, PARSE, PEARS, PRASE, RAPES, REAPS, SPARE, SPEAR,

to which we might add the French word APRÈS.]

22. [*M28*] Given the specifications of a fairly large number of directed graphs, what approach will be useful for grouping the *isomorphic* ones together? (Directed graphs are isomorphic if there is a one-to-one correspondence between their vertices and a one-to-one correspondence between their arcs, where the correspondences preserve incidence between vertices and arcs.)

23. [*30*] In a certain group of 4096 people, everyone has about 100 acquaintances. A file has been prepared listing all pairs of people who are acquaintances. (The relation is symmetric; i.e., if x is acquainted with y, then y is acquainted with x. Therefore the file contains roughly 200,000 entries.) How would you design an algorithm to list all the k-person *cliques* in this group of people, given k? (A clique is an instance of mutual acquaintances: Everyone in the clique is acquainted with everyone else.) Assume that no really large cliques are present.

24. [*30*] Three million people with distinct names were laid end-to-end, reaching from New York to California. Each participant was given a slip of paper on which he wrote down his own name and the name of the person immediately west of him in the line. The man at the extreme western end didn't understand what to do, so he threw his paper away; the remaining 2,999,999 slips of paper were put into a huge basket and taken to the National Archives in Washington, D. C. Here the contents of the basket were shuffled completely and transferred to magnetic tapes.

At this point an information scientist observed that there was enough information on the tapes to reconstruct the list of people in their original order. And a computer scientist discovered a way to do the reconstruction with less than 1000 passes through the data tapes, using only sequential accessing of tape files and a small amount of random-access memory. How did he do it?

[In other words, given the pairs (x_i, x_{i+1}), for $1 \le i < N$, in random order, where the x_i are distinct, how can the sequence $x_1, x_2, \ldots, x_N$ be obtained, restricting all operations to serial techniques suitable for use with magnetic tapes? This is the problem of sorting into order when there is no easy way to tell which of two given keys precedes the other; we have already raised this question as part of exercise 2.2.3–25.]

*5.1. COMBINATORIAL PROPERTIES OF PERMUTATIONS

A permutation of a finite set is an arrangement of its elements into a row. Permutations are of special importance in the study of sorting algorithms, since they represent the unsorted input data. In order to study the efficiency of different sorting methods, we will want to be able to count the number of permutations which cause a certain step of a sorting procedure to be executed a certain number of times.

We have, of course, met with permutations already many times in Chapters 1, 2, and 3. For example in Section 1.2.5, we discussed two basic theoretical methods of constructing the $n!$ permutations of n objects; in Section 1.3.3, we analyzed some algorithms dealing with the cycle structure and multiplicative properties of permutations; in Section 3.3.2 we studied their "runs up" and "runs down." The purpose of the present section is to study some other properties of permutations, and to consider the general case where equal elements are allowed to appear. In the course of this study we will learn a good deal about combinatorial mathematics.

The properties of permutations are sufficiently pleasing to be interesting in their own right, and it is convenient to develop them systematically in one place instead of scattering the material throughout this chapter. But readers who are not mathematically inclined and readers who are anxious to dive right into sorting techniques are advised to go on to Section 5.2 immediately, since the present section actually has little *direct* connection to sorting.

*5.1.1. Inversions

Let $a_1\, a_2 \ldots a_n$ be a permutation of the set $\{1, 2, \ldots, n\}$. If $i < j$ and $a_i > a_j$, the pair (a_i, a_j) is called an "inversion" of the permutation; for example, the permutation 3 1 4 2 has three inversions: (3, 1), (3, 2), and (4, 2). Each inversion is a pair of elements that is "out of sort," so the only permutation with no inversions is the sorted permutation $1\ 2 \ldots n$. This connection with sorting is the chief reason why we will be so interested in inversions, although we have already used the concept to analyze a dynamic storage allocation algorithm (see exercise 2.2.2–9).

The concept of inversions was introduced by G. Cramer in 1750 [*Intr. à l'Analyse des Lignes Courbes algébriques* (Geneva, 1750), 657–659; cf. Thomas Muir, *Theory of Determinants* **1** (1906), 11–14], in connection with his famous rule for solving linear equations. In essence, he defined the determinant of an $n \times n$ matrix in the following way:

$$\det \begin{pmatrix} x_{11} & x_{12} & \ldots & x_{1n} \\ \vdots & \vdots & & \vdots \\ x_{n1} & x_{n2} & \ldots & x_{nn} \end{pmatrix} = \sum (-1)^{I(a_1 a_2 \ldots a_n)} x_{1a_1} x_{2a_2} \ldots x_{na_n},$$

summed over all permutations $a_1\, a_2 \ldots a_n$, where $I(a_1\, a_2 \ldots a_n)$ is the number of inversions of the permutation.

The *inversion table* $b_1\ b_2 \ldots b_n$ of the permutation $a_1\ a_2 \ldots a_n$ is obtained by letting b_j be the number of elements to the *left* of j that are *greater* than j. (In other words, b_j is the number of inversions whose second component is j.) For example, the permutation

$$5\ 9\ 1\ 8\ 2\ 6\ 4\ 7\ 3 \tag{1}$$

has the inversion table

$$2\ 3\ 6\ 4\ 0\ 2\ 2\ 1\ 0, \tag{2}$$

since 5 and 9 are to the left of 1; 5, 9, 8 are to the left of 2; etc., 20 inversions in all. By definition we will always have

$$0 \le b_1 \le n-1, \quad 0 \le b_2 \le n-2, \quad \ldots, \quad 0 \le b_{n-1} \le 1, \quad b_n = 0. \tag{3}$$

Perhaps the most important fact about inversions is Marshall Hall's observation that *an inversion table uniquely determines the corresponding permutation.* [See *Proc. Symp. Applied Math.* **6** (American Math. Society, 1956), 203.] We can go back from any inversion table $b_1\ b_2 \ldots b_n$ satisfying (3) to the unique permutation which produces it, by successively determining the relative placement of the elements $n, n-1, \ldots, 1$ (in this order). For example, we can construct the permutation corresponding to (2) as follows: Write down the number 9; then since $b_8 = 1$, 8 is to follow 9. Since $b_7 = 2$, 7 comes after both 8 and 9. Since $b_6 = 2$, 6 follows two of the numbers already written down; so we have

$$9\ 8\ 6\ 7$$

so far. Continue by placing 5 at the left, since $b_5 = 0$; put 4 after 4 of the numbers; put 3 after 6 numbers (i.e. at the extreme right); and we have

$$5\ 9\ 8\ 6\ 4\ 7\ 3.$$

Inserting 2 and 1 in an analogous way yields (1).

This correspondence is important because we can often translate a problem stated in terms of permutations into an equivalent problem stated in terms of inversion tables, and the latter problem may be easier to solve. For example, consider the simplest question of all: How many permutations of $\{1, 2, \ldots, n\}$ are possible? The answer must be the number of possible inversion tables, and they are easily enumerated since there are n choices for b_1, independently $n-1$ choices for $b_2, \ldots, 1$ choice for b_n, making $n(n-1)\ldots 1 = n!$ choices in all. Inversions are easier to count, because the b's are completely independent of each other, while the a's must be mutually distinct.

In Section 1.2.10 we analyzed a problem dealing with the number of local maxima of a permutation, when it is read from right to left; in other words, we wanted to count how many elements are larger than any of their successors. (For example, the right-to-left maxima in (1) are 9, 8, 7, and 3.) This is the

number of j such that $b_j = n - j$. Since b_1 will equal $n - 1$ with probability $1/n$, and (independently) b_2 will be equal to $n - 2$ with probability $1/(n - 1)$, etc., it is clear by consideration of the inversions that the average number of right-to-left maxima is

$$\frac{1}{n} + \frac{1}{n-1} + \cdots + 1 = H_n.$$

The corresponding generating function is also easily derived in a similar way.

Other applications of inversion tables appear later in this chapter, in connection with specific sorting algorithms.

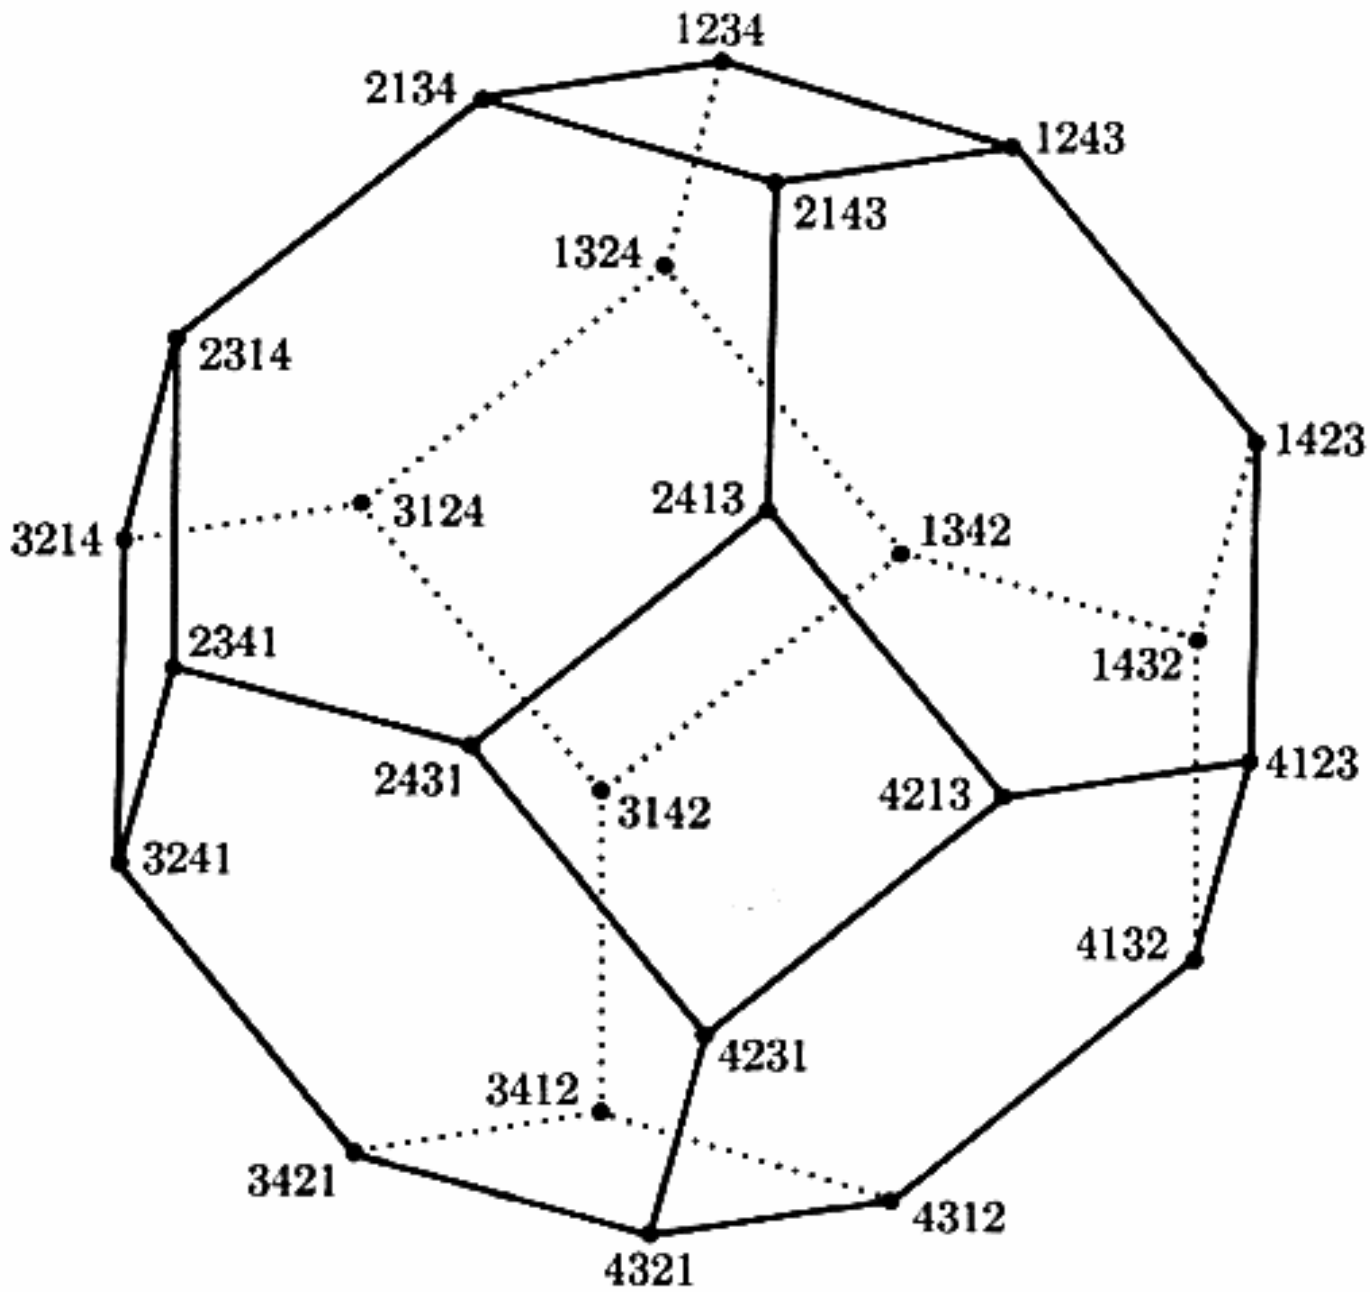


Fig. 1. The truncated octahedron, which shows the change in inversions when adjacent elements of a permutation are interchanged.

If we interchange two *adjacent* elements of a permutation, it is easy to see that the total number of inversions will increase or decrease by unity. Figure 1 shows the 24 permutations of $\{1, 2, 3, 4\}$, with lines joining permutations that differ by an interchange of adjacent elements; following a line downward increases the number of inversions by unity. Hence the number of inversions of a permutation π is the length of a downward path from 1 2 3 4 to π in Fig. 1; all such paths must have the same length.

Note that the diagram may be viewed as a three-dimensional solid, the "truncated octahedron," which has 8 hexagonal faces and 6 square faces. This is one of the uniform polyhedra discussed by Archimedes (see exercise 10).

The reader should not confuse "inversions" of a permutation with the "inverse" of a permutation. Recall that we can write a permutation in two-line form

$$\begin{pmatrix} 1 & 2 & 3 & \dots & n \\ a_1 & a_2 & a_3 & \dots & a_n \end{pmatrix}; \tag{4}$$

the *inverse* $a'_1\, a'_2\, a'_3 \dots a'_n$ of this permutation is the permutation obtained by interchanging the two rows and then sorting the columns into increasing order of the new top row:

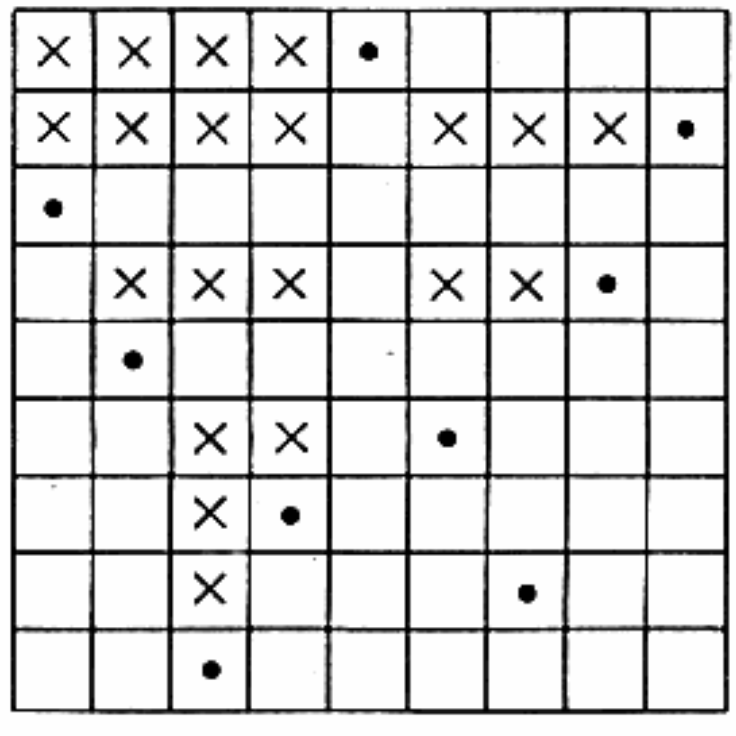
$$\begin{pmatrix} a_1 & a_2 & a_3 & \dots & a_n \\ 1 & 2 & 3 & \dots & n \end{pmatrix} = \begin{pmatrix} 1 & 2 & 3 & \dots & n \\ a'_1 & a'_2 & a'_3 & \dots & a'_n \end{pmatrix}. \tag{5}$$

For example, the inverse of 5 9 1 8 2 6 4 7 3 is 3 5 9 7 1 6 8 4 2, since

$$\begin{pmatrix} 5 & 9 & 1 & 8 & 2 & 6 & 4 & 7 & 3 \\ 1 & 2 & 3 & 4 & 5 & 6 & 7 & 8 & 9 \end{pmatrix} = \begin{pmatrix} 1 & 2 & 3 & 4 & 5 & 6 & 7 & 8 & 9 \\ 3 & 5 & 9 & 7 & 1 & 6 & 8 & 4 & 2 \end{pmatrix}.$$

Another way to define the inverse is to say that $a'_j = k$ if and only if $a_k = j$.

The inverse of a permutation was first defined by H. A. Rothe [in K. F. Hindenburg (ed.), *Sammlung combinatorisch-analytischer Abhandlungen* **2** (Leipzig, 1800), 263–305], who noticed an interesting connection between inverses and inversions: *The inverse of a permutation has exactly as many inversions as the permutation itself.* Rothe's proof of this fact was not the simplest possible one, but it is instructive and rather pretty nevertheless. We construct an $n \times n$ chessboard having a dot in column j of row i whenever $a_i = j$. Then we put X's in all squares which have dots lying both below (in the same column) and to their right (in the same row). For example, the diagram for 5 9 1 8 2 6 4 7 3 is



The number of X's is the number of inversions, since it is easy to see that b_j is the number of X's in column j. Now if we transpose the diagram (interchanging rows and columns), we get the diagram corresponding to the inverse of the original permutation; hence the number of X's (the number of inversions) is the same in both cases. Rothe used this fact to prove that the determinant of a matrix is unchanged when the matrix is transposed.

The analysis of some sorting algorithms involves the knowledge of how many permutations of n elements have exactly k inversions. Let us denote that number by $I_n(k)$; Table 1 lists the first few values of this function.

Table 1

PERMUTATIONS WITH k INVERSIONS

n	$I_n(0)$	$I_n(1)$	$I_n(2)$	$I_n(3)$	$I_n(4)$	$I_n(5)$	$I_n(6)$	$I_n(7)$	$I_n(8)$	$I_n(9)$	$I_n(10)$	$I_n(11)$
1	1	0	0	0	0	0	0	0	0	0	0	0
2	1	1	0	0	0	0	0	0	0	0	0	0
3	1	2	2	1	0	0	0	0	0	0	0	0
4	1	3	5	6	5	3	1	0	0	0	0	0
5	1	4	9	15	20	22	20	15	9	4	1	0
6	1	5	14	29	49	71	90	101	101	90	71	49

By considering the inversion table $b_1\, b_2 \ldots b_n$, it is obvious that $I_n(0) = 1$, $I_n(1) = n - 1$, and there is a symmetry property

$$I_n\left(\binom{n}{2} - k\right) = I_n(k). \tag{6}$$

Furthermore, since each of the b's can be chosen independently of the others, it is not difficult to see that the generating function

$$G_n(z) = I_n(0) + I_n(1)z + I_n(2)z^2 + \cdots \tag{7}$$

satisfies $G_n(z) = (1 + z + \cdots + z^{n-1})G_{n-1}(z)$; hence it has the comparatively simple form

$$(1 + z + \cdots + z^{n-1}) \ldots (1 + z)(1) = (1 - z^n) \ldots (1 - z^2)(1 - z)/(1 - z)^n. \tag{8}$$

From this generating function, we can easily extend Table 1, and we can verify that the numbers below the zigzag line in that table satisfy

$$I_n(k) = I_n(k - 1) + I_{n-1}(k), \qquad \text{for} \qquad k < n. \tag{9}$$

(This relation does *not* hold *above* the zigzag line.) A more complicated argument (see exercise 14) shows that, in fact, we have the formulas

$$I_n(2) = \binom{n}{2} - 1, \qquad n \geq 2;$$

$$I_n(3) = \binom{n+1}{3} - \binom{n}{1}, \qquad n \geq 3;$$

$$I_n(4) = \binom{n+2}{4} - \binom{n+1}{2}, \qquad n \geq 4;$$

$$I_n(5) = \binom{n+3}{5} - \binom{n+2}{3} + 1, \qquad n \geq 5;$$

in general, the formula for $I_n(k)$ contains about $1.6\sqrt{k}$ terms:

$$I_n(k) = \binom{n+k-2}{k} - \binom{n+k-3}{k-2} + \binom{n+k-6}{k-5} + \binom{n+k-8}{k-7} - \cdots$$
$$+ (-1)^j \left(\binom{n+k-u_j-1}{k-u_j} + \binom{n+k-u_j-j-1}{k-u_j-j} \right) + \cdots, \qquad n \geq k, \tag{10}$$

where $u_j = (3j^2 - j)/2$ is a so-called "pentagonal number."

If we divide $G_n(z)$ by $n!$ we get the generating function $g_n(z)$ for the probability distribution of the number of inversions in a random permutation of n elements. This is the product

$$g_n(z) = h_1(z)h_2(z) \ldots h_n(z), \tag{11}$$

where $h_k(z) = (1 + z + \cdots + z^{k-1})/k$ is the generating function for the uniform distribution of a random nonnegative integer less than k. It follows that

$$\begin{aligned} \text{mean}\,(g_n) &= \text{mean}\,(h_1) + \text{mean}\,(h_2) + \cdots + \text{mean}\,(h_n) \\ &= 0 + \frac{1}{2} + \cdots + \frac{n-1}{2} = \frac{n(n-1)}{4}; \end{aligned} \tag{12}$$

$$\begin{aligned} \text{var}\,(g_n) &= \text{var}\,(h_1) + \text{var}\,(h_2) + \cdots + \text{var}\,(h_n) \\ &= 0 + \frac{1}{4} + \cdots + \frac{n^2-1}{12} = \frac{n(2n+5)(n-1)}{72}. \end{aligned} \tag{13}$$

So the average number of inversions is rather large, about $\frac{1}{4}n^2$; the standard deviation is also rather large, about $\frac{1}{6}n^{3/2}$.

To bring our study of inversions to an interesting conclusion, we will discuss a remarkable discovery made by P. A. MacMahon [*Amer. J. Math.* **35** (1913), 281–322]. Let us define the *index* of the permutation $a_1\, a_2 \ldots a_n$ as the sum of all subscripts j such that $a_j > a_{j+1}$, $1 \leq j < n$. For example, the index of

5 9 1 8 2 6 4 7 3 is $2+4+6+8=20$. By coincidence the index is the same as the number of inversions in this case. If we list the 24 permutations of $\{1, 2, 3, 4\}$, namely

Permutation	Index	Inversions	Permutation	Index	Inversions
1 2 3 4	0	0	3|1 2 4	1	2
1 2 4|3	3	1	3|1 4|2	4	3
1 3|2 4	2	1	3|2|1 4	3	3
1 3 4|2	3	2	3|2 4|1	4	4
1 4|2 3	2	2	3 4|1 2	2	4
1 4|3|2	5	3	3 4|2|1	5	5
2|1 3 4	1	1	4|1 2 3	1	3
2|1 4|3	4	2	4|1 3|2	4	4
2 3|1 4	2	2	4|2|1 3	3	4
2 3 4|1	3	3	4|2 3|1	4	5
2 4|1 3	2	3	4|3|1 2	3	5
2 4|3|1	5	4	4|3|2|1	6	6

we see that *the number of permutations having a given index, k, is the same as the number having k inversions.*

At first this fact might appear to be almost obvious, but further scrutiny makes it very mysterious, and no simple direct proof is evident. MacMahon gave an ingenious indirect proof, as follows: Let $J(a_1\, a_2 \ldots a_n)$ be the index of the permutation $a_1\, a_2 \ldots a_n$, and let

$$H_n(z) = \sum z^{J(a_1\, a_2 \ldots a_n)}, \tag{14}$$

summed over all permutations of $\{1, 2, \ldots, n\}$, be the corresponding generating function. We wish to show that $H_n(z) = G_n(z)$. For this purpose we will define a one-to-one correspondence between n-tuples $(q_1, q_2, \ldots, q_n)$ of nonnegative integers, on the one hand, and ordered pairs of n-tuples,

$$((a_1, a_2, \ldots, a_n), (p_1, p_2, \ldots, p_n))$$

on the other hand, where $a_1\, a_2 \ldots a_n$ is a permutation of $\{1, 2, \ldots, n\}$ and $p_1 \geq p_2 \geq \cdots \geq p_n \geq 0$. This correspondence will satisfy the condition

$$q_1 + q_2 + \cdots + q_n = J(a_1\, a_2 \ldots a_n) + (p_1 + p_2 + \cdots + p_n). \tag{15}$$

The generating function $\sum z^{q_1+q_2+\cdots+q_n}$, summed over all n-tuples of nonnegative integers $(q_1, q_2, \ldots, q_n)$, is $Q_n(z) = 1/(1-z)^n$; and the generating function $\sum z^{p_1+p_2+\cdots+p_n}$, summed over all n-tuples of integers $(p_1, p_2, \ldots, p_n)$ such that $p_1 \geq p_2 \geq \cdots \geq p_n \geq 0$, is

$$P_n(z) = 1/(1-z)(1-z^2)\ldots(1-z^n), \tag{16}$$

as shown in exercise 15. In view of (15), the one-to-one correspondence we are about to establish will prove that $Q_n(z) = H_n(z)P_n(z)$, i.e.,

$$H_n(z) = Q_n(z)/P_n(z) = G_n(z).$$

The desired correspondence is defined by means of a "sorting" algorithm. Start with an empty list, and for $k = 1, 2, \ldots, n$ (in this order) insert q_k into the list as follows: Let the list after $k - 1$ steps contain $p_1, p_2, \ldots, p_{k-1}$, where $p_1 \geq p_2 \geq \cdots \geq p_{k-1}$; and assume that a permutation $a_1\, a_2 \ldots a_{k-1}$ on $\{n, n-1, \ldots, n-k+2\}$ has been defined. Let j be the unique integer such that $p_j > q_k \geq p_{j+1}$; if $q_k \geq p_1$, we let $j = 0$, and if $p_{k-1} > q_k$, we let $j = k - 1$. Now insert q_k into the list between p_j and p_{j+1} and insert the integer $(n - k + 1)$ into the permutation between a_j and a_{j+1}. When this has been done for all k, we will have a permutation $a_1\, a_2 \ldots a_n$ of $\{1, 2, \ldots, n\}$ and an n-tuple $(p_1, p_2, \ldots, p_n)$ such that $p_1 \geq p_2 \geq \cdots \geq p_n \geq 0$; and

$$p_j > p_{j+1} \qquad \text{whenever} \qquad a_j > a_{j+1}.$$

Finally, for $1 \leq j < n$, subtract one from each of $p_1, \ldots, p_j$ for each j such that $a_j > a_{j+1}$. The resulting pair $((a_1, a_2, \ldots, a_n), (p_1, p_2, \ldots, p_n))$ satisfies (15).

For example, suppose that $n = 6$ and $(q_1, \ldots, q_6) = (3, 1, 4, 0, 0, 1)$. The construction proceeds as follows:

k	$p_1 \ldots p_k$	$a_1 \ldots a_k$
1	3	6
2	3 1	6 5
3	4 3 1	4 6 5
4	4 3 1 0	4 6 5 3
5	4 3 1 0 0	4 6 5 2 3
6	4 3 1 1 0 0	4 6 1 5 2 3

The final adjustment gives $(p_1, \ldots, p_6) = (2, 1, 0, 0, 0, 0)$.

It is not hard to verify that this process is reversible; so the desired correspondence has been established, and MacMahon's theorem has been proved. We will meet with similar one-to-one correspondence algorithms in Section 5.1.4.

EXERCISES

1. [*10*] What is the inversion table for the permutation 2 7 1 8 4 5 9 3 6? What permutation has the inversion table 5 0 1 2 1 2 0 0?

2. [*M15*] The solution to Josephus' problem, as stated in exercise 1.3.2–22, is a permutation of $\{1, 2, \ldots, n\}$; the example given there ($n = 8$, $m = 4$) has the solution 5 4 6 1 3 8 7 2. The inversion table corresponding to this permutation is 3 6 3 1 0 0 1 0. Give a simple recurrence relation for the elements $b_1\, b_2 \ldots b_n$ of

the inversion table in the general Josephus problem for n men, with every mth man executed.

3. [*18*] If the permutation $a_1\, a_2 \ldots a_n$ corresponds to the inversion table $b_1\, b_2 \ldots b_n$, what is the permutation $\bar{a}_1\, \bar{a}_2 \ldots \bar{a}_n$ corresponding to the inversion table

$$(n - 1 - b_1)\, (n - 2 - b_2) \ldots (0 - b_n)?$$

▸ **4.** [*20*] Design an algorithm suitable for computer implementation which constructs the permutation $a_1\, a_2 \ldots a_n$ corresponding to a given inversion table $b_1\, b_2 \ldots b_n$ satisfying (3). [*Hint:* Consider a linked-memory technique.]

5. [*35*] The algorithm of exercise 4 requires an execution time roughly proportional to n^2 on typical computers; is it possible to design an algorithm whose running time is substantially better than order n^2?

▸ **6.** [*26*] Design an algorithm which computes the inversion table $b_1\, b_2 \ldots b_n$ corresponding to a given permutation $a_1\, a_2 \ldots a_n$ of $\{1, 2, \ldots, n\}$, where the running time is essentially proportional to $n \log n$ on typical computers.

7. [*20*] Several other kinds of inversion tables can be defined, corresponding to a given permutation $a_1\, a_2 \ldots a_n$ of $\{1, 2, \ldots, n\}$, besides the particular table $b_1\, b_2 \ldots b_n$ defined in the text; in this exercise we will consider three other types of inversion tables that arise in applications.

Let c_j be the number of inversions whose *first* component is j, that is, the number of elements to the *right* of j that are less than j. [Corresponding to (1) we have the table 0 0 0 1 4 2 1 5 7; clearly $0 \le c_j < j$.] Let $B_j = b_{a_j}$ and $C_j = c_{a_j}$.

Show that $0 \le B_j < j$ and $0 \le C_j \le n - j$, for $1 \le j \le n$; furthermore show that the permutation $a_1\, a_2 \ldots a_n$ can be determined uniquely when either $c_1\, c_2 \ldots c_n$ or $B_1\, B_2 \ldots B_n$ or $C_1\, C_2 \ldots C_n$ is given.

8. [*M24*] Continuing the notation of exercise 7, let $a'_1\, a'_2 \ldots a'_n$ be the inverse of $a_1\, a_2 \ldots a_n$, and let the corresponding inversion tables be $b'_1\, b'_2 \ldots b'_n$, $c'_1\, c'_2 \ldots c'_n$, $B'_1\, B'_2 \ldots B'_n$, and $C'_1\, C'_2 \ldots C'_n$. Find as many interesting relations between the a_j, b_j, c_j, B_j, C_j, a'_j, b'_j, c'_j, B'_j, C'_j as you can.

▸ **9.** [*M21*] Prove that, in the notation of exercise 7, the permutation $a_1\, a_2 \ldots a_n$ is its own inverse if and only if $b_j = C_j$ for $1 \le j \le n$.

10. [*HM20*] Consider Fig. 1 as a polyhedron in three dimensions. What is the diameter of the truncated octahedron (the distance between vertex 1234 and vertex 4321), if all of its edges have unit length?

11. [*M25*] (a) If $\pi = a_1\, a_2 \ldots a_n$ is a permutation of $\{1, 2, \ldots, n\}$, let $E(\pi) = \{(a_i, a_j) \mid i < j, a_i > a_j\}$ be the set of its inversions, and let

$$\overline{E}(\pi) = \{(a_i, a_j) \mid i > j, a_i > a_j\}$$

be the "non-inversions." Prove that $E(\pi)$ and $\overline{E}(\pi)$ are transitive. (A set S of ordered pairs is called *transitive* if (a, c) is in S whenever both (a, b) and (b, c) are in S.) (b) Conversely, let E be any transitive subset of $T = \{(x, y) \mid 1 \le y < x \le n\}$ whose complement $T \backslash E$ is also transitive. Prove that there exists a permutation π such that $E(\pi) = E$.

12. [*M28*] Continuing the notation of the previous exercise, prove that if π_1 and π_2 are permutations and if E is the smallest transitive set containing $E(\pi_1) \cup E(\pi_2)$,

then $\overline{E}$ is transitive. [Hence, if we say π_1 is "above" π_2 whenever $E(\pi_1) \subseteq E(\pi_2)$, a *lattice* of permutations is defined; there is a unique "lowest" permutation "above" two given permutations. Figure 1 is the lattice diagram when $n = 4$.]

13. [*M23*] It is well known that half of the terms in the expansion of a determinant have a $+$ sign, and half have a $-$ sign. In other words, there are just as many permutations with an *even* number of inversions as with an *odd* number, when $n \geq 2$. Show that, in general, the number of permutations having a number of inversions congruent to t modulo m is $n!/m$, regardless of the integer t, whenever $n \geq m$.

14. [*M24*] (F. Franklin.) A partition of n into k distinct parts is a representation $n = p_1 + p_2 + \cdots + p_k$, where $p_1 > p_2 > \cdots > p_k > 0$. For example, the partitions of 7 into distinct parts are 7, $6+1$, $5+2$, $4+3$, $4+2+1$. Let $f_k(n)$ be the number of partitions of n into k distinct parts; prove that $\sum_k (-1)^k f_k(n) = 0$, unless n has the form $(3j^2 \pm j)/2$, for some nonnegative integer j; in the latter case the sum is $(-1)^j$. For example, when $n = 7$ the sum is $-1+3-1 = 1$, since $7 = (3 \cdot 2^2 + 2)/2$. [*Hint:* Represent a partition as an array of dots, putting p_i dots in the ith row, for $1 \leq i \leq k$. Find the smallest j such that $p_{j+1} < p_j - 1$, and encircle the rightmost dots in the first j rows. If $j < p_k$, these j dots can usually be removed, tilted 45°, and placed as a new $(k+1)$ st row. On the other hand if $j \geq p_k$, the kth row of dots can usually be removed, tilted 45°, and placed to the right of the circled

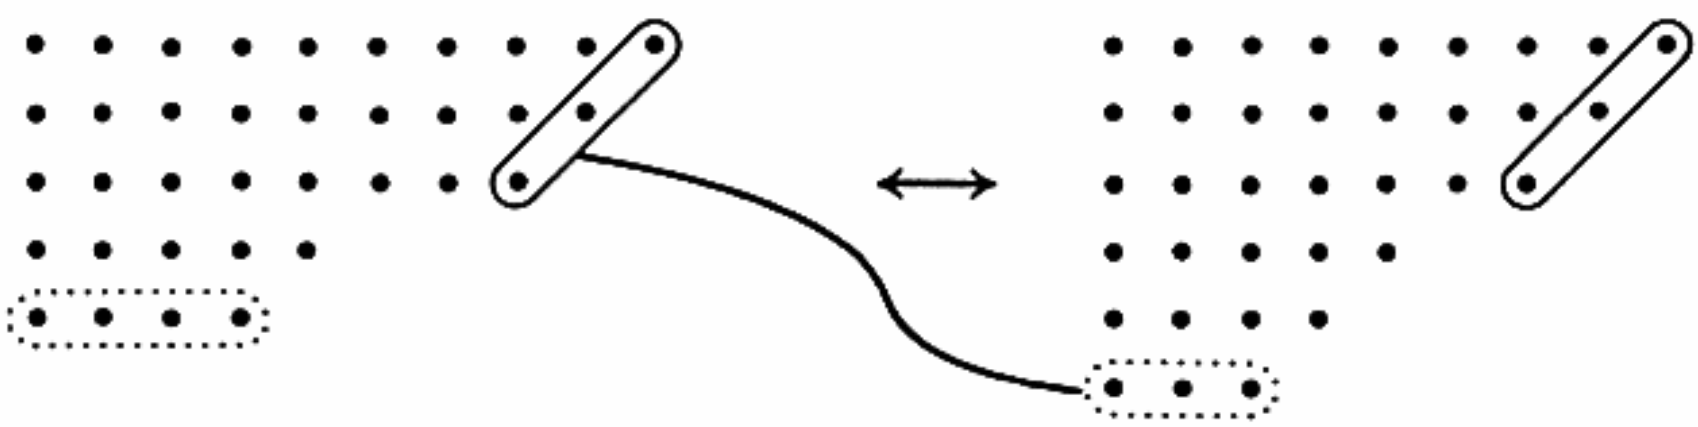


Fig. 2. Franklin's correspondence between partitions with distinct parts.

dots. (See Fig. 2.) This process pairs off partitions having an odd number of rows with partitions having an even number of rows, in most cases, so only unpaired partitions must be considered in the sum.]

Note: As a consequence, we obtain Euler's formula

$$(1-z)(1-z^2)(1-z^3)\ldots = 1 - z - z^2 + z^5 + z^7 - z^{12} - z^{15} + \cdots$$
$$= \sum_{-\infty < j < \infty} (-1)^j z^{(3j^2+j)/2}$$

Since the generating function for ordinary partitions (whose parts are not necessarily distinct) is $\sum p(n)z^n = 1/(1-z)(1-z^2)(1-z^3)\ldots$, we obtain a nonobvious recurrence relation for the partition numbers, $p(n) = p(n-1) + p(n-2) - p(n-5) - p(n-7) + p(n+12) + p(n+15) - \cdots$.

15. [*M23*] Prove that (16) is the generating function for partitions into at most n parts, i.e., prove that the coefficient of z^m in $1/(1-z)(1-z^2)\ldots(1-z^n)$ is the number of ways to write $m = p_1 + p_2 + \cdots + p_n$ with $p_1 \geq p_2 \geq \cdots \geq p_n \geq 0$.

[*Hint:* Drawing dots as in exercise 14, show that there is a one-to-one correspondence between n-tuples $(p_1, p_2, \ldots, p_n)$ such that $p_1 \geq p_2 \geq \cdots \geq p_n \geq 0$ and sequences $(P_1, P_2, P_3, \ldots)$ such that $n \geq P_1 \geq P_2 \geq P_3 \geq \cdots \geq 0$, with the property that $p_1 + p_2 + \cdots + p_n = P_1 + P_2 + P_3 + \cdots$. In other words, partitions into at most n parts correspond to partitions into parts not exceeding n.]

16. [*M25*] (L. Euler.) Prove the following identities by interpreting both sides of the equations in terms of partitions:

$$\prod_{k\geq 0} \frac{1}{(1-q^k z)} = \frac{1}{(1-z)(1-qz)(1-q^2z)\ldots}$$

$$= 1 + \frac{z}{1-q} + \frac{z^2}{(1-q)(1-q^2)} + \cdots = \sum_{n\geq 0} z^n \Big/ \prod_{1\leq k\leq n} (1-q^k).$$

$$\prod_{k\geq 0} (1+q^k z) = (1+z)(1+qz)(1+q^2z)\cdots$$

$$= 1 + \frac{z}{1-q} + \frac{z^2 q}{(1-q)(1-q^2)} + \cdots = \sum_{n\geq 0} z^n q^{n(n-1)/2} \Big/ \prod_{1\leq k\leq n} (1-q^k).$$

17. [*20*] In MacMahon's correspondence defined at the end of this section, what are the 24 quadruples (q_1, q_2, q_3, q_4) for which $(p_1, p_2, p_3, p_4) = (0, 0, 0, 0)$?

18. [*M30*] (T. Hibbard, *CACM* **6** (1963), 210.) Let $n > 0$, and assume that a sequence of 2^n n-bit integers $X_0, \ldots, X_{2^n-1}$ has been generated at random, where each bit of each number is independently equal to 1 with probability p. Consider the sequence $X_0 \oplus 0, X_1 \oplus 1, \ldots, X_{2^n-1} \oplus (2^n - 1)$, where $\oplus$ denotes the operation of taking "exclusive or" on the binary representations. Thus if $p = 0$, the sequence is $0, 1, \ldots, 2^n - 1$, and if $p = 1$ it is $2^n - 1, \ldots, 1, 0$; and when $p = \frac{1}{2}$, each element of the sequence is a random integer between 0 and $2^n - 1$. For general p this is a useful way to generate a sequence of random integers with a biased number of inversions, although the distribution of the elements of the sequence taken as a whole is uniform.

Determine the average number of inversions in such a sequence, as a function of the probability p.

19. [*M36*] (D. Foata.) Give a direct proof of MacMahon's index theorem: Find an explicit one-to-one correspondence which takes a permutation on n elements, having index k, into one having k inversions and having the same rightmost element.

20. [*M43*] The following famous identity due to Jacobi [*Fundamenta Nova Theoriæ Functionum Ellipticorum* (1829), §64] is the basis of many remarkable relationships involving elliptic functions:

$$\prod_{k\geq 1} (1-u^k v^{k-1})(1-u^{k-1}v^k)(1-u^k v^k)$$

$$= (1-u)(1-v)(1-uv)(1-u^2v)(1-uv^2)(1-u^2v^2)\cdots$$

$$= 1 - (u+v) + (u^3v + uv^3) - (u^6v^3 + u^3v^6) + \cdots$$

$$= 1 + \sum_{n\geq 1} (-1)^n (u^{(n+1)n/2} v^{(n-1)n/2} + u^{(n-1)n/2} v^{(n+1)n/2}).$$

For example, if we set $u = z$, $v = z^2$, we obtain Euler's formula of exercise 14. If we set $z = \sqrt{u/v}$, $q = \sqrt{uv}$, we obtain

$$\prod_{k\geq 1}(1 - q^{2k-1}z)(1 - q^{2k-1}z^{-1})(1 - q^{2k}) = \sum_{-\infty<n<\infty}(-1)^n z^n q^{n^2}.$$

Is there a combinatorial proof of Jacobi's identity, analogous to Franklin's proof of the special case in exercise 14? (Thus we want to consider "complex partitions"

$$m + ni = (p_1 + q_1 i) + (p_2 + q_2 i) + \cdots + (p_k + q_k i)$$

where the $p_j + q_j i$ are distinct nonzero complex numbers; p_j and q_j are nonnegative integers with $|p_j - q_j| \leq 1$. Jacobi's identity says that the number of such representations with k even is the same as the number with k odd, except when m and n are consecutive triangular numbers!) What other remarkable properties do complex partitions have?

*5.1.2. Permutations of a Multiset

So far we have been discussing permutations of a *set* of elements; this is just a special case of the concept of permutations of a *multiset*. (A multiset is like a set except that it can have repetitions of identical elements. Some basic properties of multisets have been discussed in Section 4.6.3.)

For example, consider the multiset

$$M = \{a, a, a, b, b, c, d, d, d, d\} \tag{1}$$

which contains 3 a's, 2 b's, 1 c, and 4 d's. We may also indicate the multiplicities of elements in another way, namely

$$M = \{3 \cdot a, 2 \cdot b, c, 4 \cdot d\}. \tag{2}$$

A permutation of M is an arrangement of its elements into a row, e.g.,

$$c\ a\ b\ d\ d\ a\ b\ d\ a\ d.$$

From another point of view we would call this a string of letters, containing 3 a's, 2 b's, 1 c, and 4 d's.

How many permutations of M are possible? If we regarded the elements of M as distinct, by subscripting them $a_1, a_2, a_3, b_1, b_2, c_1, d_1, d_2, d_3, d_4$, we would have $10! = 3{,}628{,}800$ permutations, but many of these would actually be the same when we removed the subscripts. In fact, each permutation of M would occur exactly $3!2!1!4! = 288$ times, since we can start with any permutation of M and put subscripts on the a's in 3! ways, on the b's (independently) in 2! ways, on the c in 1 way, and on the d's in 4! ways. Therefore the true number of permutations of M is

$$\frac{10!}{3!2!1!4!} = 12{,}600.$$

In general, we can see by this same argument that the number of permutations of any multiset is the multinomial coefficient

$$\binom{n}{n_1, n_2, \ldots} = \frac{n!}{n_1! n_2! \ldots}, \tag{3}$$

where n_1 is the number of elements of one kind, n_2 is the number of another kind, etc., and $n = n_1 + n_2 + \cdots$ is the total number of elements.

The number of permutations of a set was known in ancient times. The Hebrew Book of Creation (c. 100 A.D.), which was the earliest literary product of Jewish philosophical mysticism, gives the correct values of the first seven factorials, after which it says "Go on and obtain numbers which the mouth cannot express and the ear cannot hear." [*Sefer Yezirah*, ed. by R. Mordecai Atia (Jerusalem: Sh. Monson, 1962), verse 52 (pp. 107–108); cf. also Solomon Gandz, *Studies in Hebrew Astronomy and Mathematics* (New York: Ktav, 1970), 494–496. The Book of Creation was based on supposedly significant relations between the seven planets, the seven consonants with a double pronunciation, the seven apertures in a human head, and the seven days of creation.] This is the first known enumeration of permutations in history. The second occurs in the Indian classic *Anuyogadvarā-sutra* (c. 500 A.D.), rule 97, which gives the formula

$$6 \times 5 \times 4 \times 3 \times 2 \times 1 - 2$$

for the number of permutations of six elements which are neither in ascending nor descending order. [See G. Chakravarti, *Bull. Calcutta Math. Soc.* **24** (1932), 79–88. The *Anuyogadvarā-sutra* is one of the books in the canon of Jainism, a religious sect which flourishes in India.]

The corresponding rule for multisets seems to have appeared first in the *Líláváti* of Bháscara Áchárya (c. 1150), sections 270–271. Bháscara stated the rule rather tersely, and illustrated it only with two simple examples {2, 2, 1, 1} and {4, 8, 5, 5, 5}. Consequently the English translations of his work do not all state the rule correctly, although there is little doubt that Bháscara knew what he was talking about. He went on to give the interesting formula

$$\frac{(4 + 8 + 5 + 5 + 5) \times 120 \times 11111}{5 \times 6}$$

for the sum of the 20 numbers $48555 + 45885 + \cdots$.

The correct rule for counting permutations when only one element is repeated was found independently by the German Jesuit scholar Athanasius Kircher in his voluminous treatise on music [*Musurgia Universalis* **2** (Rome, 1650), 5–7]. Kircher was interested in the number of tunes that could be made from a given collection of notes, so he devised what he called "musarithmetic." On pp. 18–21 of his treatise he correctly gave the number of permutations of the multiset $\{m \cdot C, n \cdot D\}$ for several values of m and n, although he didn't reveal his method of calculation except when $n = 1$.

The general rule (3) then appeared in Jean Prestet's *Elémens de Mathématiques* (Paris, 1675), 351–352, one of the very first expositions of combinatorial mathematics to be written in the Western world. Prestet stated the rule correctly for a general multiset, but illustrated it only in the simple case $\{a, a, b, b, c, c\}$. He specifically pointed out that division by the *sum* of the factorials, which he considered to be the natural generalization of Kircher's rule, did not work properly. A few years later, John Wallis's *Treatise of Algebra* **2** (Oxford, 1685), 117–118 gave a clearer and somewhat more detailed discussion of the rule.

In 1965, Dominique Foata introduced an ingenious idea called the "intercalation product" which makes it possible to extend many of the known results about ordinary permutations to the general case of multiset permutations. [See *Publ. Inst. Statistique*, Univ. Paris, **14** (1965, 81–241; also *Lecture Notes in Math.* **85** (Springer, 1969).] Assuming that the elements of the multiset are linearly ordered in some way, we may consider the *two-line notation*, e.g.,

$$\begin{pmatrix} a & a & a & b & b & c & d & d & d & d \\ c & a & b & d & d & a & b & d & a & d \end{pmatrix}, \tag{4}$$

where the top line contains the elements of M sorted into nondecreasing order and the bottom line is the permutation itself. The *intercalation product* $\alpha \intercal \beta$ of two multiset permutations α and β is obtained by (a) expressing α and β in the two-line notation, (b) juxtaposing these two-line representations, and (c) sorting the columns into nondecreasing order of the top line. The sorting is to be "stable" in the sense that left-to-right order of elements in the bottom line is preserved when the corresponding top line elements are equal. For example, $c\ a\ d\ a\ b \intercal b\ d\ d\ a\ d = c\ a\ b\ d\ d\ a\ b\ d\ a\ d$, since

$$\begin{pmatrix} a & a & b & c & d \\ c & a & d & a & b \end{pmatrix} \intercal \begin{pmatrix} a & b & d & d & d \\ b & d & d & a & d \end{pmatrix} = \begin{pmatrix} a & a & a & b & b & c & d & d & d & d \\ c & a & b & d & d & a & b & d & a & d \end{pmatrix}. \tag{5}$$

It is easy to see that the intercalation product operation is associative, i.e.,

$$\alpha \intercal (\beta \intercal \gamma) = \alpha \intercal (\beta \intercal \gamma), \tag{6}$$

and that it also satisfies the cancellation laws

$$\begin{aligned} \pi \intercal \alpha = \pi \intercal \beta \quad &\text{implies} \quad \alpha = \beta, \\ \alpha \intercal \pi = \beta \intercal \pi \quad &\text{implies} \quad \alpha = \beta. \end{aligned} \tag{7}$$

There is an "identity element"

$$\alpha \intercal \epsilon = \epsilon \intercal \alpha = \alpha, \tag{8}$$

where ϵ is the null permutation, the "arrangement" of the empty set. The commutative law is not valid in general (see exercise 2), but we do have

$$\alpha \intercal \beta = \beta \intercal \alpha \qquad \text{if } \alpha \text{ and } \beta \text{ have no letters in common.} \tag{9}$$

In an analogous fashion we can extend the concept of *cycles* to cases where elements are repeated; we let

$$(x_1 \quad x_2 \quad \ldots \quad x_n) \tag{10}$$

stand for the permutation obtained in two-line form by sorting the columns of

$$\begin{pmatrix} x_1 & x_2 & \ldots & x_n \\ x_2 & x_3 & \ldots & x_1 \end{pmatrix} \tag{11}$$

by their top elements in a stable manner. For example,

$$(d\ b\ d\ d\ a\ c\ a\ a\ b\ d) = \begin{pmatrix} d & b & d & d & a & c & a & a & b & d \\ b & d & d & a & c & a & a & b & d & d \end{pmatrix} = \begin{pmatrix} a & a & a & b & b & c & d & d & d & d \\ c & a & b & d & d & a & b & d & a & d \end{pmatrix},$$

so the permutation (4) is actually a cycle. We might render this cycle in words by saying something like "d goes to b goes to d goes to d goes . . . goes to d goes back." Note that these general cycles do not share all of the properties of ordinary cycles; $(x_1\ x_2\ \ldots\ x_n)$ is not always the same as $(x_2\ \ldots\ x_n\ x_1)$.

We observed in Section 1.3.3 that every permutation of a set has a unique representation (up to order) as a product of disjoint cycles, where the "product" of permutations is defined by a law of composition. It is easy to see that *the product of disjoint cycles is exactly the same as their intercalation;* this suggests that we might be able to generalize the previous results, obtaining a unique representation (in some sense) for any permutation of a multiset, as the intercalation of cycles. In fact there are at least two natural ways to do this, each of which has important applications.

Equation (5) shows one way to factor $c\ a\ b\ d\ d\ a\ b\ d\ a\ d$ as the intercalation of shorter permutations; let us consider the general problem of finding all factorizations $\pi = \alpha \mathbin{⫲} \beta$ of a given permutation π. It will be helpful to consider a particular permutation, such as

$$\pi = \begin{pmatrix} a & a & b & b & b & b & b & c & c & c & d & d & d & d & d \\ d & b & c & b & c & a & c & d & a & d & d & b & b & b & d \end{pmatrix}, \tag{12}$$

as we investigate this factorization problem.

If we can write this permutation π in the form $\alpha \mathbin{⫲} \beta$, where α contains the letter a at least once, then the leftmost a in the top line of the two-line notation for α must appear over the letter d, so α must also contain at least one occurrence of the letter d. If we now look at the leftmost d in the top line of α, we see in the same way that it must appear over the letter d, so α must contain at least *two* d's. Looking at the second d, we see that α also contains a b. We have the partial result

$$\alpha = \begin{pmatrix} a & \ldots & b & \ldots & d\ d & \ldots \\ d & & & & d\ b & \end{pmatrix} \tag{13}$$

on the sole assumption that α is a left factor of π which contains the letter a. Proceeding in the same manner, we find that the b in the top line of (13) must

appear over the letter c, etc. Eventually this process will reach the letter a again, and we can identify this a with the first a if we choose to do so. The argument we have just made essentially proves that any left factor α of (12) which contains the letter a has the form $(d\ d\ b\ c\ d\ b\ b\ c\ a) \intercal \alpha'$, for some permutation α'. (It is convenient to write the a last in the cycle, instead of first; this is permissible since there is only one a.) Similarly, if we had assumed that α contains the letter b, we would have deduced that $\alpha = (c\ d\ d\ b) \intercal \alpha''$ for some α''.

In general, this argument shows that, *if we have any factorization* $\alpha \intercal \beta = \pi$, *where* α *contains a given letter* y, *there is a unique cycle of the form*

$$(x_1 \ldots x_n\ y), \qquad n \geq 0, \qquad x_1, \ldots, x_n \neq y, \tag{14}$$

which is a left factor of α. This cycle is easily determined when π and y are given; it is the shortest left factor of π which contains the letter y. One of the consequences of this observation is the following theorem:

Theorem A. *Let the elements of the multiset* M *be linearly ordered by the relation "*$<$*". Every permutation* π *of* M *has a unique representation as the intercalation*

$$\pi = (x_{11} \ldots x_{1n_1}y_1) \intercal (x_{21} \ldots x_{2n_2}y_2) \intercal \cdots \intercal (x_{t1} \ldots x_{tn_t}y_t), \qquad t \geq 0, \tag{15}$$

where the following two conditions are satisfied:

$$y_1 \leq y_2 \leq \cdots \leq y_t;$$

$$y_i < x_{ij} \qquad \text{for} \qquad 1 \leq j \leq n_i, \qquad 1 \leq i \leq t. \tag{16}$$

(In other words the last element in each cycle is smaller than every other element, and the sequence of last elements is in nondecreasing order.)

Proof. If $\pi = \epsilon$, we obtain such a factorization by letting $t = 0$. Otherwise we let y_1 be the smallest element permuted; and we determine $(x_{11} \ldots x_{1n_1}y_1)$, the shortest left factor of π containing y_1, as in the example above. Now $\pi = (x_{11} \ldots x_{1n_1}y_1) \intercal \rho$ for some permutation ρ; by induction on the length, we can write

$$\rho = (x_{21} \ldots x_{2n_2}y_2) \intercal \cdots \intercal (x_{t1} \ldots x_{tn_t}y_t), \qquad t \geq 1,$$

where (16) is satisfied. This proves the existence of such a factorization.

Conversely, to prove that the representation (15) satisfying (16) is unique, clearly $t = 0$ if and only if π is the null permutation ϵ. When $t > 0$, (16) implies that y_1 is the smallest element permuted, and that $(x_{11} \ldots x_{1n_1}y_1)$ is the shortest left factor containing y_1. Therefore $(x_{11} \ldots x_{1n_1}y_1)$ is uniquely determined; by the cancellation law (7) and induction, the representation is unique. ∎

For example, the "canonical" factorization of (12), satisfying the given conditions, is

$$(d\ d\ b\ c\ d\ b\ b\ c\ a) \intercal (b\ a) \intercal (c\ d\ b) \intercal (d), \tag{17}$$

if $a < b < c < d$.

It is important to note that we can actually drop the parentheses and the $\top$'s in this representation, without ambiguity! Each cycle ends just after the first appearance of the smallest remaining element. So this construction associates the permutation

$$\pi' = d\ d\ b\ c\ d\ b\ b\ c\ a\ b\ a\ c\ d\ b\ d$$

with the original permutation

$$\pi = d\ b\ c\ b\ c\ a\ c\ d\ a\ d\ d\ b\ b\ b\ d.$$

Whenever the two-line representation of π had a column of the form $\binom{y}{x}$, where $x < y$, the associated permutation has a corresponding pair of adjacent elements $\ldots yx \ldots$. Thus our example permutation π has three columns of the form $\binom{d}{b}$, and π' has three occurrences of the pair db. In general, this construction establishes the following remarkable theorem:

Theorem B. *Let M be a multiset. There is a one-to-one correspondence between the permutations of M such that, if π corresponds to π', the following conditions hold:*

a) *The leftmost element of π' equals the leftmost element of π;*

b) *For all pairs of permuted elements (x, y) with $x < y$, the number of occurrences of the column $\binom{y}{x}$ in the two-line notation of π is equal to the number of times x is immediately preceded by y in π'.* ∎

When M is a set, this is essentially the same as the "unusual correspondence" we discussed near the end of Section 1.3.3, with unimportant changes. The more general result in Theorem B is quite useful for enumerating permutations of special types, since we can often solve a problem based on a two-line constraint more easily than the equivalent problem based on an adjacent-pair constraint.

P. A. MacMahon considered problems of this type in his extraordinary book *Combinatory Analysis* **1** (Cambridge Univ. Press, 1915), 168–186. He gave a constructive proof of Theorem B in the special case that M contains only two different kinds of elements, say a and b; his construction for this case is essentially the same as that given here, although he expressed it quite differently. For the case of three different elements a, b, c, MacMahon gave a complicated nonconstructive proof of Theorem B; the general case was first proved by Foata in 1965.

As a nontrivial example of Theorem B, let us find the number of strings of letters a, b, c containing exactly

$$\begin{array}{ll} A & \text{occurrences of the letter } a; \\ B & \text{occurrences of the letter } b; \\ C & \text{occurrences of the letter } c; \\ k & \text{occurrences of the adjacent pair of letters } ca; \\ l & \text{occurrences of the adjacent pair of letters } cb; \\ m & \text{occurrences of the adjacent pair of letters } ba. \end{array} \tag{18}$$

The theorem tells us this is the same as the number of two-line arrays of the form

$$\begin{array}{c} \overbrace{}^{A} \quad \overbrace{}^{B} \quad \overbrace{}^{C} \\ \begin{pmatrix} a & \ldots & a & b & \ldots & b & c & \ldots & c \\ \sqcup & \ldots & \sqcup & \sqcup & \ldots & \sqcup & \sqcup & \ldots & \sqcup \end{pmatrix} \\ \underbrace{}_{A\text{-}k\text{-}m\ a\text{'s}} \quad \underbrace{}_{m\ a\text{'s}} \quad \underbrace{}_{k\ a\text{'s}} \\ \underbrace{}_{B\text{-}l\ b\text{'s}} \quad \underbrace{}_{l\ b\text{'s}} \\ \underbrace{}_{C\ c\text{'s}} \end{array} \tag{19}$$

The a's can be placed in the second line in

$$\binom{A}{A-k-m}\binom{B}{m}\binom{C}{k} \quad \text{ways;}$$

then the b's can be placed in the remaining positions in

$$\binom{B+k}{B-l}\binom{C-k}{l} \quad \text{ways.}$$

The positions which are still vacant must be filled by c's; hence the desired number is

$$\binom{A}{A-k-m}\binom{B}{m}\binom{C}{k}\binom{B+k}{B-l}\binom{C-k}{l}. \tag{20}$$

Let us return to the question of finding all factorizations of a given permutation. Is there such a thing as a "prime" permutation, one which has no intercalation factors except itself and ϵ? The discussion preceding Theorem A leads us quickly to conclude that *a permutation is prime if and only if it is a cycle with no repeated elements.* For if it is such a cycle, our argument proves that there are no left factors except ϵ and the cycle itself. And if a permutation contains a repeated element y, it has a nontrivial cyclic left factor in which y appears only once.

If a permutation is not prime, we can factor it further and further into smaller and smaller pieces until it has been expressed as a product of primes. Furthermore we can show that the factorization is unique, if we neglect the order of factors that commute:

Theorem C. *Every permutation of a multiset can be written as a product*

$$\sigma_1 \intercal \sigma_2 \intercal \cdots \intercal \sigma_t, \qquad t \geq 0, \tag{21}$$

where each σ_j is a cycle having no repeated elements. This representation is unique, in the sense that any two such representations of the same permutation may be transformed into each other by successively interchanging pairs of adjacent disjoint cycles.

The term "disjoint cycles" means cycles having no elements in common. As an example of this theorem, we can verify that the permutation

$$\begin{pmatrix} a & a & b & b & c & c & d \\ b & a & a & c & d & b & c \end{pmatrix}$$

has exactly five factorizations into primes, namely

$$\begin{aligned}(a\ b)_{\mathsf{T}}(a)_{\mathsf{T}}(c\ d)_{\mathsf{T}}(b\ c) &= (a\ b)_{\mathsf{T}}(c\ d)_{\mathsf{T}}(a)_{\mathsf{T}}(b\ c)\\ &= (a\ b)_{\mathsf{T}}(c\ d)_{\mathsf{T}}(b\ c)_{\mathsf{T}}(a)\\ &= (c\ d)_{\mathsf{T}}(a\ b)_{\mathsf{T}}(a)_{\mathsf{T}}(b\ c)\\ &= (c\ d)_{\mathsf{T}}(a\ b)_{\mathsf{T}}(b\ c)_{\mathsf{T}}(a). \qquad (22)\end{aligned}$$

Proof. We must show that the stated uniqueness property holds. By induction on the length of the permutation, it suffices to prove that if ρ and σ are unequal cycles having no repeated elements, and if

$$\rho_{\mathsf{T}}\alpha = \sigma_{\mathsf{T}}\beta,$$

then ρ and σ are disjoint, and

$$\alpha = \sigma_{\mathsf{T}}\theta, \qquad \beta = \rho_{\mathsf{T}}\theta,$$

for some permutation θ.

If y is any element of the cycle ρ, then any left factor of $\sigma_{\mathsf{T}}\beta$ containing the element y must have ρ as a left factor. So if ρ and σ have an element in common, σ is a multiple of ρ; hence $\sigma = \rho$ (since they are primes), contradicting our assumption. Therefore the cycle containing y, having no elements in common with σ, must be a left factor of β. The proof is completed by using the cancellation law (7). ∎

As an example of Theorem C, let us consider permutations of the multiset $M = \{A \cdot a, B \cdot b, C \cdot c\}$ consisting of A a's, B b's, and C c's. Let $N(A, B, C, m)$ be the number of permutations of M whose two-line representation contains *no* columns of the forms $\binom{a}{a}, \binom{b}{b}, \binom{c}{c}$, and exactly m columns of the form $\binom{a}{b}$. It follows that there are exactly $A - m$ columns of the form $\binom{a}{c}$, $B - m$ of the form $\binom{c}{b}$, $C - B + m$ of the form $\binom{c}{a}$, $C - A + m$ of the form $\binom{b}{c}$, and $A + B - C - m$ of the form $\binom{b}{a}$, hence

$$N(A, B, C, m) = \binom{A}{m}\binom{B}{C - A + m}\binom{C}{B - m}. \qquad (23)$$

Theorem C tells us that we can count these permutations in another way: Since columns of the forms $\binom{a}{a}, \binom{b}{b}, \binom{c}{c}$ are excluded, the only possible prime factors of the permutation are

$$(a\ b), \qquad (a\ c), \qquad (b\ c), \qquad (a\ b\ c), \qquad (a\ c\ b). \qquad (24)$$

Each pair of these cycles has at least one letter in common, so the factorization

into primes is completely unique. If the cycle $(a\ b\ c)$ occurs k times in the factorization, our previous assumptions imply that $(a\ b)$ occurs $m - k$ times, $(b\ c)$ occurs $C - A + m - k$ times, $(a\ c)$ occurs $C - B + m - k$ times, and $(a\ c\ b)$ occurs $A + B - C - 2m + k$ times. Hence $N(A, B, C, m)$ is the number of permutations of these cycles (a multinomial coefficient), summed over k:

$$\begin{aligned} &N(A, B, C, m) \\ &\quad = \sum_k \frac{(C+m-k)!}{(m-k)!(C-A+m-k)!(C-B+m-k)!k!(A+B-C-2m+k)!} \\ &\quad = \sum_k \binom{m}{k}\binom{A}{m}\binom{A-m}{C-B+m-k}\binom{C+m-k}{A}. \end{aligned} \tag{25}$$

Comparing this with (23), we find that the following identity must be valid:

$$\sum_k \binom{m}{k}\binom{A-m}{C-B+m-k}\binom{C+m-k}{A} = \binom{B}{C-A+m}\binom{C}{B-m}. \tag{26}$$

This turns out to be the identity we met in exercise 1.2.6–31, namely

$$\sum_j \binom{M-R+S}{j}\binom{N+R-S}{N-j}\binom{R+j}{M+N} = \binom{R}{M}\binom{S}{N}, \tag{27}$$

with $M = A + B - C - m$, $N = C - B + m$, $R = B$, $S = C$, and $j = C - B + m - k$.

Similarly we can count the number of permutations of $\{A \cdot a, B \cdot b, C \cdot c, D \cdot d\}$ such that the number of columns of various types is specified as follows:

Column type:	a d	a b	b a	b c	c b	c d	d a	d c
Number of times:	r	$A-r$	q	$B-q$	$B-A+r$	$D-r$	$A-q$	$D-A+q$

(28)

(Here $A + C = B + D$.) The possible cycles occurring in a prime factorization of such permutations are then

Cycle:	$(a\ b)$	$(b\ c)$	$(c\ d)$	$(d\ a)$	$(a\ b\ c\ d)$	$(d\ c\ b\ a)$
Number of times:	$A-r-s$	$B-q-s$	$D-r-s$	$A-q-s$	s	$q-A+r+s$

(29)

for some s (see exercise 12). In this case the cycles $(a\ b)$ and $(c\ d)$ commute with each other, and so do $(b\ c)$ and $(d\ a)$, so we must count the number of distinct prime factorizations. It turns out (see exercise 10) that there is always a unique factorization such that no $(c\ d)$ is immediately followed by $(a\ b)$, and

no $(d\ a)$ is immediately followed by $(b\ c)$. Hence by the result of exercise 13, we have the identity

$$\sum_{s,t}\binom{B}{t}\binom{A-q-s}{A-r-s-t}\binom{B+D-r-s-t}{B-q-s}\times\frac{D!}{(D-r-s)!(A-q-s)!s!(q-A+r+s)!}=\binom{A}{r}\binom{B+D-A}{D-r}\binom{B}{q}\binom{D}{A-q}$$

Taking out the factor $\binom{D}{A-q}$ from both sides and simplifying the factorials slightly leaves us with the complicated-looking five-parameter binomial coefficient identity

$$\sum_{s,t}\binom{B}{t}\binom{A-r-t}{s}\binom{B+D-r-s-t}{D+q-r-t}\times\binom{D-A+q}{D-r-s}\binom{A-q}{r+t-q}=\binom{A}{r}\binom{B+D-A}{D-r}\binom{B}{q}. \quad (30)$$

The sum on s can be performed using (27), and the resulting sum on t is easily evaluated; so, after all this work, we were not fortunate enough to discover any identities that we didn't already know how to derive. But at least we have learned how to count certain kinds of permutations, in two different ways, and these counting techniques are good training for the problems that lie ahead.

EXERCISES

1. [*M05*] *True or false:* Let M_1 and M_2 be multisets. If α is a permutation of M_1 and β is a permutation of M_2, then $\alpha \intercal \beta$ is a permutation of $M_1 \cup M_2$.

2. [*10*] The intercalation of $c\ a\ d\ a\ b$ and $b\ d\ d\ a\ d$ is computed in (5); find the intercalation $b\ d\ d\ a\ d \intercal c\ a\ d\ a\ b$ which is obtained when the factors are interchanged.

3. [*M13*] Is the converse of (9) valid? In other words, if α and β commute under intercalation, must they have no letters in common?

4. [*M11*] The canonical factorization of (12), in the sense of Theorem A, is given in (17) when $a < b < c < d$. Find the corresponding canonical factorization when $d < c < b < a$.

5. [*M23*] Condition (b) of Theorem B requires $x < y$; what would happen if we weakened the relation to $x \leq y$?

6. [*M15*] How many strings are there which contain exactly m a's, n b's, and no other letters, with exactly k of the a's preceded immediately by a b?

7. [*M21*] How many strings on the letters a, b, c satisfying conditions (18) begin with the letter a? with the letter b? with c?

▸ **8.** [*20*] Find all factorizations of (12) into two factors $\alpha \intercal \beta$.

9. [*33*] Write computer programs which perform the factorizations of a given multiset permutation into the forms mentioned in Theorems A and C.

▸ **10.** [*M30*] *True or false:* Although the factorization into primes isn't quite unique, according to Theorem C, we can insure uniqueness in the following way: "There is a linear ordering $\prec$ of the set of primes such that every permutation of a multiset has a unique factorization $\sigma_1 \mathbin{⫿} \sigma_2 \mathbin{⫿} \cdots \mathbin{⫿} \sigma_n$ into primes subject to the condition that $\sigma_i \preceq \sigma_{i+1}$ whenever σ_i commutes with σ_{i+1}, for $1 \le i < n$."

11. [*M26*] Let $\sigma_1, \sigma_2, \ldots, \sigma_t$ be cycles without repeated elements. Define a partial ordering $\prec$ on the t objects $\{x_1, \ldots, x_t\}$ by saying that $x_i \prec x_j$ if $i < j$ and σ_i has at least one letter in common with σ_j. Prove the following connection between Theorem C and the notion of "topological sorting" (Section 2.2.3): *The number of distinct prime factorizations of* $\sigma_1 \mathbin{⫿} \sigma_2 \mathbin{⫿} \cdots \mathbin{⫿} \sigma_t$ *is the number of ways to sort the given partial ordering topologically.* (For example, corresponding to (22) we find that there are five ways to sort the ordering $x_1 \prec x_3$, $x_2 \prec x_4$, $x_1 \prec x_4$ topologically.) Conversely, given any partial ordering on t elements, there is a set of cycles

$$\{\sigma_1, \sigma_2, \ldots, \sigma_t\}$$

which defines that partial ordering in the stated way.

12. [*M16*] Show that (29) is a consequence of the assumptions of (28).

13. [*M21*] Prove that the number of permutations of $\{A \cdot a, B \cdot b, C \cdot c, D \cdot d, E \cdot e, F \cdot f\}$ containing no occurrences of the adjacent pairs of letters ca and db is

$$\sum_t \binom{D}{A-t}\binom{A+B+E+F}{t}\binom{A+B+C+E+F-t}{B}\binom{C+D+E+F}{C,D,E,F}.$$

14. [*M30*] One way to define the "inverse" π^{-1} of a general permutation π, suggested by other definitions in this section, is to interchange the lines of the two-line representation of π and then to do a stable sort of the columns in order to bring the top row into nondecreasing order. For example, if $a < b < c < d$, this definition implies that $c\ a\ b\ d\ d\ a\ b\ d\ a\ d^{-1} = a\ c\ d\ a\ d\ a\ b\ b\ d\ d$.

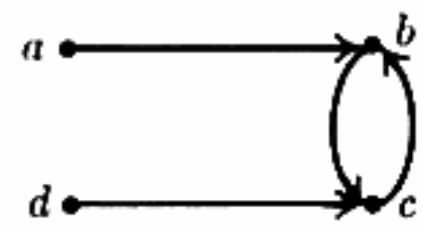
Explore properties of this inversion operation; for example, does it have any simple relation with intercalation products? Can we count the number of permutations such that $\pi = \pi^{-1}$?

▸ **15.** [*M25*] Prove that the permutation $a_1 \ldots a_n$ of the multiset

$$\{n_1 \cdot x_1, n_2 \cdot x_2, \ldots, n_m \cdot x_m\},$$

where $x_1 < x_2 < \cdots < x_n$ and $n_1 + n_2 + \cdots + n_m = m$, is a cycle if and only if the directed graph with vertices $\{x_1, x_2, \ldots, x_m\}$ and arcs from x_j to $a_{n_1+\cdots+n_j}$ contains precisely one oriented cycle. In the latter case, the number of ways to represent the permutation in cycle form is the length of the oriented cycle. For example, the directed graph corresponding to

$$\begin{pmatrix} a & a & a & b & b & c & c & c & d & d \\ d & c & b & a & c & a & a & b & d & c \end{pmatrix}$$ is



and the two ways to represent the permutation as a cycle are $(b\ a\ d\ d\ c\ a\ c\ a\ b\ c)$ and $(c\ a\ d\ d\ c\ a\ c\ b\ a\ b)$.

16. [*M35*] We found the generating function for *inversions* of permutations in the previous section, Eq. (8), in the special case that a set was being permuted. Show that, in general, if a *multiset* is permuted, the generating function for inversions is the "z-multinomial coefficient"

$$\binom{n}{n_1, n_2, \ldots}_z = \frac{n!_z}{n_1!_z n_2!_z \ldots}, \qquad \text{where} \qquad m!_z = (1 - z)(1 - z^2) \ldots (1 - z^m).$$

[Cf. (3); z-binomial coefficients were defined in Eq. 1.2.6–37.]

17. [*M24*] Find the average and standard deviation of the number of inversions in a random permutation of a given multiset, using the generating function found in exercise 16.

18. [*M30*] (P. A MacMahon.) The *index* of a permutation $a_1 a_2 \ldots a_n$ was defined in the previous section; and we proved that the number of permutations of a given set which have a given index k is the same as the number of permutations which have k inversions. Does the same result hold for permutations of a given multiset?

19. [*HM28*] Define the *Möbius function* $\mu(\pi)$ of a permutation π to be 0 if π contains repeated elements, otherwise $(-1)^k$ if π is the product of k primes. (Compare with the definition of the ordinary Möbius function, exercise 4.5.2–10.) (a) Prove that if $\pi \neq \epsilon$, we have

$$\sum \mu(\lambda) = 0,$$

summed over all permutations λ which are left factors of π (i.e., $\lambda \tau \rho = \pi$ for some ρ). (b) Given that $x_1 < x_2 < \cdots < x_m$ and $\pi = x_{i_1} x_{i_2} \cdots x_{i_n}$, where $1 \leq i_j \leq m$ for $1 \leq j \leq n$, prove that

$$\mu(\pi) = (-1)^n \epsilon(i_1\, i_2 \ldots i_n), \qquad \text{where} \qquad \epsilon(i_1\, i_2 \ldots i_n) = \operatorname{sign} \prod_{1 \leq j < k \leq n} (i_k - i_j).$$

20. [*HM33*] (D. Foata.) Let (a_{ij}) be any matrix of real numbers. In the notation of the previous exercise, part (b), define $\nu(\pi) = a_{i_1 j_1} \ldots a_{i_n j_n}$, where the two-line notation for π is

$$\begin{pmatrix} x_{i_1} & x_{i_2} & \ldots & x_{i_n} \\ x_{j_1} & x_{j_2} & \ldots & x_{j_n} \end{pmatrix}.$$

This function is useful in the computation of generating functions for permutations of a multiset, because $\sum \nu(\pi)$, summed over all permutations π of the multiset

$$\{n_1 \cdot x_1, \ldots, n_m \cdot x_m\},$$

will be the generating function for the number of permutations satisfying certain restrictions. For example, if we take $a_{ij} = z$ for $i = j$, and $a_{ij} = 1$ for $i \neq j$, then $\sum \nu(\pi)$ is the generating function for the number of "fixed points" (columns in which the top and bottom entries are equal). In order to study $\sum \nu(\pi)$ for all multisets simultaneously, we consider the function

$$G = \sum \pi \nu(\pi)$$

summed over all π in the set $\{x_1, \ldots, x_m\}^*$ of all permutations of multisets involving the elements $x_1, \ldots, x_m$, and we look at the coefficient of $x_1^{n_1} \ldots x_m^{n_m}$ in G.

In this formula for G we are treating π as the product of the x's. For example, when $m = 2$ we have

$$\begin{aligned} G &= 1 + x_1\nu(x_1) + x_2\nu(x_2) + x_1x_1\nu(x_1x_1) + x_1x_2\nu(x_1x_2) + x_2x_1\nu(x_2x_1) \\ &\quad + x_2x_2\nu(x_2x_2) + \cdots \\ &= 1 + x_1a_{11} + x_2a_{22} + x_1^2a_{11}^2 + x_1x_2a_{11}a_{22} + x_1x_2a_{21}a_{12} + x_2^2a_{22}^2 + \cdots . \end{aligned}$$

Thus the coefficient of $x_1^{n_1} \ldots x_m^{n_m}$ in G is $\sum\nu(\pi)$ summed over all permutations π of $\{n_1 \cdot x_1, \ldots, n_m \cdot x_m\}$. It is not hard to see that this coefficient is also the coefficient of $x_1^{n_1} \ldots x_m^{n_m}$ in the expression

$$(a_{11}x_1 + \cdots + a_{1m}x_m)^{n_1}(a_{21}x_1 + \cdots + a_{2m}x_m)^{n_2} \cdots (a_{m1}x_1 + \cdots + a_{mm}x_m)^{n_m}.$$

The purpose of this exercise is to prove what P. A. MacMahon called a "Master Theorem" in his *Combinatory Analysis* 1 (1915), Section 3, namely the formula

$$G = 1/D, \qquad \text{where} \qquad D = \det\begin{pmatrix} 1 - a_{11}x_1 & -a_{12}x_2 & \ldots & -a_{1m}x_m \\ -a_{21}x_1 & 1 - a_{22}x_2 & & -a_{2m}x_m \\ \vdots & & & \vdots \\ -a_{m1}x_1 & -a_{m2}x_2 & \ldots & 1 - a_{mn}x_m \end{pmatrix}.$$

For example, if $a_{ij} = 1$ for all i and j, this formula gives

$$G = 1/(1 - (x_1 + x_2 + \cdots + x_m)),$$

and the coefficient of $x_1^{n_1} \ldots x_m^{n_m}$ turns out to be $(n_1 + \cdots + n_m)!/n_1! \ldots n_m!$ as it should.

To prove the Master Theorem, show that (a) $\nu(\pi \top \rho) = \nu(\pi)\nu(\rho)$; (b) $D = \sum\pi\mu(\pi)\nu(\pi)$, in the notation of exercise 19, summed over all permutations π in

$$\{x_1, \ldots, x_m\}^*;$$

and (c) therefore $D \cdot G = 1$.

*5.1.3. Runs

In Section 3.3.2, we considered "runs up" in a permutation, as one method of testing the randomness of a sequence. If we place a vertical line at both ends of a permutation $a_1\, a_2 \ldots a_n$ and also between a_j and a_{j+1} whenever $a_j > a_{j+1}$, the *runs* are the segments between pairs of lines. For example, the permutation

$$|3\ 5\ 7|1\ 6\ 8\ 9|4|2|$$

has four runs. We determined the average number of runs of length k in a random permutation of $\{1, 2, \ldots, n\}$, as well as the covariance of the numbers of runs of lengths j and k. Runs are important in the study of sorting algorithms, because they represent sorted segments of the data, so we will now take up the subject of runs once again.

Let us use the notation

$$\left\langle {n \atop k} \right\rangle \tag{1}$$

to stand for the number of permutations of $\{1, 2, \ldots, n\}$ which have exactly k ascending runs. These numbers $\left\langle {n \atop k} \right\rangle$ arise in several contexts, and they are usually called *Eulerian numbers* since Euler discussed them in his famous book *Institutiones calculi differentialis* (St. Petersburg, 1755), 485–487 [Euler, *Opera Omnia* (1) **10** (1913), 373–375]; they should be distinguished from the so-called "Euler numbers" which are discussed in exercise 5.1.4–22.

We can use any given permutation on $\{1, \ldots, n-1\}$ to form n new permutations, by inserting the element n in all possible places. If the original permutation has k runs, exactly k of these new permutations will have k runs; the remaining $n-k$ will have $k+1$, since we increase the number of runs unless we place the element n at the end of an existing run. For example, the six permutations formed from 3 1 2 4 5 are

$$\begin{array}{lll} 6\ 3\ 1\ 2\ 4\ 5, & 3\ 6\ 1\ 2\ 4\ 5, & 3\ 1\ 6\ 2\ 4\ 5, \\ 3\ 1\ 2\ 6\ 4\ 5, & 3\ 1\ 2\ 4\ 6\ 5, & 3\ 1\ 2\ 4\ 5\ 6; \end{array}$$

all but the second and last of these have three runs instead of two. Therefore we have the recurrence relation

$$\left\langle {n \atop k} \right\rangle = k\left\langle {n-1 \atop k} \right\rangle + (n-k+1)\left\langle {n-1 \atop k-1} \right\rangle, \quad \text{integer } n \geq 1; \text{ integer } k. \tag{2}$$

By convention we will set

$$\left\langle {0 \atop k} \right\rangle = \delta_{1k}, \tag{3}$$

saying that the null permutation has one run. The reader may find it interesting to compare (2) with recurrence relations for Stirling numbers (Eqs. 1.2.6–42). Table 1 on page 37 lists the Eulerian numbers for small n.

Several patterns can be observed in Table 1. By definition, we have

$$\left\langle {n \atop 0} \right\rangle + \left\langle {n \atop 1} \right\rangle + \cdots + \left\langle {n \atop n} \right\rangle = n!; \tag{4}$$

$$\left\langle {n \atop 0} \right\rangle = 0, \qquad \left\langle {n \atop 1} \right\rangle = 1; \tag{5}$$

$$\left\langle {n \atop n} \right\rangle = 1, \qquad \text{for} \qquad n \geq 1. \tag{6}$$

There is also a rule of symmetry,

$$\left\langle {n \atop k} \right\rangle = \left\langle {n \atop n+1-k} \right\rangle, \qquad n \geq 1, \tag{7}$$

which comes from the fact that each permutation $a_1\, a_2 \ldots a_n$ having k runs corresponds to a permutation $a_n \ldots a_2 a_1$ having $n+1-k$ runs.

Another important property of the Eulerian numbers is the formula

$$\sum_k \left\langle {n \atop k} \right\rangle \binom{m+k-1}{n} = m^n, \qquad n \geq 0, \tag{8}$$

which we can prove by using the notion of sorting: Consider the m^n sequences $a_1\, a_2 \ldots a_n$ such that $1 \leq a_i \leq m$. We can sort any such sequence into non-decreasing order in a stable manner, obtaining the relation

$$a_{i_1} \leq a_{i_2} \leq \cdots \leq a_{i_n}, \tag{9}$$

where $i_1\, i_2 \ldots i_n$ is a uniquely determined permutation of $\{1, 2, \ldots, n\}$ such that $a_{i_j} = a_{i_{j+1}}$ implies $i_j < i_{j+1}$; in other words, $i_j > i_{j+1}$ implies that $a_{i_j} < a_{i_{j+1}}$. If the permutation $i_1\, i_2 \ldots i_n$ has k runs, we will show that the number of corresponding sequences $a_1\, a_2 \ldots a_n$ is $\binom{m+n-k}{n}$, and this proves (8) if we replace k by $n + 1 - k$.

For example, if $n = 9$ and $i_1\, i_2 \ldots i_n = 3\ 5\ 7\ 1\ 6\ 8\ 9\ 4\ 2$, we want to count the number of sequences $a_1\, a_2 \ldots a_n$ such that

$$1 \leq a_3 \leq a_5 \leq a_7 < a_1 \leq a_6 \leq a_8 \leq a_9 < a_4 < a_2 \leq m; \tag{10}$$

this is the number of sequences $b_1\, b_2 \ldots b_9$ such that

$$1 \leq b_1 < b_2 < b_3 < b_4 < b_5 < b_6 < b_7 < b_8 < b_9 \leq m + 5,$$

since we can let $b_1 = a_3, b_2 = a_5 + 1, b_3 = a_7 + 2, b_4 = a_1 + 2, b_5 = a_6 + 3$, etc. The number of choices of the b's is simply the number of ways of choosing 9 things out of $m + 5$, namely $\binom{m+5}{9}$; a similar proof works for general n and k, and for any permutation $i_1\, i_2 \ldots i_n$ with k runs.

Since both sides of (8) are polynomials in m, we may replace m by any real number x, and we obtain an interesting representation of powers in terms of consecutive binomial coefficients:

$$x^n = \left\langle {n \atop 1} \right\rangle \binom{x}{n} + \left\langle {n \atop 2} \right\rangle \binom{x+1}{n} + \cdots + \left\langle {n \atop n} \right\rangle \binom{x+n-1}{n}, \qquad n \geq 1. \tag{11}$$

For example,

$$x^3 = \binom{x}{3} + 4\binom{x+1}{3} + \binom{x+2}{3}.$$

This is the key property of Eulerian numbers which makes them useful in the study of discrete mathematics.

Setting $x = 1$ in (11) proves again that

$$\left\langle {n \atop n} \right\rangle = 1,$$

since the binomial coefficients vanish in all but the last term. Setting $x = 2$ yields

$$\left\langle {n \atop n-1} \right\rangle = 2^n - n - 1, \qquad n \geq 1. \tag{12}$$

Setting $x = 3, 4, \ldots$ shows that relation (11) completely defines the numbers $\left\langle {n \atop k} \right\rangle$, and leads to a formula originally given by Euler:

$$\begin{aligned} \left\langle {n \atop k} \right\rangle &= k^n - (k-1)^n \binom{n+1}{1} + (k-2)^n \binom{n+1}{2} - \cdots + (-1)^k 0^n \binom{n+1}{k} \\ &= \sum_{0 \leq j \leq k} (-1)^j (k-j)^n \binom{n+1}{j}, \qquad n \geq 0,\ k \geq 0. \end{aligned} \tag{13}$$

Now let us study the generating function for runs; if we set

$$g_n(z) = \sum_k \left\langle {n \atop k} \right\rangle z^k / n!, \tag{14}$$

the coefficient of z^k is the probability that a random permutation of $\{1, 2, \ldots, n\}$ has exactly k runs. Since k runs are just as likely as $n + 1 - k$, the average

Table 1

EULERIAN NUMBERS

n	$\left\langle {n \atop 0} \right\rangle$	$\left\langle {n \atop 1} \right\rangle$	$\left\langle {n \atop 2} \right\rangle$	$\left\langle {n \atop 3} \right\rangle$	$\left\langle {n \atop 4} \right\rangle$	$\left\langle {n \atop 5} \right\rangle$	$\left\langle {n \atop 6} \right\rangle$	$\left\langle {n \atop 7} \right\rangle$
0	0	1	0	0	0	0	0	0
1	0	1	0	0	0	0	0	0
2	0	1	1	0	0	0	0	0
3	0	1	4	1	0	0	0	0
4	0	1	11	11	1	0	0	0
5	0	1	26	66	26	1	0	0
6	0	1	57	302	302	57	1	0
7	0	1	120	1191	2416	1191	120	1

number of runs must be $\frac{1}{2}(n+1)$, hence $g_n'(1) = \frac{1}{2}(n+1)$. Exercise 2(b) shows that there is a simple formula for *all* the derivatives of $g_n(z)$ at the point $z = 1$:

$$g_n^{(m)}(1) = \left\{ {n+1 \atop n+1-m} \right\} \Big/ \binom{n}{m}, \qquad n \geq m. \tag{15}$$

Thus in particular the variance $g_n''(1) + g_n'(1) - g_n'(1)^2$ comes to $\frac{1}{12}(n+1)$, for $n \geq 2$, indicating a rather stable distribution about the mean. (We found

this same quantity in Eq. 3.3.2–18, where it was called covar (R_1', R_1').) Since $g_n(z)$ is a polynomial, we can use formula (15) to deduce the Taylor series expansions

$$\begin{aligned} g_n(z) &= \frac{1}{n!} \sum_{0\le k\le n} (z-1)^{n-k} k! \left\{ {n+1 \atop k+1} \right\} \\ &= \frac{1}{n!} \sum_{0\le k\le n} z^{k+1}(1-z)^{n-k} k! \left\{ {n+1 \atop k+1} \right\}. \end{aligned} \tag{16}$$

The second of these equations follows from the first, since

$$g_n(z) = z^{n+1} g_n(1/z), \qquad n \ge 1, \tag{17}$$

by the symmetry condition (7). The Stirling number recurrence

$$\left\{ {n+1 \atop k+1} \right\} = (k+1) \left\{ {n \atop k+1} \right\} + \left\{ {n \atop k} \right\}$$

gives two slightly simpler representations,

$$g_n(z) = \frac{1}{n!} \sum_{0\le k\le n} z(z-1)^{n-k} k! \left\{ {n \atop k} \right\} = \frac{1}{n!} \sum_{0\le k\le n} z^k (1-z)^{n-k} k! \left\{ {n \atop k} \right\}. \tag{18}$$

The super generating function

$$g(z, x) = \sum_{n\ge 0} g_n(z) x^n = \sum_{k,n\ge 0} \left\langle {n \atop k} \right\rangle z^k x^n / n! \tag{19}$$

is therefore equal to

$$z \sum_{k,n\ge 0} \frac{((z-1)x)^n}{(z-1)^k} \left\{ {n \atop k} \right\} \frac{k!}{n!} = z \sum_{k\ge 0} \left(\frac{e^{(z-1)x} - 1}{z-1} \right)^k = \frac{z(1-z)}{e^{(z-1)x} - z}; \tag{20}$$

this is another relation discussed by Euler.

Further properties of the Eulerian numbers may be found in a survey paper by L. Carlitz [*Math. Magazine* **33** (1959), 247–260]; see also J. Riordan, *Introduction to Combinatorial Analysis* (New York: Wiley, 1958), 38–39, 214–219, 234–237.

Let us now consider the length of runs; how long will a run be, on the average? We have already studied the expected number of runs of given length, in Section 3.3.2; the average run length is approximately 2, in agreement with the fact that about $\frac{1}{2}(n+1)$ runs appear in a random permutation of length n. For applications to sorting algorithms, a slightly different viewpoint is useful; we will consider the length of the kth run of the permutation from left to right, for $k = 1, 2, \ldots$.

For example, how long is the first (leftmost) run of a random permutation $a_1\, a_2 \ldots a_n$? Its length is always ≥ 1, and its length is ≥ 2 exactly one-half the time (namely when $a_1 < a_2$). Its length is ≥ 3 exactly one-sixth the time (when $a_1 < a_2 < a_3$), and, in general, its length is $\geq m$ with probability $q_m = 1/m!$, for $1 \leq m \leq n$. The probability that its length is exactly equal to m is therefore

$$\begin{aligned} &p_m = q_m - q_{m+1} = 1/m! - 1/(m+1)!, \qquad \text{for} \qquad 1 \leq m < n; \\ &p_n = 1/n!. \end{aligned} \tag{21}$$

The average length is therefore

$$\begin{aligned} p_1 + 2p_2 + \cdots + np_n &= (q_1 - q_2) + 2(q_2 - q_3) + \cdots + (n-1)(q_{n-1} - q_n) + nq_n \\ &= q_1 + q_2 + \cdots + q_n \\ &= \frac{1}{1!} + \frac{1}{2!} + \cdots + \frac{1}{n!}. \end{aligned} \tag{22}$$

If we let $n \to \infty$, the limit is $e - 1 = 1.71828\ldots$, and for finite n the value is $e - 1 - \delta_n$ where δ_n is quite small;

$$\delta_n = \frac{1}{(n+1)!}\left(1 + \frac{1}{n+2} + \frac{1}{(n+2)(n+3)} + \cdots\right) < \frac{e-1}{(n+1)!}.$$

For practical purposes it is therefore convenient to study runs in a random *infinite* sequence of distinct numbers

$$a_1, a_2, a_3, \ldots;$$

by "random" we mean in this case that each of the $n!$ possible relative orderings of the first n elements in the sequence is equally likely. The average length of the first run in a random infinite sequence is therefore $e - 1$.

By slightly sharpening this method, we can ascertain the average length of the kth run in a random sequence. Let q_{km} be the probability that the first k runs have total length $\geq m$; then q_{km} is $1/m!$ times the number of permutations of $\{1, 2, \ldots, m\}$ that have $\leq k$ runs,

$$q_{km} = \left(\left\langle {m \atop 1} \right\rangle + \cdots + \left\langle {m \atop k} \right\rangle\right) \Big/ m!. \tag{23}$$

The probability that the first k runs have total length m is $q_{km} - q_{k(m+1)}$. Therefore if L_k denotes the average length of the kth run, we find that

$$\begin{aligned} L_1 + \cdots + L_k &= \text{average total length of first } k \text{ runs} \\ &= (q_{k1} - q_{k2}) + 2(q_{k2} - q_{k3}) + 3(q_{k3} - q_{k4}) + \cdots \\ &= q_{k1} + q_{k2} + q_{k3} + \cdots. \end{aligned}$$

Subtracting $L_1 + \cdots + L_{k-1}$ and using the value of q_{km} in (23) yields the desired formula

$$L_k = \frac{1}{1!}\left\langle {1 \atop k} \right\rangle + \frac{1}{2!}\left\langle {2 \atop k} \right\rangle + \frac{1}{3!}\left\langle {3 \atop k} \right\rangle + \cdots = \sum_{m \geq 1} \left\langle {m \atop k} \right\rangle \frac{1}{m!}. \tag{24}$$

Since $\left\langle {0 \atop k} \right\rangle = 0$ except when $k = 1$, L_k turns out to be the coefficient of z^k in the generating function $g(z, 1) - z$ (see Eq. 19), so we have

$$L(z) = \sum_{k \geq 0} L_k z^k = \frac{z(1 - z)}{e^{z-1} - z} - z. \tag{25}$$

From Euler's formula (13) we obtain a representation of L_k as a polynomial in e:

$$\begin{aligned} L_k &= \sum_{m \geq 0} \sum_{0 \leq j \leq k} (-1)^{k-j} \binom{m+1}{k-j} \frac{j^m}{m!} \\ &= \sum_{0 \leq j \leq k} (-1)^{k-j} \sum_{m \geq 0} \binom{m}{k-j} \frac{j^m}{m!} + \sum_{0 \leq j \leq k} (-1)^{k-j} \sum_{m \geq 0} \binom{m}{k-j-1} \frac{j^m}{m!} \\ &= \sum_{0 \leq j \leq k} \frac{(-1)^{k-j} j^{k-j}}{(k-j)!} \sum_{n \geq 0} \frac{j^n}{n!} + \sum_{0 \leq j \leq k} \frac{(-1)^{k-j} j^{k-j-1}}{(k-j-1)!} \sum_{n \geq 0} \frac{j^n}{n!} \\ &= k \sum_{0 \leq j \leq k} e^j \frac{(-1)^{k-j} j^{k-j-1}}{(k-j)!}. \end{aligned} \tag{26}$$

This formula for L_k was first obtained by B. J. Gassner [see *CACM* **10** (1967), 89–93]. In particular, we have

$$\begin{aligned} L_1 &= e - 1 && \approx 1.71828\ldots; \\ L_2 &= e^2 - 2e && \approx 1.95249\ldots; \\ L_3 &= e^3 - 3e^2 + \tfrac{3}{2}e && \approx 1.99579\ldots. \end{aligned}$$

So the second run is expected to be longer than the first, and the third run will be longer yet, on the average! This may seem surprising at first glance, but a moment's reflection shows that, since the first element of the second run tends to be small (it caused the first run to terminate), there is a better chance for the second run to go on longer. The first element of the third run will tend to be even smaller than that of the second.

The numbers L_k are of importance in the theory of replacement-selection sorting (Section 5.4.1), so it is interesting to study their values in detail. Table 2, which has been computed by J. W. Wrench, Jr., shows the first 18 values of L_k to 15 decimal places. Our discussion in the preceding paragraph might lead us to suspect at first that $L_{k+1} > L_k$, but in fact the values oscillate back and forth. Note that L_k rapidly approaches the limiting value 2; it is quite remarkable to see these monic polynomials in the transcendental number e con-

Table 2

AVERAGE LENGTH OF THE kTH RUN

k	L_k	k	L_k
1	1.71828 18284 59045+	10	2.00000 00012 05997+
2	1.95249 24420 12560−	11	2.00000 00001 93672+
3	1.99579 13690 84285−	12	1.99999 99999 99909+
4	2.00003 88504 76806−	13	1.99999 99999 97022−
5	2.00005 75785 89716+	14	1.99999 99999 99719+
6	2.00000 50727 55710−	15	2.00000 00000 00019+
7	1.99999 96401 44022+	16	2.00000 00000 00006+
8	1.99999 98889 04744+	17	2.00000 00000 00000+
9	1.99999 99948 43434−	18	2.00000 00000 00000−

verging to the rational number 2 so quickly! The polynomials (26) are also somewhat interesting from the standpoint of numerical analysis, since they provide an excellent example of the loss of significant figures when nearly equal numbers are subtracted; using 19-digit floating-point arithmetic, Gassner incorrectly concluded that $L_{12} > 2$, and Wrench has remarked that 42-digit floating-point arithmetic gives L_{28} correct to only 29 significant digits.

The asymptotic behavior of L_k can be determined by using simple principles of complex variable theory. The denominator of (25) is zero only when $e^{z-1} = z$, i.e. (writing $z = x + iy$) when

$$e^{x-1}\cos y = x \qquad \text{and} \qquad e^{x-1}\sin y = y. \tag{27}$$

Figure 3 shows the superimposed graphs of these two equations, and we note that they intersect at the points $z = z_0, z_1, \bar{z}_1, z_2, \bar{z}_2, \ldots$, where $z_0 = 1$,

$$z_1 = (3.08884\ 30156\ 13044-) + (7.46148\ 92856\ 54255-)i, \tag{28}$$

and the imaginary part $\Im(z_{k+1})$ is roughly equal to $\Im(z_k) + 2\pi$ for large k. Since

$$\lim_{z\to z_k}\left(\frac{1-z}{e^{z-1}-z}\right)(z - z_k) = -1, \qquad \text{for} \qquad k > 0,$$

and since the limit is -2 for $k = 0$, the function

$$R_m(z) = L(z) + \frac{2}{z - z_0} + \frac{z_1}{z - z_1} + \frac{\bar{z}_1}{z - \bar{z}_1} + \frac{z_2}{z - z_2} + \frac{\bar{z}_2}{z - \bar{z}_2} + \cdots + \frac{z_m}{z - z_m} + \frac{\bar{z}_m}{z - \bar{z}_m}$$

has no singularities in the complex plane for $|z| < |z_{m+1}|$. Hence $R_m(z)$ has a power series expansion $\sum_k \rho_k z^k$ which converges absolutely when $|z| < |z_{m+1}|$; it follows that $\rho_k M^k \to 0$ as $k \to \infty$, where $M = |z_{m+1}| - \epsilon$. The coefficients

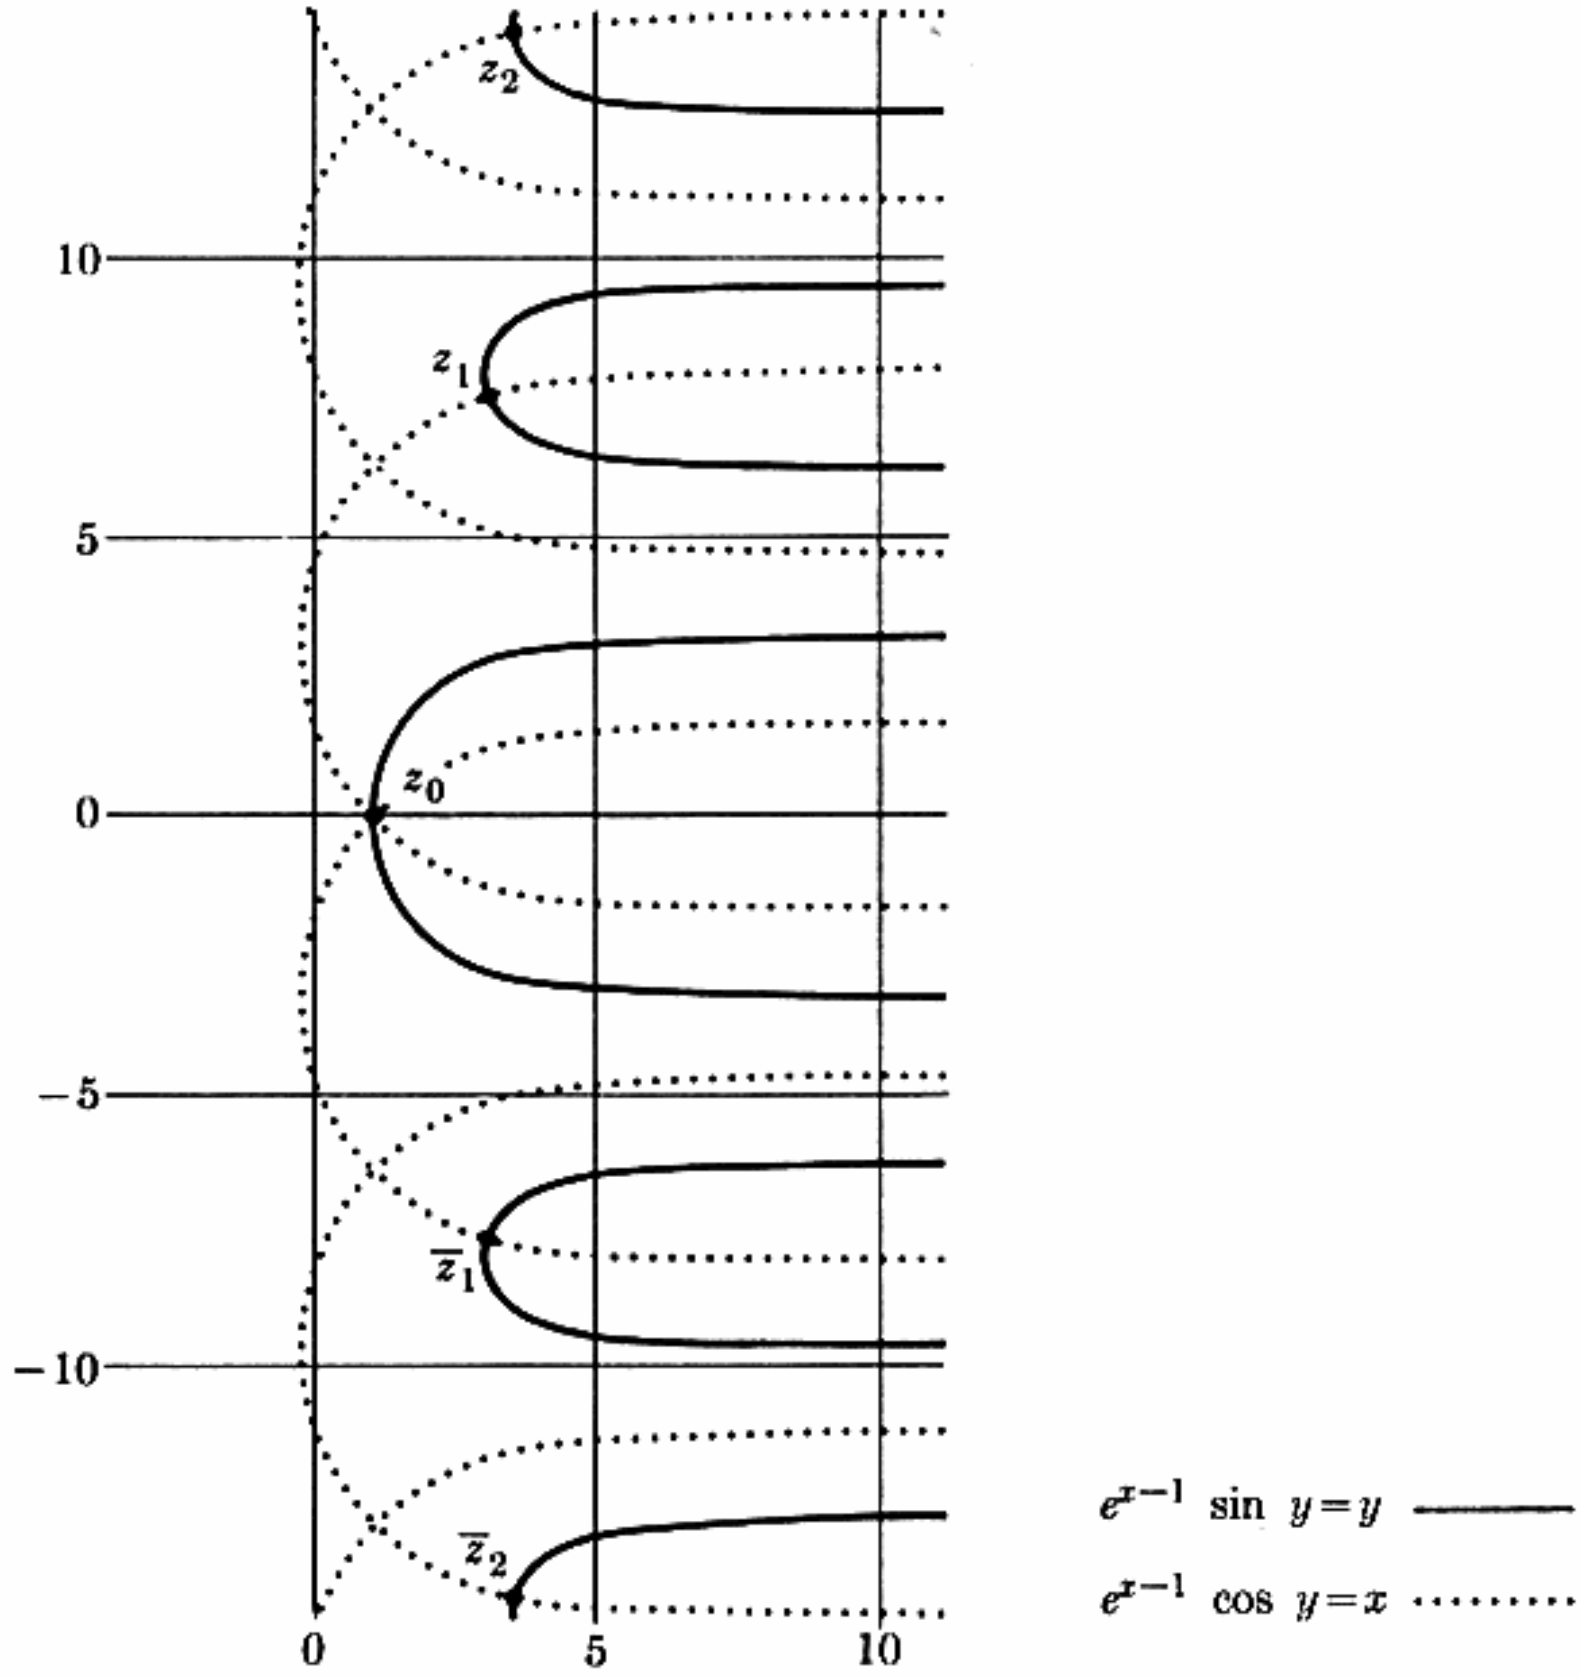


Fig. 3. Roots of $e^{z-1} = z$.

of $L(z)$ are the coefficients of

$$\frac{2}{1-z} + \frac{1}{1-z/z_1} + \frac{1}{1-z/\bar{z}_1} + \cdots + \frac{1}{1-z/z_m} + \frac{1}{1-z/\bar{z}_m} + R_m(z),$$

namely,

$$L_n = 2 + 2r_1^{-n}\cos n\theta_1 + 2r_2^{-n}\cos n\theta_2 + \cdots + 2r_m^{-n}\cos n\theta_m + O(r_{m+1}^{-n}), \quad (29)$$

if we let

$$z_k = r_k e^{i\theta_k}. \quad (30)$$

This shows the asymptotic behavior of L_n. We have

$$\begin{aligned} r_1 &= 8.07556\ 64528\ 89526-, \\ \theta_1 &= 1.17830\ 39784\ 74668+; \end{aligned}$$

$$\begin{aligned} r_2 &= 14.35457-, & \theta_2 &= 1.31269-; \\ r_3 &= 20.62073+, & \theta_3 &= 1.37428-; \\ r_4 &= 26.88795+, & \theta_4 &= 1.41050-; \end{aligned} \quad (31)$$

so the main contribution to $L_n - 2$ is due to r_1 and θ_1, and convergence of

(29) is quite rapid. The stated values of r_1 and θ_1 were determined by J. W. Wrench, Jr. Further analysis [W. W. Hooker, *CACM* **12** (1969), 411–413] shows that $R_m(z) \to -z$ as $m \to \infty$; hence the series $2\sum_{k\geq 0} r_k^{-n} \cos n\theta_k$ actually *converges* to L_n when $n > 1$.

A more careful examination of probabilities can be carried out to determine the complete probability distribution for the length of the kth run and for the total length of the first k runs (see exercises 9, 10, 11). The sum $L_1 + \cdots + L_k$ turns out to be asymptotically $2k - \frac{1}{3}$.

Let us conclude this section by considering the properties of runs when equal elements are allowed to appear in the permutations. The famous nineteenth-century American astronomer Simon Newcomb amused himself by playing a game of solitaire related to this question. He would deal a deck of cards into a pile, so long as the face values were in nondecreasing order; but whenever the next card to be dealt had a face value lower than its predecessor, he would start a new pile. He wanted to know the probability that a given number of piles would be formed after the entire deck had been dealt out in this manner.

Simon Newcomb's problem therefore consists of finding the probability distribution of runs in a random permutation of a multiset. The general answer is rather complicated (see exercise 12), although we have already seen how to solve the special case when all cards have a distinct face value. We will content ourselves here with a derivation of the *average* number of piles which appear in the game.

Suppose first that there are m different types of cards, each occurring exactly p times. An ordinary bridge deck, for example, has $m = 13$ and $p = 4$ if suits are disregarded. A remarkable symmetry applying to this case was discovered by P. A. MacMahon [*Combinatory Analysis* **1** (Cambridge, 1915), 212–213]: The number of permutations with $k+1$ runs is the same as the number with $mp - p - k + 1$ runs. When $p = 1$, this relation is easy to verify (Eq. 7), but for $p > 1$ it is quite surprising.

We can prove the symmetry by setting up a one-to-one correspondence between the permutations in such a way that each permutation with $k+1$ runs corresponds to another having $mp - p - k + 1$. The reader is urged to try his hand at discovering such a correspondence before reading further.

No very simple correspondence is evident; MacMahon's proof was based on generating functions instead of a combinatorial construction. But Foata's correspondence (Theorem 5.1.2B) provides a useful simplification, because it tells us that there is a one-to-one correspondence between permutations with $k+1$ runs and permutations whose two-line notation contains exactly k columns $\binom{y}{x}$ with $x < y$.

Suppose the given multiset is $\{p \cdot 1, p \cdot 2, \ldots, p \cdot m\}$, and consider the permutation whose two-line notation is

$$\begin{pmatrix} 1 & \ldots & 1 & 2 & \ldots & 2 & \ldots & m & \ldots & m \\ x_{11} & \ldots & x_{1p} & x_{21} & \ldots & x_{2p} & \ldots & x_{m1} & \ldots & x_{mp} \end{pmatrix}. \tag{32}$$

We can associate this permutation with another permutation of the same multiset,

$$\begin{pmatrix} 1 & \dots & 1 & 2 & \dots & 2 & \dots & m & \dots & m \\ x'_{11} & \dots & x'_{1p} & x'_{m1} & \dots & x'_{mp} & \dots & x'_{21} & \dots & x'_{2p} \end{pmatrix}, \tag{33}$$

where $x' = m + 1 - x$. If (32) contains k columns of the form $\binom{y}{x}$ with $x < y$, then (33) contains $(m-1)p - k$ such columns; for we need only consider the case $y > 1$, and $x < y$ is equivalent to $x' \geq m + 2 - y$. Since (32) corresponds to a permutation with $k+1$ runs, and (33) corresponds to a permutation with $mp - p - k + 1$ runs, and since the transformation which takes (32) into (33) is reversible [it takes (33) back into (32)], MacMahon's symmetry condition has been established. See exercise 14 for an example of this construction.

Because of the symmetry property, the average number of runs in a random permutation must be $\frac{1}{2}\big((k+1) + (mp - p - k + 1)\big) = 1 + \frac{1}{2}p(m-1)$. For example, the average number of piles resulting from Simon Newcomb's solitaire game using a standard deck will be 25 (so it doesn't appear to be a very exciting way to play solitaire).

We can actually determine the average number of runs in general, using a fairly simple argument, given *any* multiset $\{n_1 \cdot x_1, n_2 \cdot x_2, \dots, n_m \cdot x_m\}$ where the x's are distinct. Let $n = n_1 + n_2 + \cdots + n_m$, and imagine that all of the permutations $a_1\, a_2 \dots a_n$ of this multiset have been written down; we will count how often a_i is greater than a_{i+1}, for each fixed value of i, $1 \leq i < n$. The number of times $a_i > a_{i+1}$ is just half of the number of times $a_i \neq a_{i+1}$; and it is not difficult to see that $a_i = a_{i+1} = x_j$ exactly $Nn_j(n_j - 1)/n(n-1)$ times, where N is the total number of permutations. Hence $a_i = a_{i+1}$ exactly

$$\frac{N}{n(n-1)}\left(n_1(n_1-1) + \cdots + n_m(n_m-1)\right) = \frac{N}{n(n-1)}\left(n_1^2 + \cdots + n_m^2 - n\right)$$

times, and $a_i > a_{i+1}$ exactly

$$\frac{N}{2n(n-1)}\left(n^2 - (n_1^2 + \cdots + n_m^2)\right)$$

times. Summing over i and adding N, since a run ends at a_n in each permutation, we obtain the total number of runs among all N permutations:

$$N\left(\frac{n}{2} - \frac{1}{2n}(n_1^2 + \cdots + n_m^2) + 1\right). \tag{34}$$

Dividing by N gives the desired average number of runs.

Since runs are important in the study of "order statistics," there is a fairly large literature dealing with them, including several other types of runs not considered here. For additional information, see the book *Combinatorial Chance* by F. N. David and D. E. Barton (London: Griffin, 1962), Chapter 10; and

the survey paper by D. E. Barton and C. L. Mallows, *Annals of Math. Statistics* **36** (1965), 236–260. Further connections between Eulerian numbers and permutations appear in *Théorie Géométrique des Polynômes Eulériens* by D. Foata and M. P. Schützenberger, *Lecture Notes in Math.* **138** (Berlin: Springer, 1970), 94 pp.

EXERCISES

1. [*M26*] Derive Euler's formula (13).

▶ **2.** [*M22*] (a) Extend the idea used in the text to prove (8), considering those sequences $a_1\, a_2 \ldots a_n$ which contain exactly q distinct elements, in order to prove that

$$\sum_k \left\langle {n \atop k} \right\rangle \binom{k-1}{n-q} = \left\{ {n \atop q} \right\} q!.$$

(b) Use this identity to prove that

$$\sum_k \left\langle {n \atop k} \right\rangle \binom{k}{m} = \left\{ {n+1 \atop n+1-m} \right\} (n-m)!, \qquad \text{for} \qquad n \geq m.$$

3. [*HM25*] Evaluate the sum $\sum_k \langle {n \atop k} \rangle (-1)^k$.

4. [*M21*] What is the value of

$$\sum_k (-1)^k \left\{ {n \atop k} \right\} k! \binom{n-k}{m} ?$$

5. [*M20*] Find the value of $\langle {p \atop k} \rangle \bmod p$ when p is prime.

▶ **6.** [*M21*] Mr. B. C. Dull noticed that, by Eqs. (4) and (13),

$$n! = \sum_{k\geq 0} \left\langle {n \atop k} \right\rangle = \sum_{k\geq 0} \sum_{j\geq 0} (-1)^{k-j} \binom{n+1}{k-j} j^n.$$

Carrying out the sum on k first, he found that $\sum_{k\geq 0}(-1)^{k-j}\binom{n+1}{k-j} = 0$ for all $j \geq 0$; hence $n! = 0$ for all $n \geq 0$. Did he make a mistake?

7. [*HM40*] Is the probability distribution of runs, given by (14), asymptotically normal? (Cf. exercise 1.2.10–13.)

8. [*M24*] (P. A. MacMahon.) Show that the probability that the first run of a sufficiently long permutation has length l_1, the second has length l_2, . . . , and the kth has length $\geq l_k$, is

$$\det \begin{pmatrix} 1/l_1! & 1/(l_1+l_2)! & 1/(l_1+l_2+l_3)! & \ldots & 1/(l_1+l_2+l_3+\cdots+l_k)! \\ 1 & 1/l_2! & 1/(l_2+l_3)! & \ldots & 1/(l_2+l_3+\cdots+l_k)! \\ 0 & 1 & 1/l_3! & \ldots & 1/(l_3+\cdots+l_k)! \\ \vdots & & & & \vdots \\ 0 & 0 & \ldots & 1 & 1/l_k! \end{pmatrix}.$$

9. [*M30*] Let $h_k(z) = \sum p_{km} z^m$, where p_{km} is the probability that m is the total

length of the first k runs in a random (infinite) sequence. Find "simple" expressions for $h_1(z)$, $h_2(z)$, and the super generating function $h(z, x) = \sum_k h_k(z)x^k$.

10. [*HM30*] Find the asymptotic behavior of the mean and variance of the distributions $h_k(z)$ in the preceding exercise, for large k.

11. [*M40*] Let $H_k(z) = \sum p_{km}z^m$, where p_{km} is the probability that m is the length of the kth run in a random (infinite) sequence. Express $H_1(z)$, $H_2(z)$, and the super generating function $H(z, x) = \sum_k H_k(z)x^k$ in terms of familiar functions.

12. [*M33*] (P. A. MacMahon.) Generalize Eq. (13) to permutations of a multiset, by proving that the number of permutations of $\{n_1 \cdot 1, n_2 \cdot 2, \ldots, n_m \cdot m\}$ having exactly k runs is

$$\sum_{0\le j\le k} (-1)^j \binom{n+1}{j} \binom{n_1 - 1 + k - j}{n_1} \binom{n_2 - 1 + k - j}{n_2} \cdots \binom{n_m - 1 + k - j}{n_m},$$

where $n = n_1 + n_2 + \cdots + n_m$.

13. [*05*] If Simon Newcomb's solitaire game is played with a standard bridge deck, ignoring face value but treating ♣ < ♦ < ♥ < ♠, what is the average number of piles?

14. [*M17*] The permutation 3 1 1 1 2 3 1 4 2 3 3 4 2 2 4 4 has 5 runs; find the corresponding permutation with 9 runs, according to the text's construction for MacMahon's symmetry condition.

▸ **15.** [*M21*] (*Alternating runs.*) The classical nineteenth-century literature of combinatorial analysis did not treat the topic of runs in permutations, as we have considered them, but there were several papers dealing with "runs" which are alternately ascending and descending. Thus 5 3 2 4 7 6 1 8 was considered to have 4 runs,

5 3 2, 2 4 7, 7 6 1, 1 8.

(The first run would be ascending or descending, according as $a_1 < a_2$ or $a_1 > a_2$; thus $a_1\, a_2 \ldots a_n$ and $a_n \ldots a_2\, a_1$ and $(n+1-a_1)(n+1-a_2)\ldots(n+1-a_n)$ all have the same number of alternating runs.) When n elements are being permuted, the maximum number of runs of this kind is $n - 1$.

Find the average number of alternating runs in a random permutation of the set $\{1, 2, \ldots, n\}$. [*Hint:* Consider the proof of (34).]

16. [*M30*] Continuing the previous exercise, let $\langle\langle {n \atop k} \rangle\rangle$ be the number of permutations of $\{1, 2, \ldots, n\}$ which have exactly k alternating runs. Find a recurrence relation, by means of which a table of $\langle\langle {n \atop k} \rangle\rangle$ can be computed; and find the corresponding recurrence relation for the generating function $G_n(z) = \sum_k \langle\langle {n \atop k} \rangle\rangle z^k/n!$. Use the latter recurrence to discover a simple formula for the *variance* of the number of alternating runs in a random permutation of $\{1, 2, \ldots, n\}$.

17. [*M25*] Among all 2^n sequences $a_1\, a_2 \ldots a_n$, where each a_j is either 0 or 1, how many have exactly k runs (i.e., $k - 1$ occurrences of $a_j > a_{j+1}$)?

18. [*M27*] Among all $n!$ sequences $a_1\, a_2 \ldots a_n$, where each a_j is an integer in the range $0 \le a_j \le n - j$, how many have exactly k runs (i.e., $k - 1$ occurrences of $a_j > a_{j+1}$)?

▸ **19.** [*M26*] (J. Riordan.) (a) In how many ways can n nonattacking rooks (i.e., no two in the same row or column) be placed on an $n \times n$ chessboard, so that exactly k lie on a given side of the main diagonal? (b) In how many ways can k nonattacking rooks be placed on a given side of the main diagonal of an $n \times n$ chessboard?

For example, Fig. 4 shows one of the 15619 ways to put eight nonattacking rooks on a standard chessboard with three rooks in the unshaded portion below the main diagonal, together with one of the 1050 ways to put three nonattacking rooks on a triangular board.

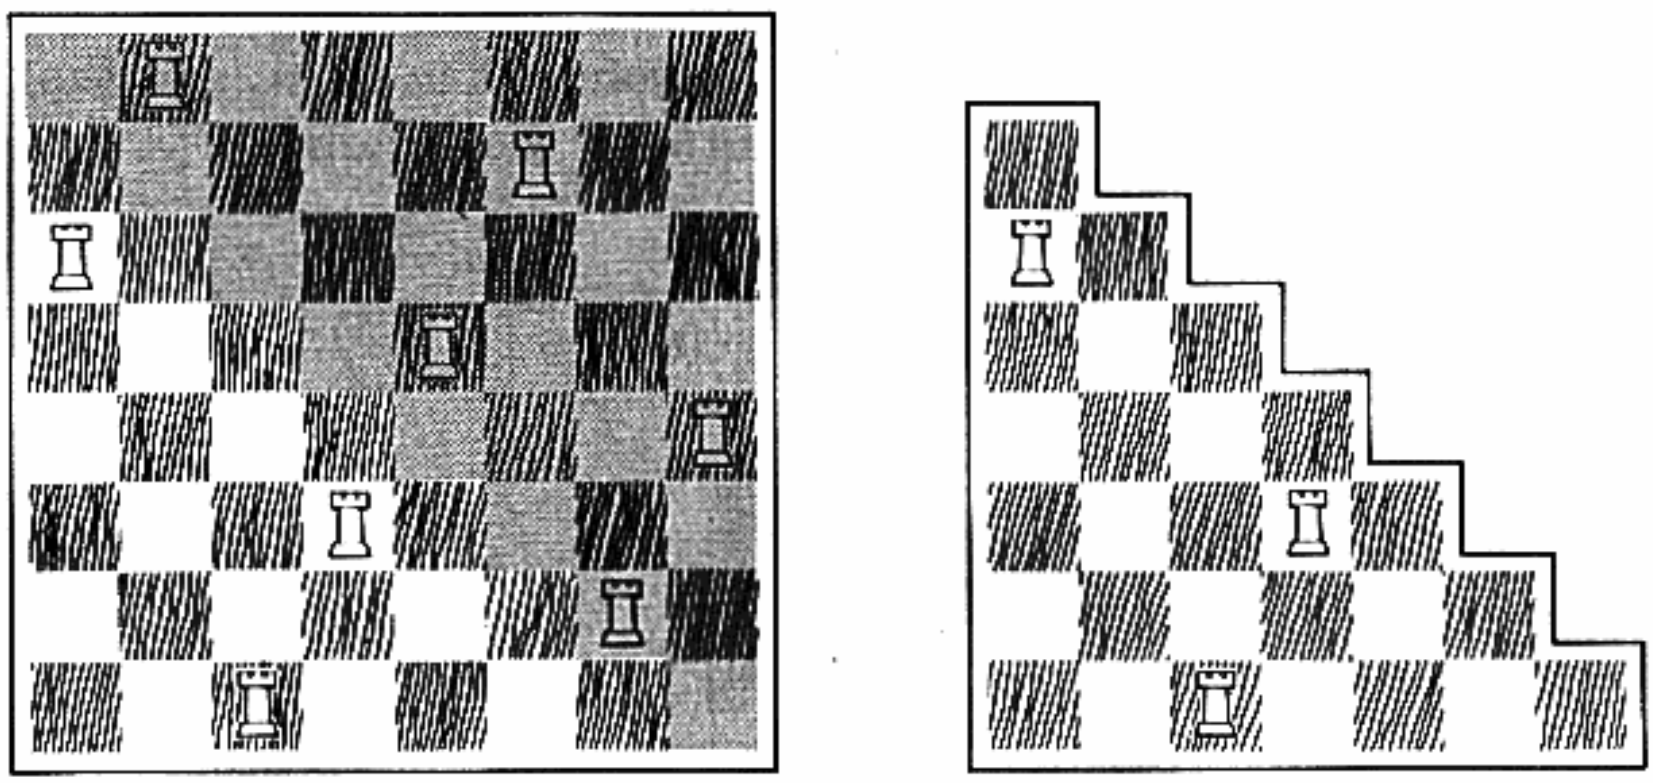

Fig. 4. Nonattacking rooks on a chessboard, with a given number below the main diagonal.

▸ **20.** [*M21*] A permutation is said to require k *readings* if we must scan it k times from left to right in order to read off its elements in nondecreasing order. For example, the permutation

4 9 1 8 2 5 3 6 7

requires four readings: On the first reading we obtain 1, 2, 3; on the second we get 4, 5, 6, 7; then 8; then 9. Find a connection between runs and readings.

21. [*M22*] If the permutation $a_1\, a_2 \ldots a_n$ of $\{1, 2, \ldots, n\}$ has k runs and requires j readings, in the sense of exercise 20, what can be said about $a_n \ldots a_2\, a_1$?

22. [*M26*] (L. Carlitz, D. P. Roselle, and R. A. Scoville.) Show that there is no permutation of $\{1, 2, \ldots, n\}$ with $n + 1 - r$ runs, and requiring s readings, if $rs < n$; but such permutations do exist if $n \geq n + 1 - r \geq s \geq 1$, $rs \geq n$.

23. [*HM42*] (Walter Weissblum.) The "long runs" of a permutation $a_1\, a_2 \ldots a_n$ are obtained by placing vertical lines just before a segment fails to be monotonic; long runs are either increasing or decreasing, depending on the order of their first two elements, so the length of each long run (except possibly the last) is ≥ 2. For example, 7 5|6 2|3 8 9|1 4 has four long runs. Find the average length of the first two long runs of an infinite permutation, and prove that the limiting long-run length is

$$(1 + \cot \tfrac{1}{2})/(3 - \cot \tfrac{1}{2}) \approx 2.4202.$$

24. [*M30*] What is the average number of runs in sequences generated as in exercise 5.1.1–18, as a function of p?

To complete our survey of the combinatorial properties of permutations, we will discuss some remarkable relations which connect permutations with arrays of integers called tableaux. A *Young tableau of shape* $(n_1, n_2, \ldots, n_m)$, where $n_1 \geq n_2 \geq \cdots \geq n_m \geq 0$, is an arrangement of $n_1 + n_2 + \cdots + n_m$ distinct integers in an array of left-justified rows, with n_i elements in row i, such that the entries of each row are in increasing order from left to right, and the entries of each column are increasing from top to bottom. For example,

1	2	5	9	10	15
3	6	7	13		
4	8	12	14		
11					

(1)

is a Young tableau of shape (6, 4, 4, 1). Such arrangements were introduced by Alfred Young in 1900 as an aid to the study of matrix representations of permutations [see, for example, D. E. Rutherford, *Substitutional Analysis* (New York: Hafner, 1968)]. For simplicity, we will simply say "tableau" instead of "Young tableau."

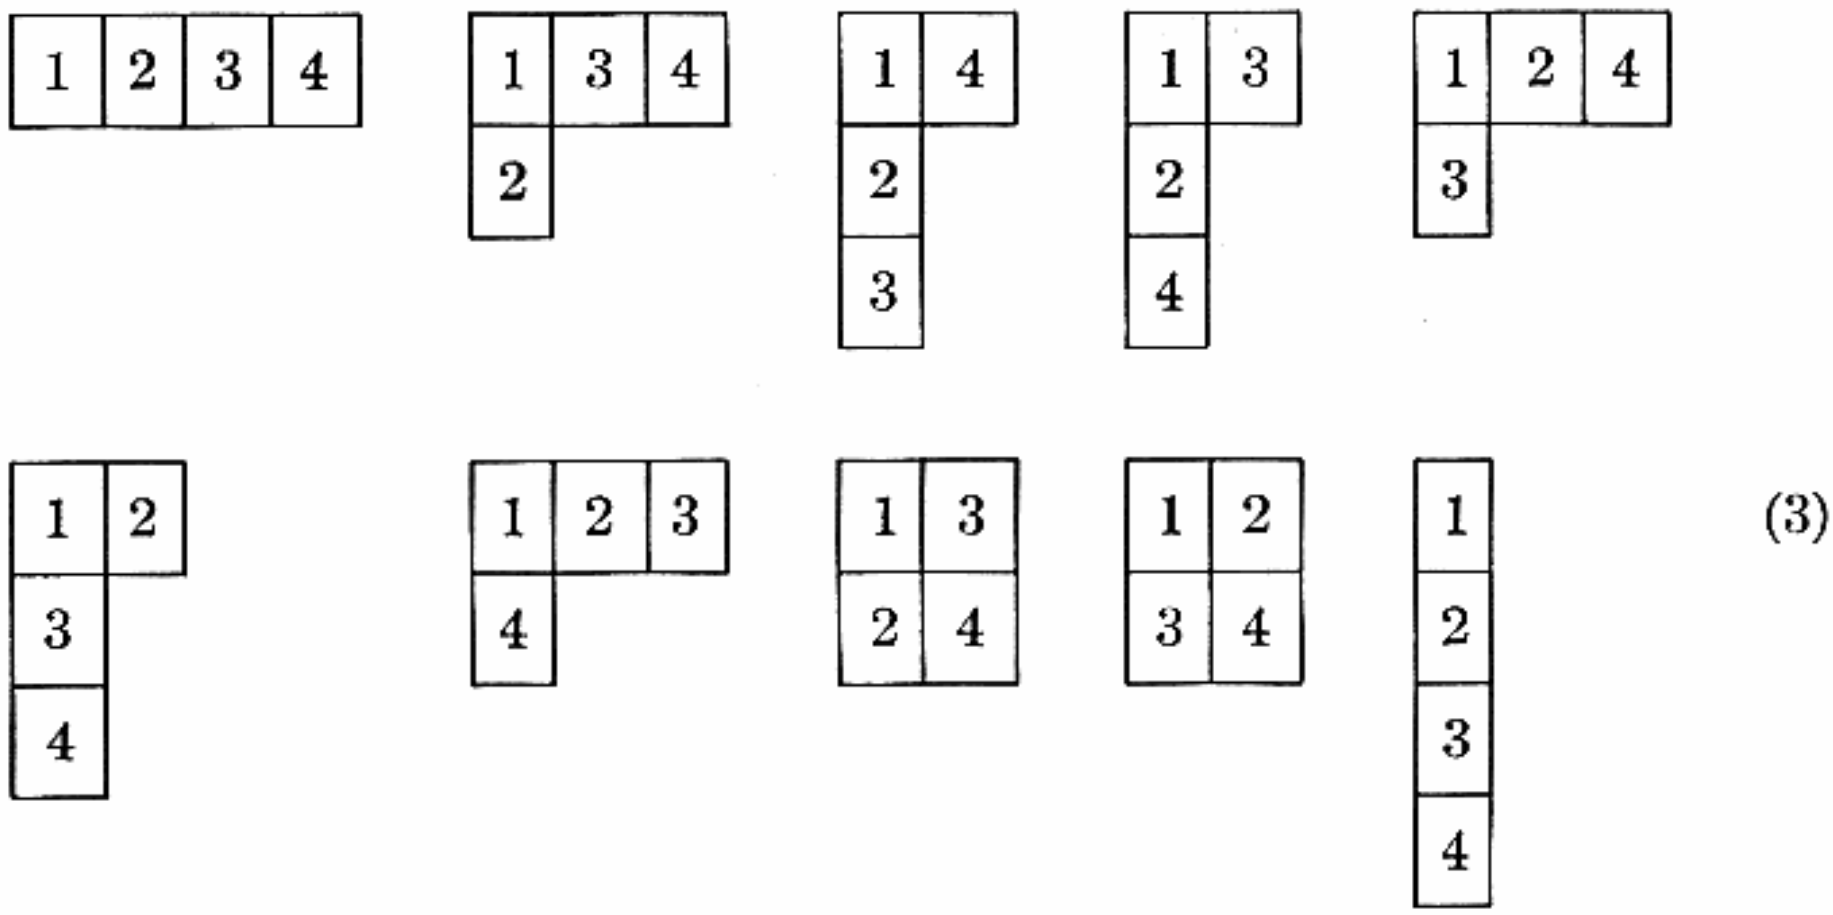
An *involution* is a permutation which is its own inverse. For example, there are 10 involutions of {1, 2, 3, 4},

$$\begin{pmatrix}1&2&3&4\\1&2&3&4\end{pmatrix}\ \begin{pmatrix}1&2&3&4\\2&1&3&4\end{pmatrix}\ \begin{pmatrix}1&2&3&4\\3&2&1&4\end{pmatrix}\ \begin{pmatrix}1&2&3&4\\4&2&3&1\end{pmatrix}\ \begin{pmatrix}1&2&3&4\\1&3&2&4\end{pmatrix}$$
$$\begin{pmatrix}1&2&3&4\\1&4&3&2\end{pmatrix}\ \begin{pmatrix}1&2&3&4\\1&2&4&3\end{pmatrix}\ \begin{pmatrix}1&2&3&4\\2&1&4&3\end{pmatrix}\ \begin{pmatrix}1&2&3&4\\3&4&1&2\end{pmatrix}\ \begin{pmatrix}1&2&3&4\\4&3&2&1\end{pmatrix} \tag{2}$$

The term "involution" originated in classical geometry problems; involutions in the general sense considered here were first studied by H. A. Rothe when he introduced the concept of inverses (see Section 5.1.1).

It may appear strange that we should be discussing both tableaux and involutions at the same time, but there is an extraordinary connection between these two apparently unrelated concepts: *The number of involutions of* $\{1, 2, \ldots, n\}$ *is the same as the number of tableaux that can be formed from the*

elements $\{1, 2, \ldots, n\}$. For example, exactly 10 tableaux can be formed from $\{1, 2, 3, 4\}$, namely,

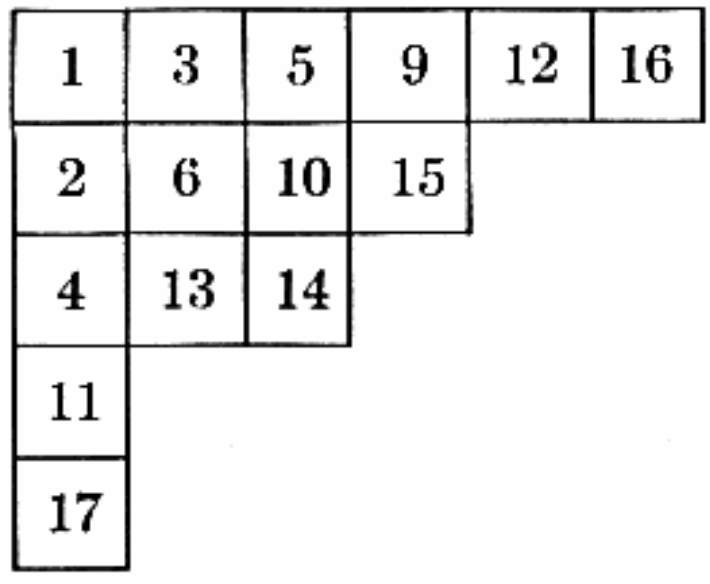


(3)

corresponding respectively to the 10 involutions (2).

This connection between involutions and tableaux is by no means obvious, and there is probably no very simple way to prove it. The proof we will discuss involves an interesting tableau-construction algorithm which has several other surprising properties; it is based on a special procedure which inserts new elements into a tableau.

For example, suppose that we want to insert the element 8 into the tableau



(4)

The method we will use starts by placing the 8 into row 1, in the spot previously occupied by 9, since 9 is the least element greater than 8 in that row. Element 9 is "bumped down" into row 2, where it displaces the 10. The 10 then "bumps" the 13 from row 3 to row 4; and since row 4 contains no element greater than 13, the process terminates by inserting 13 at the right end of row 4. The tableau

has been transformed into

1	3	5	8	12	16
2	6	9	15		
4	10	14			
11	13				
17					

(5)

A precise description of this process, together with a proof that it always preserves the tableau properties, appears in Algorithm I.

Algorithm I (*Insertion into a tableau*). Let $P = (P_{ij})$ be a tableau of positive integers, and let x be a positive integer not in P. This algorithm transforms P into another tableau which contains x in addition to its original elements. The new tableau has the same shape as the old, except for the addition of a new position in row s, column t, where s and t are quantities determined by the algorithm.

(Parenthesized remarks in this algorithm serve to prove its validity, since it is easy to verify inductively that the remarks are valid and that the array P remains a tableau throughout the process. For convenience we will assume that the tableau has been bordered by zeros at the top and left and with ∞'s to the right and below, so that P_{ij} is defined for all $i, j \geq 0$. If we define the relation

$$a \lesssim b \quad \text{if and only if} \quad a < b \quad \text{or} \quad a = b = \infty, \tag{6}$$

the tableau inequalities can be expressed in the convenient form

$$P_{ij} = 0 \quad \text{if} \quad i = 0 \quad \text{or} \quad j = 0;$$
$$P_{ij} \lesssim P_{i(j+1)} \quad \text{and} \quad P_{ij} \lesssim P_{(i+1)j}, \quad \text{for all} \quad i, j \geq 0. \tag{7}$$

The statement "$x \notin P$" means that either $x = \infty$ or $x \neq P_{ij}$ for all $i, j \geq 0$.)

I1. [Input x.] Set $i \leftarrow 1$, set $x_1 \leftarrow x$, and set j to the smallest value such that $P_{1j} = \infty$.

I2. [Find x_{i+1}.] (At this point $P_{(i-1)j} < x_i < P_{ij}$ and $x_i \notin P$.) If $x_i < P_{i(j-1)}$, decrease j by 1 and repeat this step. Otherwise set $x_{i+1} \leftarrow P_{ij}$ and set $r_i \leftarrow j$.

I3. [Replace by x_i.] (Now $P_{i(j-1)} < x_i < x_{i+1} = P_{ij} \lesssim P_{i(j+1)}$, $P_{(i-1)j} < x_i < x_{i+1} = P_{ij} \lesssim P_{(i+1)j}$, and $r_i = j$. Set $P_{ij} \leftarrow x_i$.

I4. [Is $x_{i+1} = \infty$?] (Now $P_{i(j-1)} < P_{ij} = x_i < x_{i+1} \lesssim P_{i(j+1)}$, $P_{(i-1)j} < P_{ij} = x_i < x_{i+1} \lesssim P_{(i+1)j}$, $r_i = j$, and $x_{i+1} \notin P$.) If $x_{i+1} \neq \infty$, increase i by 1 and return to step I2.

I5. [Determine s, t.] Set $s \leftarrow i$, $t \leftarrow j$, and terminate the algorithm. (At this point the conditions

$$P_{st} \neq \infty, P_{(s+1)t} = P_{s(t+1)} = \infty \tag{8}$$

are satisfied.) ∎

Note that this algorithm defines a "bumping sequence"

$$x = x_1 < x_2 < \cdots < x_s < x_{s+1} = \infty, \tag{9}$$

as well as an auxiliary sequence of column indices

$$r_1 \geq r_2 \geq \cdots \geq r_s = t; \tag{10}$$

element P_{ir_i} has been changed from x_{i+1} to x_i, for $1 \leq i \leq s$. For example, when we inserted 8 into (4), the bumping sequence was 8, 9, 10, 13, ∞, and the auxiliary sequence was 4, 3, 2, 2. We could have reformulated the algorithm so that it used much less temporary storage (only the current values of j, x_i, and x_{i+1} need to be remembered), but sequences (9) and (10) have been introduced so that we can prove interesting things about the algorithm.

The key fact we will use about Algorithm I is that it can be "run backwards"; given the values of s and t determined in step I5, we can transform P back into its original form again, determining and removing the element x which was inserted. For example, consider (5) and suppose we are told that element 13 is in the position that used to be blank. Then 13 must have been bumped down from row 3 by the 10, since 10 is the greatest element less than 13 in that row; similarly the 10 must have been bumped from row 2 by the 9, and the 9 must have been bumped from row 1 by the 8. Thus we can go from (5) back to (4). The following algorithm specifies this process in detail:

Algorithm D (*Deletion from a tableau*). Given a tableau P and positive integers s, t satisfying (8), this algorithm transforms P into another tableau, having almost the same shape, but with ∞ in column t of row s. An element x, determined by the algorithm, is deleted from P.

(As in Algorithm I, parenthesized assertions are included here to facilitate proving that P remains a tableau throughout the process.)

D1. [Input s, t.] Set $j \leftarrow t$, $i \leftarrow s$, $x_{s+1} \leftarrow \infty$.

D2. [Find x_i.] (At this point $P_{ij} < x_{i+1} \lesssim P_{(i+1)j}$ and $x_{i+1} \notin P$.) If $P_{i(j+1)} < x_{i+1}$, increase j by 1 and repeat this step. Otherwise set $x_i \leftarrow P_{ij}$ and $r_i \leftarrow j$.

D3. [Replace by x_{i+1}.] (Now $P_{i(j-1)} < P_{ij} = x_i < x_{i+1} \lesssim P_{i(j+1)}$, $P_{(i-1)j} < P_{ij} = x_i < x_{i+1} \lesssim P_{(i+1)j}$, and $r_i = j$.) Set $P_{ij} \leftarrow x_{i+1}$.

D4. [Is $i = 1$?] (Now $P_{i(j-1)} < x_i < x_{i+1} = P_{ij} \lesssim P_{i(j+1)}$, $P_{(i-1)j} < x_i < x_{i+1} = P_{ij} \lesssim P_{(i+1)j}$, and $r_i = j$.) If $i > 1$, decrease i by 1 and return to step D2.

D5. [Determine x.] Set $x \leftarrow x_1$ and terminate the algorithm. (Now $0 < x < \infty$.) ∎

The parenthesized assertions appearing in Algorithms I and D are not only a useful way to prove that the algorithms preserve the tableau structure; they also serve to verify that *Algorithms I and D are perfect inverses of each other*. If we perform Algorithm I first, given some tableau P and some positive integer $x \notin P$, it will insert x and determine positive integers s, t satisfying (8); Algorithm D applied to the result will recompute x and will restore P. Conversely, if we perform Algorithm D first, given some tableau P and some positive integers s, t satisfying (8), it will modify P, deleting some positive integer x; Algorithm I applied to the result will recompute s, t and will restore P. The reason is that the parenthesized assertions of steps I3 and D4 are identical, as are the assertions of steps I4 and D3, and these assertions characterize the value of j uniquely. Hence the auxiliary sequences (9), (10) are the same in each case.

Now we are ready to prove a basic property of tableaux:

Theorem A. *There is a one-to-one correspondence between the set of all permutations of* $\{1, 2, \ldots, n\}$ *and the set of ordered pairs* (P, Q) *of tableaux formed from* $\{1, 2, \ldots, n\}$, *where* P *and* Q *have the same shape.*

(An example of this theorem appears within the proof which follows.)

Proof. It is convenient to prove a slightly more general result. Given any two-line array

$$\begin{pmatrix} q_1 & q_2 & \cdots & q_n \\ p_1 & p_2 & \cdots & p_n \end{pmatrix}, \qquad \begin{array}{l} q_1 < q_2 < \cdots < q_n, \\ p_1, p_2, \ldots, p_n \text{ distinct}, \end{array} \tag{11}$$

we will construct two corresponding tableaux P and Q, where the elements of P are $\{p_1, \ldots, p_n\}$ and the elements of Q are $\{q_1, \ldots, q_n\}$ and the shape of P is the shape of Q.

Let P and Q be empty initially. Then, for $i = 1, 2, \ldots, n$ (in this order), do the following operation: Insert p_i into tableau P using Algorithm I; then set $Q_{st} \leftarrow q_i$, where s and t specify the newly-filled position of P.

For example, if the given permutation is $\left(\begin{smallmatrix}1&3&5&6&8\\7&2&9&5&3\end{smallmatrix}\right)$, we obtain

	P	Q
Insert 7:	7	1
Insert 2:	2 7	1 3
Insert 9:	2 9 7	1 5 3
Insert 5:	2 5 7 9	1 5 3 6
Insert 3:	2 3 5 9 7	1 5 3 6 8

(12)

so the tableaux (P, Q) corresponding to $\left(\begin{smallmatrix}1&3&5&6&8\\7&2&9&5&3\end{smallmatrix}\right)$ are

$$P = \begin{array}{|c|c|}\hline 2 & 3 \\ \hline 5 & 9 \\ \hline 7 \\ \cline{1-1}\end{array}, \qquad Q = \begin{array}{|c|c|}\hline 1 & 5 \\ \hline 3 & 6 \\ \hline 8 \\ \cline{1-1}\end{array}. \tag{13}$$

It is clear from this construction that P and Q always have the same shape; furthermore, since we always add elements on the periphery of Q, in increasing order, Q is a tableau.

Conversely, given two equal-shape tableaux P and Q, we can find the corresponding two-line array (11) as follows. Let the elements of Q be

$$q_1 < q_2 < \cdots < q_n.$$

For $i = n, \ldots, 2, 1$ (in this order), let p_i be the element x that is removed when Algorithm D is applied to P, using the values s, t such that $Q_{st} = q_i$.

For example, this construction will start with (13) and will successively undo the calculation (12) until P is empty, and $\left(\begin{smallmatrix}1&3&5&6&8\\7&2&9&5&3\end{smallmatrix}\right)$ is obtained.

Since Algorithms I and D are inverses of each other, the two constructions we have described are inverses of each other, and the one-to-one correspondence has been established. ∎

The correspondence defined in the proof of Theorem A has many startling properties, and we will now proceed to derive some of them. The reader is urged to try his hand at the example in exercise 1, in order to become familiar with the construction, before reading further.

Once an element has been bumped from row 1 to row 2, it doesn't affect row 1 any longer; furthermore rows 2, 3, . . . are built up from the sequence of "bumped" elements in exactly the same way as rows 1, 2, . . . are built up from the original permutation. These facts suggest that we can look at the construction of Theorem A in another way, concentrating only on the first rows of P and Q. For example, the permutation $\left(\begin{smallmatrix}1&3&5&6&8\\7&2&9&5&3\end{smallmatrix}\right)$ causes the following action in row 1 [cf. (12)]:

$$\begin{aligned}
&1: \quad \text{Insert 7, set } Q_{11} \leftarrow 1.\\
&3: \quad \text{Insert 2, bump 7.}\\
&5: \quad \text{Insert 9, set } Q_{12} \leftarrow 5.\\
&6: \quad \text{Insert 5, bump 9.}\\
&8: \quad \text{Insert 3, bump 5.}
\end{aligned} \tag{14}$$

Thus the first row of P is 2 3, and the first row of Q is 1 5. Furthermore, the remaining rows of P and Q are the tableaux corresponding to the "bumped" two-line array

$$\begin{pmatrix}3&6&8\\7&9&5\end{pmatrix}. \tag{15}$$

In order to study the behavior of the construction on row 1, we can consider the elements which go into a given column of this row. Let us say that (q_i, p_i) is in *class* t with respect to the two-line array

$$\begin{pmatrix}q_1&q_2&\cdots&q_n\\p_1&p_2&\cdots&p_n\end{pmatrix}, \qquad \begin{aligned}&q_1 < q_2 < \cdots < q_n,\\&p_1, p_2, \ldots p_n \text{ distinct,}\end{aligned} \tag{16}$$

if $p_i = P_{1t}$ after Algorithm I has been applied successively to $p_1, p_2, \ldots, p_i$,

starting with an empty tableau P. (Remember that Algorithm I always inserts the given element into row 1.)

It is easy to see that (q_i, p_i) is in class 1 if and only if p_i has $(i - 1)$ inversions, i.e., $p_i = \min\{p_1, p_2, \ldots, p_i\}$ is a "left-to-right minimum." If we cross out the columns of class 1 in (16), we obtain another two-line array

$$\begin{pmatrix} q'_1 & q'_2 & \cdots & q'_m \\ p'_1 & p'_2 & \cdots & p'_m \end{pmatrix} \tag{17}$$

such that (q, p) is in class t with respect to (17) if and only if it is in class $t + 1$ with respect to (16). The operation of going from (16) to (17) represents removing the leftmost position of row 1. This gives us a systematic way to determine the classes. For example in $\left(\begin{smallmatrix} 1 & 3 & 5 & 6 & 8 \\ 7 & 2 & 9 & 5 & 3 \end{smallmatrix}\right)$ the elements which are left-to-right minima are 7 and 2, so class 1 is $\{(1, 7), (3, 2)\}$; in the remaining array $\left(\begin{smallmatrix} 5 & 6 & 8 \\ 9 & 5 & 3 \end{smallmatrix}\right)$ all elements are minima, so class 2 is $\{(5, 9), (6, 5), (8, 3)\}$. In the "bumped" array (15), class 1 is $\{(3, 7), (8, 5)\}$ and class 2 is $\{(6, 9)\}$.

For any fixed value of t, the elements of class t can be labeled

$$(q_{i_1}, p_{i_1}), \ldots, (q_{i_k}, p_{i_k})$$

in such a way that

$$\begin{aligned} q_{i_1} &< q_{i_2} < \cdots < q_{i_k}, \\ p_{i_1} &> p_{i_2} > \cdots > p_{i_k}, \end{aligned} \tag{18}$$

since tableau position P_{1t} takes on the decreasing sequence of values $p_{i_1}, \ldots, p_{i_k}$ as the insertion algorithm proceeds. At the end of the construction we have

$$P_{1t} = p_{i_k}, \qquad Q_{1t} = q_{i_1}; \tag{19}$$

and the "bumped" two-line array which defines rows 2, 3, ... of P and Q contains the columns

$$\begin{pmatrix} q_{i_2} & q_{i_3} & \cdots & q_{i_k} \\ p_{i_1} & p_{i_2} & \cdots & p_{i_{k-1}} \end{pmatrix}, \tag{20}$$

plus other columns formed in a similar way from the other classes.

These observations lead to a simple method for calculating P and Q by hand (see exercise 3), and they also provide us with the means to prove a rather unexpected result:

Theorem B. *If the permutation*

$$\begin{pmatrix} 1 & 2 & \ldots & n \\ a_1 & a_2 & \ldots & a_n \end{pmatrix}$$

corresponds to tableaux (P, Q) in the construction of Theorem A, then the inverse permutation corresponds to (Q, P).

This fact is quite startling, since P and Q are formed by such completely different methods in Theorem A, and since the inverse of a permutation is obtained by juggling the columns of the two-line array rather capriciously.

Proof. Suppose that we have a two-line array (16); interchanging the lines and sorting the columns so that the new top line is in increasing order gives the "inverse" array,

$$\begin{aligned}\begin{pmatrix} q_1 & q_2 & \cdots & q_n \\ p_1 & p_2 & \cdots & p_n \end{pmatrix}^{-1} &= \begin{pmatrix} p_1 & p_2 & \cdots & p_n \\ q_1 & q_2 & \cdots & q_n \end{pmatrix} \\ &= \begin{pmatrix} p'_1 & p'_2 & \cdots & p'_n \\ q'_1 & q'_2 & \cdots & q'_n \end{pmatrix}, \quad \begin{matrix} p'_1 < p'_2 < \cdots < p'_n; \\ q'_1, q'_2, \ldots, q'_n \text{ distinct.} \end{matrix}\end{aligned} \tag{21}$$

We will show that this operation corresponds to interchanging P and Q in the construction of Theorem A.

Exercise 2 reformulates our remarks about class determination so that the class of (q_i, p_i) doesn't depend on the fact that $q_1, q_2, \ldots, q_n$ are in ascending order. Since the resulting condition is symmetrical in the q's and the p's, the operation (21) does not destroy the class structure; if (q, p) is in class t with respect to (16), then (p, q) is in class t with respect to (21). If we therefore arrange the elements of the latter class t as

$$\begin{aligned} p_{i_k} < \cdots < p_{i_2} < p_{i_1}, \\ q_{i_k} > \cdots > q_{i_2} > q_{i_1}; \end{aligned} \tag{22}$$

[cf. (18)], we have

$$P_{1t} = q_{i_1}, \qquad Q_{1t} = p_{i_k} \tag{23}$$

as in (19), and the columns

$$\begin{pmatrix} p_{i_{k-1}} & \cdots & p_{i_2} & p_{i_1} \\ q_{i_k} & \cdots & q_{i_3} & q_{i_2} \end{pmatrix} \tag{24}$$

go into the "bumped" array as in (20). Hence the first rows of P and Q are interchanged. Furthermore the "bumped" two-line array for (21) is the inverse of the "bumped" two-line array for (16), so the proof is completed by induction on the number of rows in the tableaux. ∎

Corollary. *The number of tableaux which can be formed from* $\{1, 2, \ldots, n\}$ *is the number of involutions on* $\{1, 2, \ldots, n\}$.

Proof. If π is an involution corresponding to (P, Q), then $\pi = \pi^{-1}$ corresponds to (Q, P); hence $P = Q$. Conversely, if π is any permutation corresponding to (P, P), then π^{-1} also corresponds to (P, P); hence $\pi = \pi^{-1}$. So there is a one-to-one correspondence between involutions π and tableaux P. ∎

It is clear that the upper-left corner element of a tableau is always the smallest. This suggests a possible way to sort a set of numbers: First we can put them into a tableau, by using Algorithm I repeatedly; this brings the smallest element to the corner. Then we delete this smallest element, rearranging the remaining elements so that they form another tableau; then we delete the new smallest element; and so on.

Let us therefore consider what happens when we delete the corner element from the tableau

1	3	5	8	12	16
2	6	9	15		
4	10	14			
11	13				
17					

(25)

If the 1 is removed, the 2 must come to take its place. Then we can move the 4 up to where the 2 was, but we can't move the 11 to the position of the 4; the 10 can be moved instead, then the 13 in place of the 10. In general, we are led to the following procedure.

Algorithm S (*Delete corner element*). Given a tableau P, this algorithm deletes the upper left corner element of P and moves other elements so that the tableau properties are preserved. The notational conventions of Algorithms I and D are used.

S1. [Initialize.] Set $r \leftarrow 1$, $s \leftarrow 1$.

S2. [Done?] If $P_{rs} = \infty$, the process is complete.

S3. [Compare.] If $P_{(r+1)s} \lesssim P_{r(s+1)}$, go to step S5. (We examine the elements just to the right and below the vacant cell, and we will move the smaller of these.)

S4. [Shift left.] Set $P_{rs} \leftarrow P_{r(s+1)}$, $s \leftarrow s + 1$, and return to S3.

S5. [Shift up.] Set $P_{rs} \leftarrow P_{(r+1)s}$, $r \leftarrow r + 1$, and return to S2. ∎

It is easy to prove that P is still a tableau after Algorithm S has deleted its corner element (see exercise 10). So if we repeat Algorithm S until P is empty, we can read out its elements in increasing order. Unfortunately this doesn't turn out to be as efficient a sorting algorithm as other methods we will see; its minimum running time is proportional to $n^{1.5}$, but similar algorithms which use trees instead of tableau structures have an execution time on the order of $n \log n$.

In spite of the fact that Algorithm S doesn't lead to a superbly-efficient sorting algorithm, it has some very interesting properties.

Theorem C (M. P. Schützenberger). *If P is the tableau formed by the construction of Theorem A from the permutation $a_1\ a_2\ \ldots\ a_n$, and if $a_i = \min\{a_1\ a_2, \ldots, a_n\}$, then Algorithm S changes P into the tableau corresponding to $a_1 \ldots a_{i-1}\ a_{i+1} \ldots a_n$.*

Proof. See exercise 13. ∎

After we apply Algorithm S to a tableau, let us put the deleted element into the newly-vacated place P_{rs}, with parentheses around it to indicate that it isn't really part of the tableau. For example, after applying this procedure to (25) we would have

2	3	5	8	12	16
4	6	9	15		
10	13	14			
11	(1)				
17					

and two more applications yields

4	5	8	12	16	(2)
6	9	14	15		
10	13	(3)			
11	(1)				
17					

Continuing until all elements are parenthesized, then removing the parentheses, gives

17	15	14	13	11	2
16	10	6	4		
12	5	3			
9	1				
8					

(26)

which has the same shape as the original tableau (25). This configuration may be called a *dual tableau*, since it is like a tableau except that the "dual order" (reversing the roles of $<$ and $>$) has been used. Let us denote the dual tableau formed from P in this way by the symbol P^S.

From P^S we can determine P uniquely; in fact, we can obtain the original tableau P from P^S, by applying exactly the same algorithm (reversing the order, since P^S is a dual tableau). For example, two steps of the algorithm applied to (26) give

15	14	13	11	2	(16)
12	10	6	4		
9	5	3			
8	1				
(17)					

and eventually (25) will be reproduced again! This remarkable fact is one of the consequences of our next theorem.

Theorem D (C. Schensted, M. P. Schützenberger). *Let*

$$\begin{pmatrix} q_1 & q_2 & \cdots & q_n \\ p_1 & p_2 & \cdots & p_n \end{pmatrix} \tag{27}$$

be the two-line array corresponding to the tableaux (P, Q).

a) *Using dual (reverse) order on the q's, but not on the p's, the two-line array*

$$\begin{pmatrix} q_n & \cdots & q_2 & q_1 \\ p_n & \cdots & p_2 & p_1 \end{pmatrix} \tag{28}$$

corresponds to $(P^T, (Q^S)^T)$.

(As usual, "T" denotes the operation of transposing rows and columns; P^T is a tableau, while $(Q^S)^T$ is a dual tableau, since the order of the q's is reversed.)

b) *Using dual order on the p's, but not on the q's, the two-line array* (27) *corresponds to* $((P^S)^T, Q^T)$.

c) *Using dual order on both the p's and the q's, the two-line array* (28) *corresponds to* (P^S, Q^S).

Proof. No simple proof of this theorem is known. The fact that case (a) corresponds to (P^T, X) for some dual tableau X is proved in exercise 6; hence by Theorem B, case (b) corresponds to (Y, Q^T) for some dual tableau Y, and Y must have the shape of P^T.

Let $p_i = \min\{p_1, \ldots, p_n\}$; since p_i is the "largest" element in the dual order, it appears on the periphery of Y, and it doesn't bump any elements in the construction of Theorem A. Thus, if we successively insert $p_1, \ldots, p_{i-1}$, $p_{i+1}, \ldots, p_n$ using the dual order, we get $Y - \{p_i\}$, that is, Y with p_i removed. By Theorem C if we successively insert $p_1, \ldots, p_{i-1}, p_{i+1}, \ldots, p_n$ using the normal order, we get the tableau $d(P)$ obtained by applying Algorithm S to P. By induction on n, $Y - \{p_i\} = (d(P)^S)^T$. But since

$$(P^S)^T - \{p_i\} = (d(P)^S)^T, \tag{29}$$

by definition of the operation S, and since Y has the same shape as $(P^S)^T$, we must have $Y = (P^S)^T$.

This proves (b), and (a) follows by an application of Theorem B. Applying (a) and (b) successively then shows that case (c) corresponds to $(((P^T)^S)^T, ((Q^S)^T)^T)$; and this is (P^S, Q^S) since $(P^S)^T = (P^T)^S$ by the row-column symmetry of operation S. ∎

In particular, this theorem establishes two surprising facts about the tableau insertion algorithm: If successive insertion of distinct elements $p_1, \ldots, p_n$ into an empty tableau yields tableau P, insertion in the opposite order $p_n, \ldots, p_1$ yields the *transposed* tableau P^T. And if we not only insert the p's in this order $p_n, \ldots, p_1$ but also interchange the roles of $<$ and $>$, as well as 0 and ∞, in the insertion process, we obtain the dual tableau P^S. The reader is urged to try out these processes on some simple examples. The unusual nature of these coincidences might lead us to suspect that some sort of witchcraft is operating behind the scenes! No simple explanation for these phenomena is yet known; there seems to be no obvious way to prove even that case (c) corresponds to tableaux having the same *shape* as P and Q.

The correspondence of Theorem A was given by G. de B. Robinson [*American J. Math.* **60** (1938), 745–760, Sec. 5], in a somewhat vague and different form, as part of a solution to a rather difficult problem in group theory. It is not difficult to verify that his construction is essentially identical to that given here. He stated Theorem B without proof. Many years later, C. Schensted independently rediscovered the correspondence, which he stated in essentially the fashion we have used [*Canadian J. Math.* **13** (1961), 179–191]. He also proved the "P" part of Theorem D(a). M. P. Schützenberger [*Math. Scand.* **12** (1963), 117–128] proved Theorem B and the "Q" part of Theorem D(a), from which (b) and (c) follow. It is possible to extend the correspondence to permutations of *multisets;* the case that $p_1, \ldots, p_n$ need not be distinct was considered by Schensted, and the "ultimate" generalization to the case that both the p's and the q's may contain repeated elements was investigated by Knuth [*Pacific J. Math.* **34** (1970), 709–727].

Let us now turn to a related question: *How many tableaux formed from*

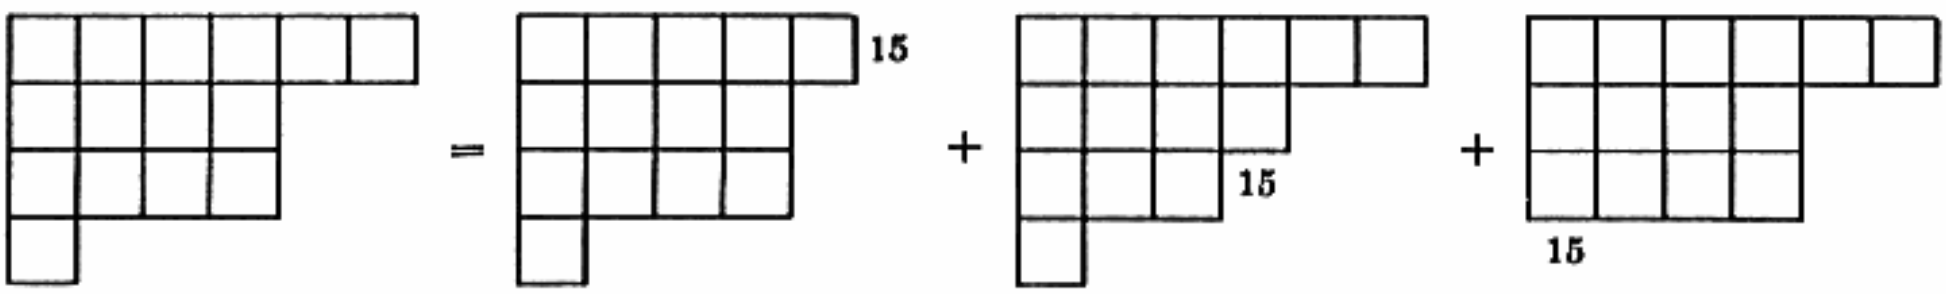
$\{1, 2, \ldots, n\}$ *have a given shape* $(n_1, n_2, \ldots, n_m)$, *where* $n_1 + n_2 + \cdots + n_m = n$? If we denote this number by $f(n_1, n_2, \ldots, n_m)$, it must satisfy the relations

$$f(n_1, n_2, \ldots, n_m) = 0 \qquad \text{unless} \qquad n_1 \geq n_2 \geq \cdots \geq n_m \geq 0; \tag{30}$$

$$f(n_1, n_2, \ldots, n_m, 0) = f(n_1, n_2, \ldots, n_m); \tag{31}$$

$$f(n_1, n_2, \ldots, n_m) = f(n_1 - 1, n_2, \ldots, n_m) + f(n_1, n_2 - 1, \ldots, n_m) + \cdots + f(n_1, n_2, \ldots, n_m - 1), \quad \text{if} \quad n_1 \geq n_2 \geq \cdots \geq n_m \geq 1. \tag{32}$$

The latter recurrence comes from the fact that removing the largest element of a tableau always leaves another tableau; for example, the number of tableaux of shape (6, 4, 4, 1) is $f(5, 4, 4, 1) + f(6, 3, 4, 1) + f(6, 4, 3, 1) + f(6, 4, 4, 0) = f(5, 4, 4, 1) + f(6, 4, 3, 1) + f(6, 4, 4)$, since every tableau of shape (6, 4, 4, 1) on $\{1, 2, \ldots, 15\}$ is formed by inserting the element 15 into the appropriate place in a tableau of shape (5, 4, 4, 1), (6, 4, 3, 1), or (6, 4, 4). Schematically,



(33)

The function $f(n_1, n_2, \ldots, n_m)$ which satisfies these relations has a fairly simple form,

$$f(n_1, n_2, \ldots, n_m) = \frac{\Delta(n_1 + m - 1, n_2 + m - 2, \ldots, n_m) n!}{(n_1 + m - 1)!(n_2 + m - 2)! \ldots m_m!}, \quad \text{for} \quad n_1 + m - 1 \geq n_2 + m - 2 \geq \cdots \geq n_m, \tag{34}$$

where Δ denotes the "discriminant" function

$$\Delta(x_1, x_2, \ldots, x_m) = \det \begin{pmatrix} x_1^{m-1} & x_2^{m-1} & \ldots & x_m^{m-1} \\ \vdots & & & \vdots \\ x_1^2 & x_2^2 & & x_m^2 \\ x_1 & x_2 & & x_m \\ 1 & 1 & \ldots & 1 \end{pmatrix} = \prod_{1 \leq i < j \leq m} (x_i - x_j). \tag{35}$$

Formula (34) was derived by G. Frobenius [*Sitzungsberichte Preuss. Akad. der Wissenchaften* (Berlin, 1900), 516–534, Sec. 3], in connection with an equivalent

problem in group theory, using a rather deep group-theoretical argument; a combinatorial proof was independently given by MacMahon [*Philosophical Trans.* **A-209** (London, 1909), 153–175]. The formula can be established by induction, since relations (30) and (31) are readily proved and (32) follows by setting $y = -1$ in the identity of exercise 17.

Theorem A gives a remarkable identity in connection with this formula for the number of tableaux. If we sum over all shapes, we have

$$n! = \sum_{\substack{k_1 \geq \cdots \geq k_n \geq 0 \\ k_1 + \cdots + k_n = n}} f(k_1, \ldots, k_n)^2 = n!^2 \sum_{\substack{k_1 \geq \cdots \geq k_n \geq 0 \\ k_1 + \cdots + k_n = n}} \frac{\Delta(k_1 + n - 1, \ldots, k_n)^2}{(k_1 + n - 1)!^2 \ldots k_n!^2}$$

$$= n!^2 \sum_{\substack{q_1 > q_2 > \cdots > q_n \geq 0 \\ q_1 + \cdots + q_n = (n+1)n/2}} \frac{\Delta(q_1, \ldots, q_n)^2}{q_1!^2 \ldots q_n!^2};$$

hence

$$\sum_{\substack{q_1 + \cdots + q_n = (n+1)n/2 \\ q_1, \ldots, q_n \geq 0}} \frac{\Delta(q_1, \ldots, q_n)^2}{q_1!^2 \ldots q_n!^2} = 1. \tag{36}$$

The inequalities $q_1 > q_2 > \cdots > q_n$ have been removed in the latter sum, since the summand is a symmetric function of the q's which vanishes when $q_i = q_j$. A similar identity appears in exercise 24.

The formula for the number of tableaux can be expressed in a somewhat more interesting manner, based on the idea of "hooks." The *hook* corresponding to a cell in a tableau is defined to be the cell itself plus the cells lying below and to its right. For example, the shaded area in Fig. 5 is the hook corresponding to cell (2, 3) in row 2, column 3; it contains six cells. Each cell of Fig. 5 has been filled in with the length of its hook.

12	11	8	7	5	4	1
10	9	**6**	**5**	**3**	**2**	•
9	8	**5**	4	2	1	•
6	5	**2**	1	•		
3	2	•				
2	1	•				

Fig. 5. Hooks and hook lengths.

If the shape of the tableau is $(n_1, n_2, \ldots, n_m)$, with $n_m \geq 1$, the longest hook has length $n_1 + m - 1$. Further examination of the hook lengths shows that row 1 contains all the lengths $n_1 + m - 1, n_1 + m - 2, \ldots, 1$ *except* for $(n_1 + m - 1) - (n_m)$, $(n_1 + m - 1) - (n_{m-1} + 1), \ldots, (n_1 + m - 1) - (n_2 + m - 2)$. In Fig. 5, for example, the hook lengths in row 1 are 12, 11,

10, . . . , 1 except for 10, 9, 6, 3, 2; the exceptions correspond to five nonexistent hooks, from nonexistent cells (6, 3), (5, 3), (4, 5), (3, 7), (2, 7) leading up to cell (1, 7). Similarly, row j contains all hook lengths $n_j + m - j, \ldots, 1$, except for $(n_j - m - j) - (n_m), \ldots, (n_j - m - j) - (n_{j+1} - m - j - 1)$. It follows that the product of all the hook lengths is equal to

$$(n_1 + m - 1)! \ldots (n_m)!/\Delta(n_1 + m - 1, \ldots, n_m).$$

This is just what happens in Eq. (34), so we have

Theorem H (J. S. Frame, G. de B. Robinson, R. M. Thrall). *The number of tableaux on* $\{1, 2, \ldots, n\}$ *having a specified shape is* $n!$ *divided by the product of the hook lengths.* ∎

Since this is such a simple result, it deserves a simple proof; but (like most of the known facts about tableaux) no more direct proof is known. Each element of a tableau is the smallest in its hook; if we fill the tableau shape at random, the probability that cell (i, j) will contain the minimum element of the corresponding hook is the reciprocal of the hook length. Multiplying these probabilities over all i and j gives Theorem H; but this argument is fallacious, since the probabilities are far from independent. All known proofs of Theorem C are based on an uninspiring induction argument which doesn't really explain why the theorem is true (since it doesn't really use the properties of hooks).

Theorem H has an interesting connection with the enumeration of trees, which we considered in Chapter 2. We observed that binary trees with n nodes correspond to permutations that can be obtained with a stack, and that such permutations correspond to sequences $a_1\ a_2 \ldots a_{2n}$ of S's and X's, where the number of S's is never less than the number of X's as we read from left to right. (See exercises 2.3.1–6 and 2.2.1–3.) The latter sequences correspond in a natural way to tableaux of shape (n, n); we place in row 1 the indices i such that $a_i = \mathrm{S}$, and in row 2 we put those indices with $a_i = \mathrm{X}$. For example, the sequence

$$\mathrm{S\ S\ S\ X\ X\ S\ S\ X\ X\ S\ X\ X}$$

corresponds to the tableau

1	2	3	6	7	10
4	5	8	9	11	12

. (37)

The column constraint is satisfied in this tableau if and only if the number of S's never exceeds the number of X's from left to right. By Theorem H, the number of tableaux of shape (n, n) is

$$(2n)!/(n + 1)!n!,$$

so this is the number of binary trees (in agreement with Eq. 2.3.4.4–13). Further-

more, this argument solves the more general "ballot problem" considered in the answer to exercise 2.2.1–4, if we use tableaux of shape (n, m) for $n \geq m$. So Theorem H includes some rather complex enumeration problems as simple special cases.

Any tableau A of shape (n, n) on the elements $\{1, 2, \ldots, 2n\}$ corresponds to two tableaux (P, Q) of the same shape, in the following way suggested by MacMahon [*Combinatory Analysis* **1** (1915), 130–131]. Let P consist of the elements $\{1, \ldots, n\}$ as they appear in A; Q is formed by taking the remaining elements, rotating the configuration by 180°, and replacing $n + 1, n + 2, \ldots, 2n$ by $n, n - 1, \ldots, 1$, respectively. For example, (37) splits into

1	2	3	6
4	5		

and

		7	10
8	9	11	12

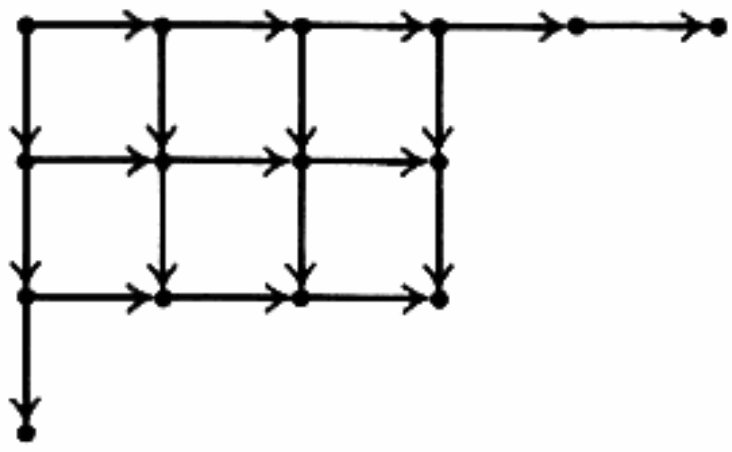
;

rotation and renaming of the latter yields

$$P = \begin{array}{|c|c|c|c|}\hline 1 & 2 & 3 & 6 \\ \hline 4 & 5 \\ \cline{1-2}\end{array}, \qquad Q = \begin{array}{|c|c|c|c|}\hline 1 & 2 & 4 & 5 \\ \hline 3 & 6 \\ \cline{1-2}\end{array}. \tag{38}$$

Conversely, any pair of equal-shape tableaux of at most two rows, each containing n cells, corresponds in this way to a tableau of shape (n, n). Hence by exercise 7 *the number of permutations* $a_1\, a_2 \ldots a_n$ *of* $\{1, 2, \ldots, n\}$ *containing no decreasing subsequence* $a_i > a_j > a_k$ *for* $i < j < k$ *is the number of binary trees with* n *nodes.* Curiously there seems to be no apparent way to establish a correspondence between such permutations and binary trees, except for the roundabout method via Algorithm I that we have used here. It is interesting to compare this situation to the rather direct correspondence between binary trees and permutations having no instances of $a_j > a_k > a_i$ for $i < j < k$ (see exercise 2 2.1–5).

The number of ways to fill a tableau of shape (6, 4, 4, 1) is obviously the number of ways to put the labels $\{1, 2, \ldots, 15\}$ onto the vertices of the directed graph



(39)

in such a way that the label of vertex u is less than the label of vertex v whenever $u \longrightarrow v$. In other words, it is the number of ways to sort the partial ordering (39) topologically, in the sense of Section 2.2.3.

In general, we can ask the same question for any directed graph which contains no oriented cycles. It would be nice if there were some simple formula which would generalize Theorem H to the case of an arbitrary directed graph; but not all graphs have such pleasant properties as the graphs corresponding to tableaux. Some other classes of directed graphs for which the labelling problem has a simple solution are discussed in the exercises at the close of this section. There also are exercises which show that some directed graphs have *no* simple formula corresponding to Theorem H. For example, the number of ways to do the labelling is not always a divisor of $n!$.

To complete our investigations, let us count the total number of tableaux that can be formed from n distinct elements; we will denote this number by t_n. By the corollary to Theorem B, t_n is the number of involutions of $\{1, 2, \ldots, n\}$. A permutation is its own inverse if and only if its cycle form consists solely of one-cycles (fixed points) and two-cycles (transpositions). Since t_{n-1} of the t_n involutions have (n) as a one-cycle, and since t_{n-2} of them have $(j\ n)$ as a two-cycle, for fixed $j < n$, we obtain the formula

$$t_n = t_{n-1} + (n-1)t_{n-2} \tag{40}$$

which Rothe devised in 1800 to tabulate t_n for small n.

Counting another way, let us suppose that there are k two-cycles and $(n - 2k)$ one-cycles. There are $\binom{n}{2k}$ ways to choose the fixed points, and the multinomial coefficient $(2k)!/(2!)^k$ is the number of ways to arrange the other elements into k distinguishable transpositions; dividing by $k!$ to make the transpositions indistinguishable we therefore obtain

$$t_n = \sum_{k \geq 0} t_n(k), \qquad t_n(k) = \frac{n!}{(n-2k)!2^k k!}. \tag{41}$$

Unfortunately this sum cannot be further simplified, as far as anyone knows, so we resort to two indirect approaches in order to better understand t_n:

a) We can find the generating function

$$\sum_n t_n z^n/n! = e^{z+z^2/2}; \tag{42}$$

see exercise 25.

b) We can determine the asymptotic behavior of t_n. This is an instructive problem, because it involves some general techniques that will be useful to us in other connections, so we will conclude this section with an analysis of the asymptotic behavior of t_n.

The first step in analyzing the asymptotic behavior of (41) is to locate the main contribution to the sum. Since

$$\frac{t_n(k+1)}{t_n(k)} = \frac{(n-2k)(n-2k-1)}{2(k+1)}, \tag{43}$$

we can see that the terms gradually increase from $k = 0$ until k is approximately $\frac{1}{2}(n - \sqrt{n})$, then they decrease to zero when k is approximately $\frac{1}{2}n$. The main contribution clearly comes from the vicinity of $k = \frac{1}{2}(n - \sqrt{n})$. It is usually preferable to have the main contribution at the value 0, so we write

$$k = \tfrac{1}{2}(n - \sqrt{n}) + x, \tag{44}$$

and we will investigate the size of $t_n(k)$ as a function of x.

One useful way to get rid of the factorials in $t_n(k)$ is to use Stirling's approximation, Eq. 1.2.11.2–18. For this purpose it is convenient (as we shall see in a moment) to restrict x to the range

$$-(n^{\epsilon+1/4}) \le x \le n^{\epsilon+1/4}, \tag{45}$$

where $\epsilon = 0.001$, say, so that an error term can be included. A somewhat laborious calculation which should really have been done by computer yields the formula

$$\begin{aligned} t_n(k) = \exp\big(&\tfrac{1}{2}n\ln n - \tfrac{1}{2}n + \sqrt{n} - \tfrac{1}{4}\ln n - 2x^2/\sqrt{n} - \tfrac{1}{4} - \tfrac{1}{2}\ln\pi \\ &- \tfrac{4}{3}x^3/n + 2x/\sqrt{n} + \tfrac{1}{3}/\sqrt{n} - \tfrac{4}{3}x^4/n\sqrt{n} + O(n^{5\epsilon-3/4})\big). \end{aligned} \tag{46}$$

The restriction on x in (45) can be justified by the fact that we may set $x = \pm n^{\epsilon+1/4}$ to get an upper bound for all of the discarded terms, namely

$$e^{-2n^{2\epsilon}} \cdot \exp\big(\tfrac{1}{2}n\ln n - \tfrac{1}{2}n + \sqrt{n} - \tfrac{1}{4}\ln n - \tfrac{1}{4} - \tfrac{1}{2}\ln\pi + O(n^{3\epsilon-1/4})\big), \tag{47}$$

and if we multiply this by n we get an upper bound for the sum of the excluded terms. The upper bound is of lesser order than the terms we will compute for x in the restricted range (45), because of the factor $\exp(-2n^{2\epsilon})$ which is much less than any polynomial in n.

We can evidently remove the factor

$$\exp\big(\tfrac{1}{2}n\ln n - \tfrac{1}{2}n + \sqrt{n} - \tfrac{1}{4}\ln n - \tfrac{1}{4} - \tfrac{1}{2}\ln\pi + \tfrac{1}{3}/\sqrt{n}\big) \tag{48}$$

from the sum, and this leaves us with the task of summing

$$\begin{aligned} &\exp\big(-2x^2/\sqrt{n} - \tfrac{4}{3}x^3/n + 2x/\sqrt{n} - \tfrac{4}{3}x^4/n\sqrt{n} + O(n^{5\epsilon-3/4})\big) \\ &\quad = \exp\left(\frac{-2x^2}{\sqrt{n}}\right)\cdot\left(1 - \frac{4}{3}\,\frac{x^3}{n} + \frac{8}{9}\,\frac{x^6}{n^2}\right) \\ &\qquad \cdot\left(1 + 2\frac{x}{\sqrt{n}} + 2\frac{x^2}{n}\right)\cdot\left(1 - \frac{4}{3}\,\frac{x^4}{n\sqrt{n}}\right)\cdot(1 + O(n^{9\epsilon-3/4})) \end{aligned} \tag{49}$$

over the range $x = \alpha, \alpha + 1, \ldots, \beta - 2, \beta - 1$ where $-\alpha$ and β (not necessarily integers) are approximately equal to $n^{t+1/4}$. Euler's summation formula, Eq. 1.2.11.2–10, can be written

$$\sum_{\alpha \le x < \beta} f(x) = \int_\alpha^\beta f(x)\,dx - \tfrac{1}{2}f(x)\Big|_\alpha^\beta + \tfrac{1}{2}B_2 \cdot \frac{f'(x)}{1!}\Big|_\alpha^\beta + \cdots + \frac{1}{m+1}B_{m+1} \cdot \frac{f^{(m)}(x)}{m!}\Big|_\alpha^\beta + R_{m+1}, \quad (50)$$

by translation of the interval of summation. Here $|R_m| \le (4/(2\pi)^m)\int_\alpha^\beta |f^{(m)}(x)|dx$. If we let $f(x) = x^t \exp(-2x^2/\sqrt{n})$, where t is a fixed nonnegative integer, we find that $\int_\alpha^\beta f(x)\,dx$ differs from $\int_{-\infty}^{\infty} f(x)\,dx$ by $O(\exp(-2n^t))$, so we may take $\alpha = -\infty$, $\beta = \infty$. Euler's summation formula will give an asymptotic series for $\sum f(x)$ as $n \to \infty$, in this case, since

$$f^{(m)}(x) = n^{(t-m)/4} g^{(m)}(n^{-1/4}x), \qquad g(y) = y^t e^{-2y^2}, \quad (51)$$

and $g(y)$ is a well-behaved function independent of n; this shows that $R_m = O(n^{(t+1-m)/4})$. Since $f^{(m)}(-\infty) = f^{(m)}(\infty) = 0$, we have proved that

$$\sum_{\alpha \le x < \beta} f(x) = \int_{-\infty}^{\infty} f(x)\,dx + O(n^{-m}), \qquad \text{for all} \qquad m \ge 0; \quad (52)$$

only the integral is really significant, given this particular choice of $f(x)$! The integral is not difficult to evaluate (see exercise 26), so we can multiply out and sum formula (49), giving

$$\sqrt{\frac{\pi}{2}}\, n^{1/4}(1 - \tfrac{1}{24}n^{-1/4} + O(n^{-1/2}));$$

$$t_n = \frac{1}{\sqrt{2}}\, n^{n/2} e^{-n/2+\sqrt{n}-1/4}(1 + \tfrac{7}{24}n^{-1/2} + O(n^{-3/4})). \quad (53)$$

In principle, this method could be extended to obtain $O(n^{-k})$ for any k, instead of $O(n^{-3/4})$. This asymptotic series for t_n was first determined (using a different method) by Moser and Wyman, *Canadian J. Math.* **7** (1955), 159–168. For further examples and extensions of the technique used to derive (53), see the conclusion of Section 5.2.2.

EXERCISES

1. [*16*] What tableaux (P, Q) correspond to the two-line array

$$\begin{pmatrix} 1 & 2 & 3 & 4 & 5 & 6 & 7 & 8 & 9 \\ 6 & 4 & 9 & 5 & 7 & 1 & 2 & 8 & 3 \end{pmatrix},$$

in the construction of Theorem A? What two-line array corresponds to the tableaux

$$P = \begin{array}{|c|c|c|}\hline 1 & 4 & 7 \\ \hline 2 & 8 \\ \cline{1-2} 5 & 9 \\ \cline{1-2}\end{array}\,, \qquad Q = \begin{array}{|c|c|c|}\hline 1 & 3 & 7 \\ \hline 4 & 5 \\ \cline{1-2} 8 & 9 \\ \cline{1-2}\end{array}\,?$$

2. [*M21*] Prove that (q, p) belongs to class t with respect to (16) if and only if t is the largest number of indices $i_1, \ldots, i_t$ such that

$$p_{i_1} < p_{i_2} < \cdots < p_{i_t} = p, \qquad q_{i_1} < q_{i_2} < \cdots < q_{i_t} = q.$$

▸ **3.** [*M24*] Show that the correspondence defined in the proof of Theorem A can also be carried out by constructing a table such as this:

Line 0	1	3	5	6	8
Line 1	7	2	9	5	3
Line 2	∞	7	∞	9	5
Line 3		∞		∞	7
Line 4					∞

Here lines 0 and 1 constitute the given two-line array. For $k \geq 1$, line $k+1$ is formed from line k by the following procedure:

a) Set $p \leftarrow \infty$.
b) Let column j be the leftmost column in which line k contains an integer $< p$, but line $k+1$ is blank. If no such columns exist, and if $p = \infty$, line $k+1$ is complete; if no such columns exist and $p < \infty$, return to (a).
c) Insert p into column j in line $k+1$, then set p equal to the entry in column j of line k and return to (b).

Once the table has been constructed in this way, row k of P consists of those integers in line k which are not in line $(k+1)$; row k of Q consists of those integers in line 0 which appear in a column containing ∞ in line $k+1$.

4. [*M26*] (M. P. Schützenberger.) Let π be an involution with k fixed points. Prove that the tableau corresponding to π, in the proof of the corollary to Theorem B, has exactly k columns of odd length.

▸ **5.** [*M30*] Let $a_1 \ldots a_{j-1}\, a_j \ldots a_n$ be a permutation of distinct elements, and assume that $1 < j \leq n$. The permutation $a_1 \ldots a_{j-2}\, a_j\, a_{j-1}\, a_{j+1} \ldots a_n$, obtained by interchanging a_{j-1} with a_j, is called "admissible" if either

i) $j \geq 3$ and a_{j-2} lies between a_{j-1} and a_j; or
ii) $j < n$ and a_{j+1} lies between a_{j-1} and a_j.

For example, exactly three admissible interchanges can be performed on the permutation 1 5 4 6 8 3 7; we can interchange the 1 and the 5 since $1 < 4 < 5$; we can

interchange the 8 and the 3 since $3 < 6 < 8$ (or since $3 < 7 < 8$); but we cannot interchange the 5 and the 4, or the 3 and the 7.

a) Prove that an admissible interchange does not change the tableau P formed from the permutation by successive insertion of the elements $a_1, a_2, \ldots, a_n$ into an initially empty tableau.

b) Conversely, prove that any two permutations which have the same P tableau can be transformed into each other by a sequence of one or more admissible interchanges. [*Hint:* Given that the shape of P is $(n_1, n_2, \ldots, n_m)$, show that any permutation which corresponds to P can be transformed into the "canonical permutation" $P_{m1} \ldots P_{mn_m} \ldots P_{21} \ldots P_{2n_2} P_{11} \ldots P_{1n_1}$ by a sequence of admissible interchanges.]

▸ **6.** [*M22*] Let P be the tableau corresponding to the permutation $a_1\, a_2 \ldots a_n$; use exercise 5 to prove that P^T is the tableau corresponding to $a_n \ldots a_2\, a_1$.

7. [*M20*] (C. Schensted.) Let P be the tableau corresponding to the permutation $a_1\, a_2 \ldots a_n$. Prove that the number of *columns* in P is the longest length c of an increasing subsequence $a_{i_1} < a_{i_2} < \cdots < a_{i_c}$, where $i_1 < i_2 < \cdots < i_c$; the number of *rows* in P is the longest length r of a decreasing subsequence $a_{j_1} > a_{j_2} > \cdots > a_{j_r}$ where $j_1 < j_2 < \cdots < j_r$.

8. [*M18*] (P. Erdös, G. Szekeres.) Prove that any permutation containing more than n^2 elements has a monotonic subsequence of length greater than n; but there are permutations of n^2 elements with no monotonic subsequences of length greater than n. [*Hint:* See the previous exercise.]

9. [*M24*] Continuing exercise 8, find a "simple" formula for the exact number of permutations of $\{1, 2, \ldots, n^2\}$ having no monotonic subsequences of length greater than n.

10. [*M20*] Prove that P is a tableau when Algorithm S terminates, if it was a tableau initially.

11. [*20*] Given only the values of r and s after Algorithm S terminates, is it possible to restore P to its original condition?

12. [*M24*] How many times is step S3 performed, if Algorithm S is used repeatedly to delete all elements of a tableau P whose shape is $(n_1, n_2, \ldots, n_m)$? What is the minimum of this quantity, taken over all shapes with $n_1 + n_2 + \cdots + n_m = n$?

13. [*M28*] Prove Theorem C.

14. [*M43*] Find a more direct proof of Theorem D, part (c).

15. [*M20*] How many permutations of the multiset $\{l \cdot a, m \cdot b, n \cdot c\}$ have the property that, as we read the permutation from left to right, the number of c's never exceeds the number of b's, and the number of b's never exceeds the number of a's? (For example, *a a b c a b b c a c a* is such a permutation.)

16. [*M08*] In how many ways can the partial ordering represented by (39) be sorted topologically?

17. [*HM25*] Let

$$g(x_1, x_2, \ldots, x_n; y) = x_1\, \Delta(x_1 + y, x_2, \ldots, x_n) + x_2\, \Delta(x_1, x_2 + y, \ldots, x_n) + \cdots + x_n\, \Delta(x_1, x_2, \ldots, x_n + y).$$

Prove that

$$g(x_1, x_2, \ldots, x_n; y) = \left(x_1 + x_2 + \cdots + x_n + \binom{n}{2} y\right) \Delta(x_1, x_2, \ldots, x_n).$$

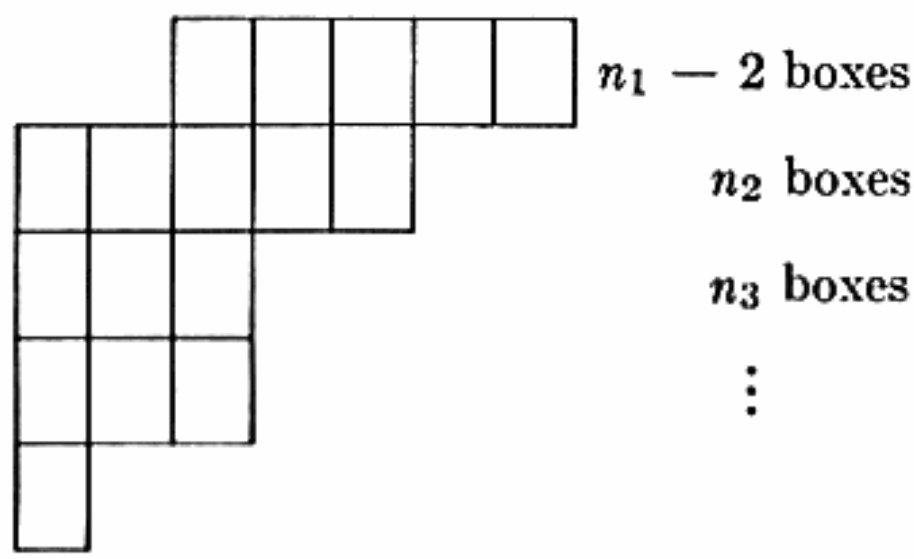
[*Hint:* The polynomial g is homogeneous (all terms have the same total degree); and it is antisymmetric in the x's (interchanging x_i and x_j changes the sign of g).]

18. [*HM30*] Generalizing exercise 17, evaluate the sum

$$x_1^m \Delta(x_1 + y, x_2, \ldots, x_n) + x_2^m \Delta(x_1, x_2 + y, \ldots, x_n) + \cdots + x_n^m \Delta(x_1, x_2, \ldots, x_n + y),$$

when $m \geq 0$.

19. [*M40*] Find a formula for the number of ways to fill an array which is like a tableau but with two boxes removed at the left of row 1; for example,



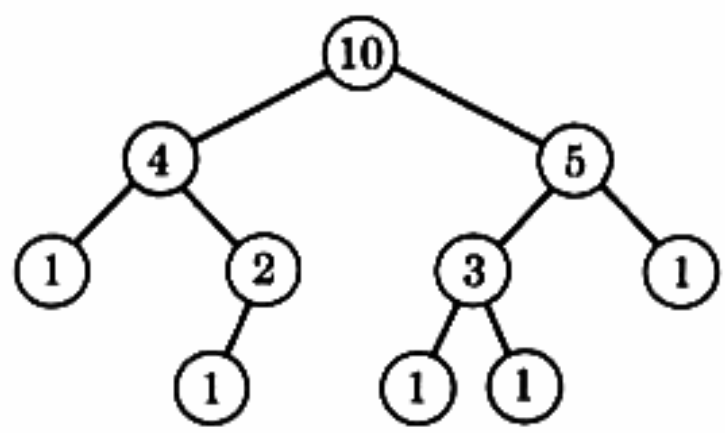
is such a shape. (The rows and columns are to be in increasing order, as in ordinary tableaux.)

In other words, how many of the $f(n_1, n_2, \ldots, n_m)$ tableaux of shape

$$(n_1, n_2, \ldots, n_m)$$

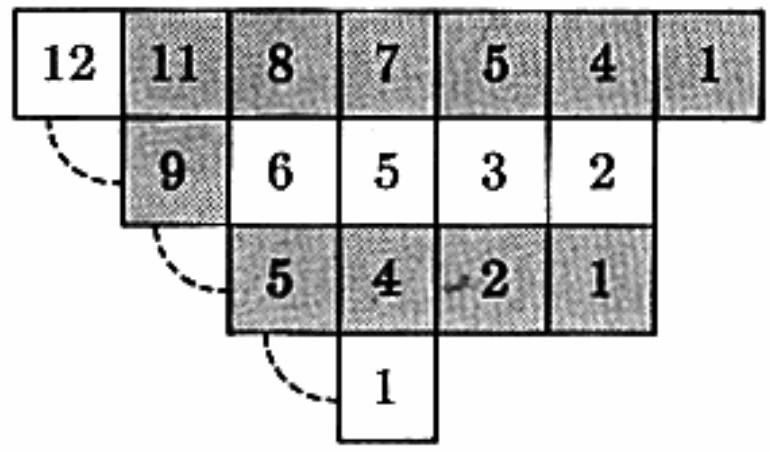
on $\{1, 2, \ldots, n_1 + \cdots + n_m\}$ have both of the elements 1 and 2 in the first row?

▸ **20.** [*M24*] Prove that the number of ways to label the nodes of a given binary tree with the elements $\{1, 2, \ldots, n\}$, such that the label of each node is less than that of its descendants, is $n!$ divided by the product of the "subtree lengths," i.e., the number of nodes in each subtree. (Cf. Theorem H.) For example, the number of ways to label the nodes of



is $10! / 10 \cdot 4 \cdot 5 \cdot 1 \cdot 2 \cdot 3 \cdot 1 \cdot 1 \cdot 1 \cdot 1 = 9 \cdot 8 \cdot 7 \cdot 6$.

21. [*HM31*] (R. M. Thrall.) Let $n_1 > n_2 > \cdots > n_m$ specify the shape of a "shifting tableau" where row $i+1$ starts one position to the right of row i; for example, a shifting tableau of shape (7, 5, 4, 1) has the form of the diagram

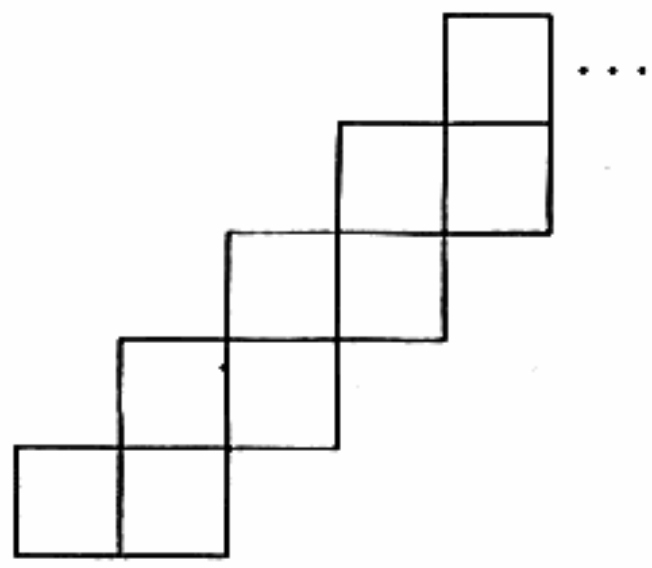


Prove that the number of ways to put the integers $1, 2, \ldots, n = n_1 + n_2 + \cdots + n_m$ into shifting tableaux of shape $(n_1, n_2, \ldots, n_m)$, so that rows and columns are in increasing order, is $n!$ divided by the product of the "generalized hook lengths"; a generalized hook of length 11, corresponding to the cell in row 1 column 2, has been shaded in the above diagram. (Hooks in the "inverted staircase" portion of the array, at the left, have a U-shape, tilted 90°, instead of an L-shape.) Thus there are

$$17!/12\cdot 11\cdot 8\cdot 7\cdot 5\cdot 4\cdot 1\cdot 9\cdot 6\cdot 5\cdot 3\cdot 2\cdot 5\cdot 4\cdot 2\cdot 1\cdot 1$$

ways to fill the above shape with rows and columns in increasing order.

▸ **22.** [*HM30*] (D. André.) In how many ways, A_n, can the numbers $\{1, 2, \ldots, n\}$ be placed into the array of n cells



in such a way that the rows and columns are in increasing order? Find the generating function $g(z) = \sum A_n z^n/n!$.

23. [*M39*] In how many ways can an array of shape $(n_1, n_2, \ldots, n_m)$ be filled with elements from the set $\{1, 2, \ldots, N\}$ *with repetitions allowed*, so that the rows are nondecreasing and the columns are strictly increasing? For example, the simple m-rowed shape $(1, 1, \ldots, 1)$ can be filled in $\binom{N}{m}$ ways; the 1-rowed shape (m) can be filled in $\binom{m+N-1}{m}$ ways; the shape (2, 2) in $\frac{1}{3}\binom{N+1}{2}\binom{N}{2}$ ways.

24. [*M28*] Prove that

$$\sum_{\substack{q_1+\cdots+q_n=t\\ 0\le q_1,\ldots,q_n\le m}} \binom{m}{q_1}\cdots\binom{m}{q_n}\Delta(q_1,\ldots,q_n)^2$$

$$= n!\binom{nm-(n^2-n)}{t-\frac{1}{2}(n^2-n)}\binom{m}{n-1}\binom{m}{n-2}\cdots\binom{m}{0}\Delta(n-1,\ldots,0)^2.$$

[*Hints:* Prove that $\Delta(k_1+n-1,\ldots,k_n)=\Delta(m-k_n+n-1,\ldots,m-k_1)$; decompose an $n\times(m-n+1)$ tableau in a fashion analogous to (38); and manipulate the sum as in the derivation of (36).]

25. [*M20*] Why is (42) the generating function for involutions?

26. [*HM21*] Evaluate $\int_{-\infty}^{\infty} x^t \exp(-2x^2/\sqrt{n})\,dx$ when t is a nonnegative integer.

27. [*M24*] Let Q be a Young tableau on $\{1, 2, \ldots, n\}$; let the element i be in row r_i and column c_i. We say that i is "above" j when $r_i < r_j$.

a) Prove that, for $1 \le i < n$, i is above $i+1$ if and only if $c_i \ge c_{i+1}$.

b) Given that Q is such that (P, Q) corresponds to the permutation

$$\begin{pmatrix} 1 & 2 & \ldots & n \\ a_1 & a_2 & \ldots & a_n \end{pmatrix},$$

prove that i is above $i+1$ if and only if $a_i > a_{i+1}$. (Therefore we can determine the number of runs in the permutation, knowing only Q. This result is due to M. P. Schützenberger.)

c) Prove that, for $1 \le i < n$, i is above $i+1$ in Q if and only if $i+1$ is above i in Q^s.

28. [*M47*] What is the asymptotic behavior of the average length of the longest increasing sequence of a random permutation on $\{1, 2, \ldots, n\}$? (This is the average length of row 1 in the correspondence of Theorem A. Extensive tables computed by R. M. Baer and P. Brock, *Math. Comp.* **22** (1968), 385–410, in connection with what they call "natural sorting" for some obscure reason, suggest that the average is approximately $2\sqrt{n}$; the data is also consistent with other hypotheses such as $1.97\sqrt{n}$.)

29. [*M50*] Investigate three-dimensional arrays, in order to see how many of the properties of two-dimensional tableaux can be generalized.

30. [*M42*] (M. P. Schützenberger.) Show that the operation of going from P to P^s is a special case of an operation applicable in connection with *any* finite partially ordered set, not merely a tableau: Label the elements of a partially ordered set with the integers $\{1, 2, \ldots, n\}$ such that the partial order is consistent with the labeling. Find a dual labeling analogous to (26), by successively deleting the tables 1, 2, ... while moving the other labels in a fashion analogous to Algorithm S and placing (1), (2), ... in the vacated places. Show that this operation, when repeated on the dual labeling in reverse numerical order, yields the original labeling; and explore other properties of the operation.

31. [*HM30*] Let x_n be the number of ways to place n mutually nonattacking rooks on an $n\times n$ chessboard, where the arrangement is unchanged by reflection about one of the diagonals and by 180° rotation. Find the asymptotic behavior of x_n.

Let's begin our discussion of good "sortmanship" by conducting a little experiment. How would you solve the following programming problem?

> "Memory locations R+1, R+2, R+3, R+4, and R+5 contain five numbers. Write a computer program which rearranges these numbers, if necessary, so that they are in ascending order."

(If you already are familiar with some sorting methods, please do your best to forget about them momentarily; imagine that you are attacking this problem for the first time, without any prior knowledge of how to proceed.)

Before reading any further, you are requested to construct a solution to this problem.

. . . . . .

The time you spent working on the above problem will pay dividends as you continue to read this chapter. Chances are your solution is one of the following types:

A. *An insertion sort.* The items are considered one at a time, and each new item is inserted into the appropriate position relative to the previously-sorted items. (This is the way many bridge players sort their hands, picking up one card at a time.)

B. *An exchange sort.* If two items are found to be out of order, they are interchanged. This process is repeated until no more exchanges are necessary.

C. *A selection sort.* First the smallest (or perhaps the largest) item is located, and it is somehow separated from the rest; then the next smallest (or next largest) is selected, and so on.

D. *An enumeration sort.* Each item is compared with each of the others; counting the number of smaller keys determines the item's final position.

E. *A special-purpose sort,* which works nicely for sorting five elements as stated in the problem, but does not readily generalize to larger numbers of items.

F. *A lazy attitude,* with which you ignored the suggestion above and decided not to solve the problem at all. Sorry, by now you have read too far and you have lost your chance.

G. *A new, super sorting technique* which is a definite improvement over known methods. (Please communicate this to the author at once.)

If the problem had been posed for, say, 1000 items, not merely 5, you may also have discovered some of the more subtle techniques which will be mentioned later. At any rate, when attacking a new problem it is often wise to find some fairly obvious procedure which works, and then try to improve upon it. Cases A, B, and C above lead to important classes of sorting techniques which are refinements of the simple ideas stated.

Many different sorting algorithms have been invented, and we will be discussing about 25 of them in this book. This rather alarming number of methods is actually only a fraction of the algorithms that have been devised so far; many methods which are now obsolete will be omitted from our discussion, or mentioned only briefly. Why are there so many sorting methods? For computer programming, this is a special case of the question, "Why are there so many x methods?", where x ranges over the set of problems; and the answer is that each method has its own advantages and disadvantages, so that it outperforms the others on some configurations of data and hardware. Unfortunately, there is no known "best" way to sort; there are *many* best methods, depending on what is to be sorted on what machine for what purpose. In the words of Rudyard Kipling, "There are nine and sixty ways of constructing tribal lays, and every single one of them is right."

It is a good idea to learn the characteristics of each sorting method, so that an intelligent choice can be made for particular applications. Fortunately, it is not a formidable task to learn these algorithms, since they are interrelated in interesting ways.

At the beginning of this chapter we defined the basic terminology and notation to be used in our study of sorting: The records

$$R_1, R_2, \ldots, R_N \tag{1}$$

are to be sorted into nondecreasing order of their keys $K_1, K_2, \ldots, K_N$, essentially by discovering a permutation $p(1)\ p(2) \ldots p(N)$ such that

$$K_{p(1)} \le K_{p(2)} \le \cdots \le K_{p(N)}. \tag{2}$$

In the present section we are concerned with *internal sorting*, when the number of records to be sorted is small enough that the entire process can be performed in a computer's high-speed memory.

In some cases we will want the records to be physically rearranged in memory so that their keys are in order, while in other cases it may be sufficient merely to have an auxiliary table of some sort which specifies the permutation. If the records and/or the keys each take up quite a few words of computer memory, it is often better to make up a new table of link addresses which point to the records, and to manipulate these link addresses instead of moving the bulky records around. This method is called *address table sorting* (see Fig. 6). If the key is short but the satellite information of the records is long, the key may be placed with the link addresses for greater speed; this is called *key sorting*. Other sorting schemes utilize an auxiliary link field which is included in each record; these links are manipulated in such a way that, in the final result, the records are linked together to form a straight linear list, with each link pointing to the following record. This is called *list sorting* (see Fig. 7).

After sorting with an address table or list method, the records can be rearranged into increasing order as desired. There are several ways to do this,

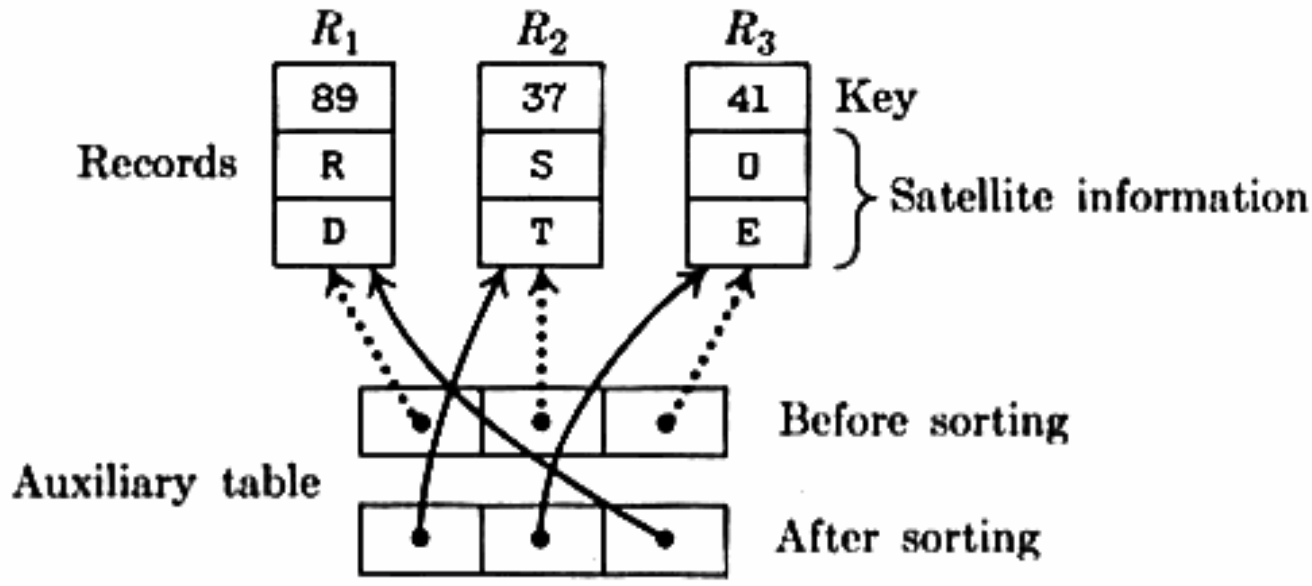


Fig. 6. Address table sorting.

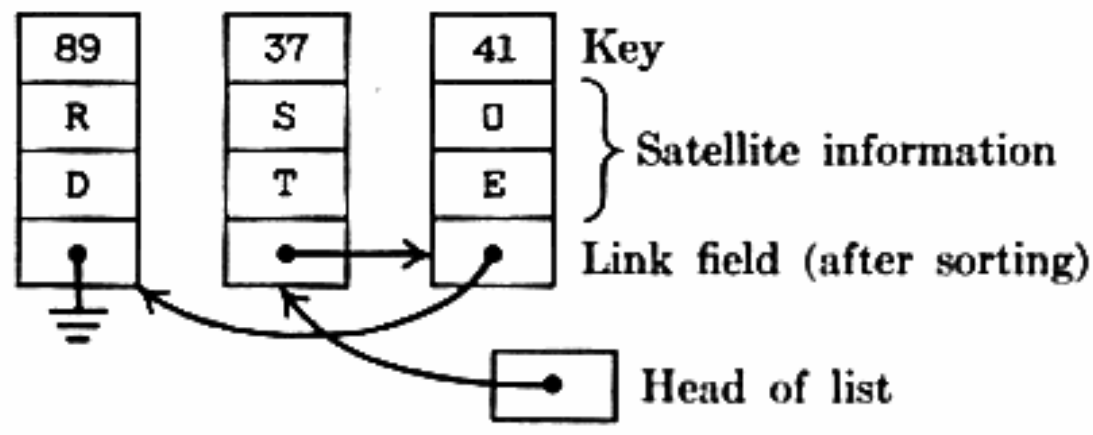

Fig. 7. List sorting.

requiring only enough additional memory space to hold one record (see exercises 10 through 12); alternatively, we can simply move the records into a new area capable of holding all records. The latter method is usually about twice as fast as the former, but it demands nearly twice as much storage space. It is unnecessary to move the records at all, in many applications, since the link fields are often adequate for subsequent addressing operations.

All of the sorting methods which we shall examine "in depth" will be illustrated in four ways, by means of

a) an English-language description of the algorithm,

b) a flow diagram,

c) a MIX program, and

d) an example of the sorting method applied to a given set of numbers.

[Wherever appropriate, the latter example will deal with a certain set of 16 numbers which were chosen at random by the author on March 19, 1963, using a set of decimal dice; cf. exercise 3.1–1(c).]

For convenience, the MIX programs will usually be given under the assumption that the key is numeric and that it fits in a single word; sometimes we will even restrict the key to part of a word. The order relation $<$ will be ordinary arithmetic order; and the record will consist of the key alone, with no satellite information. These assumptions make the programs shorter and easier to understand, and it should be clear how to modify the programs (e.g., by

using address table sorting) for the general case. An analysis of the running time of each sorting algorithm will be given with the MIX programs.

Sorting by counting. As a simple example of the way in which we shall study internal sorting methods, let us consider the "counting" idea mentioned near the beginning of this section. This simple method is based on the idea that the jth key in the final sorted sequence is greater than exactly $(j - 1)$ of the other keys. Putting this another way, if we know that a certain key exceeds exactly 27 others, the corresponding record should go into position 28 after sorting. So the idea is to compare each pair of keys, counting how many are less than each particular one.

The obvious way to do the comparisons is to

$$\big((\text{compare } K_j \text{ with } K_i) \text{ for } 1 \le j \le N\big) \text{ for } 1 \le i \le N;$$

but it is easy to see that over half of these comparisons are redundant, since it is unnecessary to compare a key with itself, and it is unnecessary to compare K_a with K_b and later to compare K_b with K_a. We need merely to

$$\big((\text{compare } K_j \text{ with } K_i) \text{ for } 1 \le j \le i\big) \text{ for } 1 < i \le N.$$

Hence we are led to the following algorithm.

Algorithm C (*Comparison counting*). This algorithm sorts $R_1, \ldots, R_N$ on the keys $K_1, \ldots, K_N$ by maintaining an auxiliary table COUNT[1], ..., COUNT[N] to count the number of keys less than a given key. After the conclusion of the algorithm, COUNT[j] + 1 specifies the final position of record R_j.

C1. [Clear COUNTs.] Set COUNT[1] through COUNT[N] to zero.

C2. [Loop on i.] Perform step C3, for $i = N, N - 1, \ldots, 2$; then terminate the algorithm.

C3. [Loop on j.] Perform step C4, for $j = i - 1, i - 2, \ldots, 1$.

C4. [Compare K_i, K_j.] If $K_i < K_j$, increase COUNT[j] by 1; otherwise increase COUNT[i] by 1. ∎

Note that this algorithm involves no movement of records. It is similar to an address table sort, since the COUNT table specifies the final arrangement of records; but it is somewhat different because COUNT[j] tells us where to move R_j, instead of indicating which record should be moved into the place of R_j. (Thus the "inverse" of the permutation $p(1) \ldots p(n)$ is specified in the COUNT table; see Section 5.1.1.)

In our discussion preceding this algorithm we failed to consider the possibility of equal keys. This is a potentially serious omission, for if equal keys corresponded to equal COUNTs the final rearrangement of records would be rather complicated. Fortunately, as exercise 2 shows, Algorithm C gives the correct result no matter how many equal keys are present.

Table 1

SORTING BY COUNTING (ALGORITHM C)

KEYS:	503	087	512	061	908	170	897	275	653	426	154	509	612	677	765	703
COUNT(init.):	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0
COUNT($i = N$):	0	0	0	0	1	0	1	0	0	0	0	0	0	0	1	12
COUNT($i = N - 1$):	0	0	0	0	2	0	2	0	0	0	0	0	0	0	13	12
COUNT($i = N - 2$):	0	0	0	0	3	0	3	0	0	0	0	0	0	11	13	12
COUNT($i = N - 3$):	0	0	0	0	4	0	4	0	1	0	0	0	9	11	13	12
COUNT($i = N - 4$):	0	0	1	0	5	0	5	0	2	0	0	7	9	11	13	12
COUNT($i = N - 5$):	1	0	2	0	6	1	6	1	3	1	2	7	9	11	13	12
. . . . .																
COUNT($i = 2$):	6	1	8	0	15	3	14	4	10	5	2	7	9	11	13	12

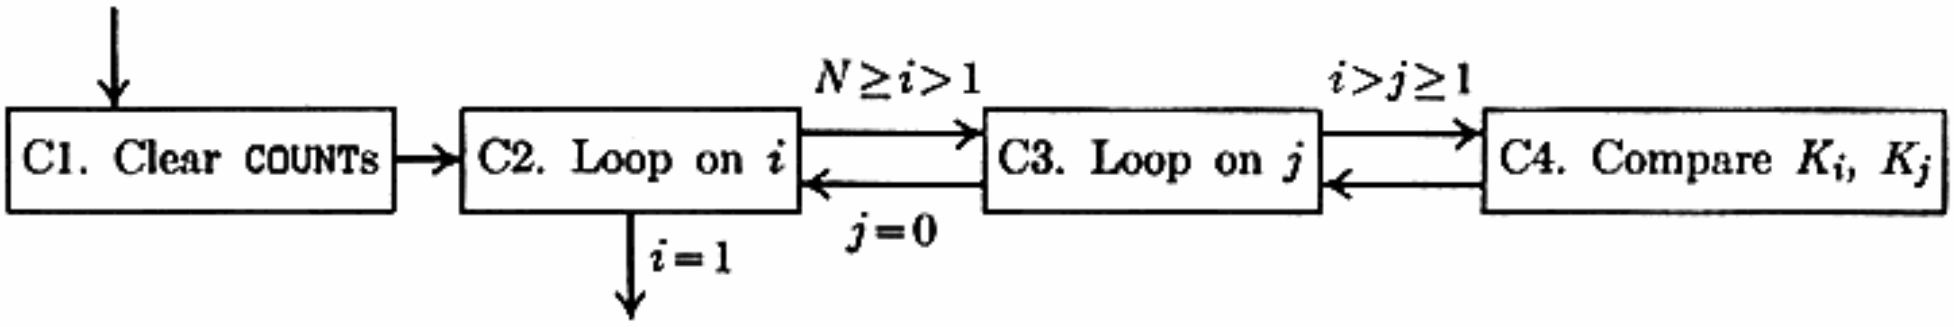

Fig. 8. Algorithm C: Comparison counting.

Program C (*Comparison counting*). The following MIX implementation of Algorithm C assumes that R_j is stored in location INPUT $+ j$, and COUNT[j] in location COUNT $+ j$, for $1 \leq j \leq N$; rI1 $\equiv i$; rI2 $\equiv j$; rA $\equiv K_i \equiv R_i$; rX $\equiv$ COUNT[i].

```
1  START  ENT1  N          1        C1. Clear COUNTs.
2         STZ   COUNT,1    N        COUNT[i] ← 0.

20 1H     ENT2  -1,1         N      N ≥ i > j > 0.
21        J2P   2B           N      ∎
```

The running time of this program is $13N + 6A + 5B - 4$ units, where N is the number of records; A is the number of choices of two things from a set of N objects, namely $\binom{N}{2} = (N^2 - N)/2$; and B is the number of pairs of indices with $j < i$ and $K_j > K_i$. Thus, B is the number of *inversions* of the permutation $K_1, \ldots, K_N$; this is the quantity that was analyzed extensively in Section 5.1.1, where we found (Eqs. 5.1.1–12, 13) that, for unequal keys in random order,

$$B = (\min 0, \text{ave } (N^2 - N)/4, \max (N^2 - N)/2, \text{dev } \sqrt{N(N-1)(N+2.5)/6}).$$

Hence Program C requires between $3N^2 + 10N - 4$ and $5.5N^2 + 7.5N - 4$ units of time, and the average running time lies halfway between these two extremes. For example, the data in Table 1 has $N = 16$, $A = 120$, $B = 41$, so Program C will sort it in $1129u$. See exercise 5 for a modification of Program C which has slightly different timing characteristics.

The factor N^2 which dominates this running time shows that Algorithm C isn't an efficient way to sort when N is large; doubling the number of records increases the running time fourfold. Since the method requires a comparison of all distinct pairs of keys (K_i, K_j), there is no apparent way to get rid of the dependence on N^2, although we will see later in this chapter that the average running time can be reduced to order $N \log N$ using the "partition exchange" technique. Our main interest in Algorithm C is its simplicity, not its efficiency; it serves as an example of the style in which we will be describing more complex (and more efficient) methods.

There is another way to sort by counting which *is* quite important from the standpoint of efficiency; it is primarily applicable in the case that many equal keys are present, and when all keys fall into the range $u \le K_j \le v$, where $(v - u)$ is small. These assumptions appear to be quite restrictive, but in fact we shall see quite a few applications of the idea; for example, if we apply this method to the leading digits of keys instead of applying it to entire keys, the file will be partially sorted and it will be comparatively simple to complete the job.

In order to understand the principles involved, suppose that all keys lie between 1 and 100. In one pass through the file we can count how many 1's, 2's, . . . , 100's are present; and in a second pass we can move the records into the appropriate place in an output area. The following algorithm spells things out in more detail:

Algorithm D (*Distribution counting*). Assuming that all keys are integers in the range $u \le K_j \le v$ for $1 \le j \le N$, this algorithm sorts the records $R_1, \ldots, R_N$ by making use of an auxiliary table COUNT[u], . . . , COUNT[v]. At the conclusion of the algorithm the records are moved to an output area $S_1, \ldots, S_N$ in the desired order.

D1. [Clear COUNTs.] Set COUNT[u] through COUNT[v] all to zero.

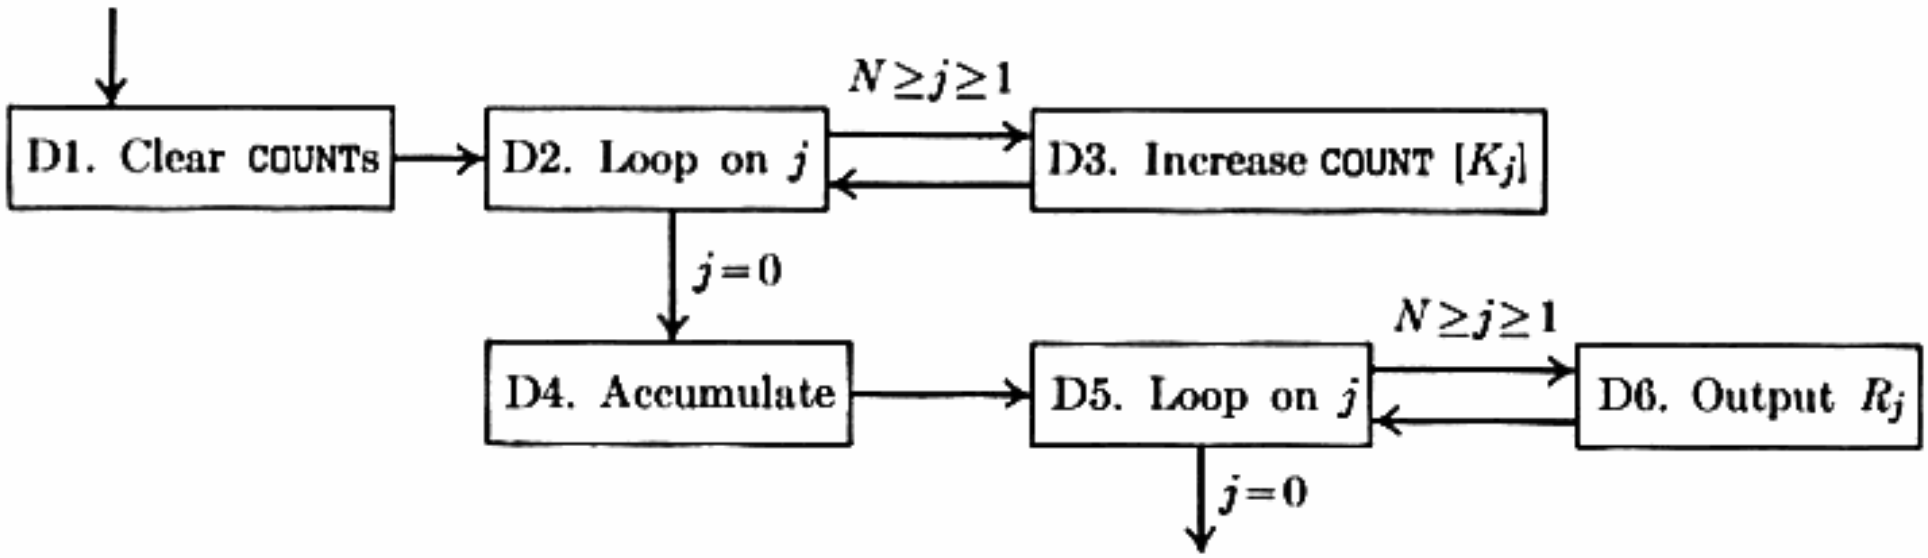

Fig. 9. Algorithm D: Distribution counting.

D2. [Loop on j.] Perform step D3 for $1 \leq j \leq N$; then go to step D4.

D3. [Increase COUNT$[K_j]$.] Increase the value of COUNT$[K_j]$ by 1.

D4. [Accumulate.] (At this point COUNT$[i]$ is the number of keys which are equal to i.) Set COUNT$[i] \leftarrow$ COUNT$[i]$ + COUNT$[i-1]$, for $i = u+1, u+2, \ldots, v$.

D5. [Loop on j.] (At this point COUNT$[i]$ is the number of keys which are less than or equal to i; in particular COUNT$[v] = N$.) Perform step D6 for $j = N, N-1, \ldots, 1$; then terminate the algorithm.

D6. [Output R_j.] Set $i \leftarrow$ COUNT$[K_j]$, $S_i \leftarrow R_j$, and COUNT$[K_j] \leftarrow i - 1$. ∎

An example of this algorithm is worked out in exercise 6; a MIX program appears in exercise 9. Under the conditions stated above, this sorting procedure is very fast.

Sorting by comparison counting as in Algorithm C was first mentioned in print by E. H. Friend [*JACM* **3** (1956), 152], although he didn't claim it as his own invention. Distribution sorting as in Algorithm D was first developed by H. Seward in 1954 for use with radix sorting techniques which we will discuss later (see Section 5.2.5); it was also published under the name "Mathsort" by W. Feurzig, *CACM* **3** (1960), 601.

EXERCISES

1. [*15*] Would Algorithm C still work if i varies from 2 up to N in step C2, instead of from N down to 2? What if j varies from 1 up to $i - 1$ in step C3?

2. [*21*] Show that Algorithm C works properly when equal keys are present. If $K_j = K_i$ and $j < i$, does R_j come before or after R_i in the final ordering?

▶ **3.** [*21*] Would Algorithm C still work properly if the test in step D4 were changed from "$K_i < K_j$" to "$K_i \leq K_j$"?

4. [*16*] Write a `MIX` program which "finishes" the sorting begun by Program C; your program should transfer the keys to locations `OUTPUT+1` through `OUTPUT+N`, in ascending order. How much time does your program require?

5. [*22*] Does the following set of changes improve Program C?

New line 8a: `INCX 0,2`
Change line 10: `JGE  5F`
Change line 14: `DECX 1`
Delete line 15

6. [*18*] Simulate Algorithm D by hand, showing intermediate results when the 16 records `5T`, `0C`, `5U`, `0D`, `9.`, `1N`, `8S`, `2R`, `6A`, `4A`, `1G`, `5L`, `6T`, `6I`, `7O`, `7N` are being sorted. Here the numeric digit is the key, and the alphabetic information is just carried along with the records.

7. [*13*] Is Algorithm D a "stable" sorting method?

8. [*15*] Would Algorithm D still work properly if j were to vary from 1 up to N in step D5, instead of from N down to 1?

9. [*23*] Write a `MIX` program for Algorithm D, analogous to Program C and exercise 4. What is the execution time of your program, as a function of N and $(v - u)$?

10. [*25*] Design an efficient algorithm which replaces the N quantities $(R_1, \ldots, R_N)$ by $(R_{p(1)}, \ldots, R_{p(N)})$, respectively, given the values of $R_1, \ldots, R_N$ and the permutation $p(1) \ldots p(N)$ of $\{1, \ldots, N\}$. Try to avoid using excess memory space. (This problem arises if we wish to rearrange records in memory after an address table sort, without requiring room for storing $2N$ records.)

11. [*M27*] Write a `MIX` program for the algorithm of exercise 10, and analyze its efficiency.

▶ **12.** [*25*] Design an efficient algorithm suitable for rearranging the records $R_1, \ldots, R_N$ into sorted order, after a list sort (Fig. 7) has been completed. Try to avoid using excess memory space.

▶ **13.** [*27*] Algorithm D requires space for $2N$ records $R_1, \ldots, R_N$ and $S_1, \ldots, S_N$. Show that it is possible to get by with only N records $R_1, \ldots, R_N$, if a new unshuffling procedure is substituted for steps D5 and D6. (Thus the problem is to design an algorithm which rearranges $R_1, \ldots, R_N$ in place, based on the values of

$$\texttt{COUNT}[u], \ldots, \texttt{COUNT}[v]$$

after step D4, without using additional memory space; this is essentially a generalization of the problem considered in exercise 10.)

5.2.1. Sorting by Insertion

One of the important families of sorting techniques is based on the "bridge player" method mentioned near the beginning of Section 5.2: Before examining record R_j, we assume that the preceding records $R_1, \ldots, R_{j-1}$ have already been sorted; then we insert R_j into its proper place among the previously sorted records. Several interesting variations on this basic theme are possible.

Straight insertion. The simplest insertion sort is the most obvious one. Assume that $1 < j \leq N$ and that records $R_1, \ldots, R_{j-1}$ have been rearranged so that

$$K_1 \leq K_2 \leq \cdots \leq K_{j-1}.$$

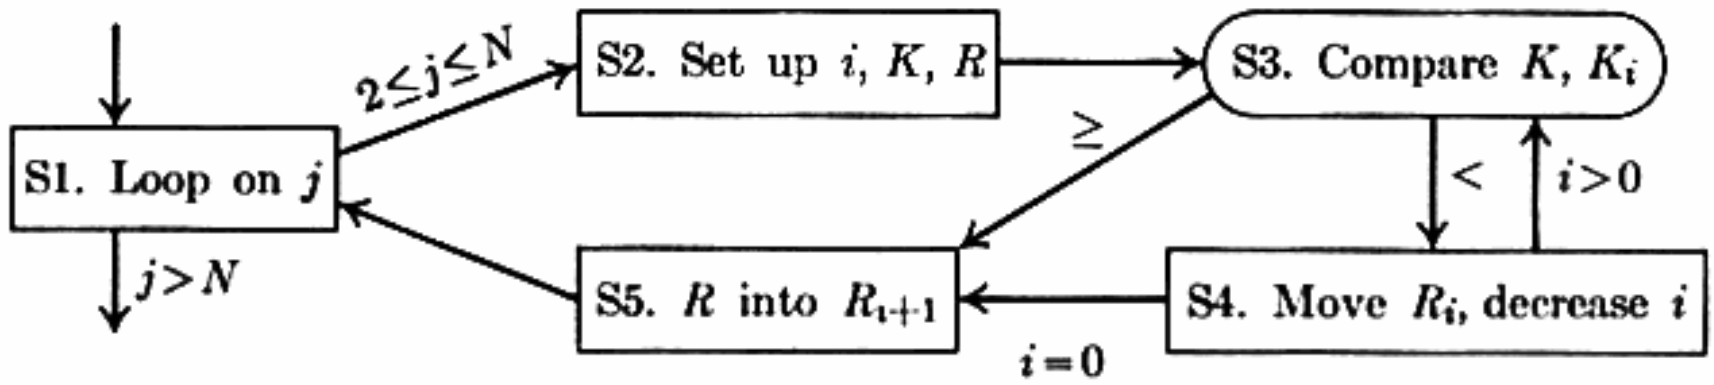

Fig. 10. Algorithm S: Straight insertion.

(Remember that, throughout this chapter, K_j denotes the key portion of R_j.) We compare the new key K_j with K_{j-1}, K_{j-2}, . . . , in turn, until discovering that R_j should be inserted between records R_i and R_{i+1}; then we move records $R_{i+1}, \ldots, R_{j-1}$ up one space and put the new record into position $i + 1$. It is convenient to combine the comparison and moving operations, interleaving them as shown in the following algorithm; since R_j "settles to its proper level" this method of sorting has often been called the *sifting* or *sinking* technique.

Algorithm S (*Straight insertion sort*). Records $R_1, \ldots, R_N$ are rearranged in place; after sorting is complete, their keys will be in order, $K_1 \le \cdots \le K_N$.

S1. [Loop on j.] Perform steps S2 through S5 for $j = 2, 3, \ldots, N$; then terminate the algorithm.

S2. [Set up i, K, R.] Set $i \leftarrow j - 1$, $K \leftarrow K_j$, $R \leftarrow R_j$. (In the following steps we will attempt to insert R into the correct position, by comparing K with K_i for decreasing values of i.)

S3. [Compare K, K_i.] If $K \ge K_i$, go to step S5. (We have found the desired position for record R.)

S4. [Move R_i, decrease i.] Set $R_{i+1} \leftarrow R_i$, then $i \leftarrow i - 1$. If $i > 0$, go back to step S3. (If $i = 0$, K is the smallest key found so far, so record R belongs in position 1.)

S5. [R into R_{i+1}.] Set $R_{i+1} \leftarrow R$. ∎

Table 1 shows how our sixteen example numbers are sorted by Algorithm S. This method is extremely easy to implement on a computer; in fact the following MIX program is the shortest decent sorting routine in this book.

Program S (*Straight insertion sort*). The records to be sorted are in locations INPUT+1 through INPUT+N; they are sorted in place in the same area, on a full-word key. rI1 $\equiv j - N$; rI2 $\equiv i$; rA $\equiv R \equiv K$; assume that $N \ge 2$.

01	START	ENT1	2-N	1	*S1. Loop on j.* $j \leftarrow 2$.
02	2H	LDA	INPUT+N,1	$N - 1$	*S2. Set up i, K, R.*
03		ENT2	N-1,1	$N - 1$	$i \leftarrow j - 1$.
04	3H	CMPA	INPUT,2	$B + N - 1 - A$	*S3. Compare K, K_i.*
05		JGE	5F	$B + N - 1 - A$	To S5 if $K \ge K_i$.

06	4H	LDX	INPUT,2	B	*S4. Move R_i, decrease i.*
07		STX	INPUT+1,2	B	$R_{i+1} \leftarrow R_i$.
08		DEC2	1	B	$i \leftarrow i - 1$.
09		J2P	3B	B	To S3 if $i > 0$.
10	5H	STA	INPUT+1,2	$N - 1$	*S5. R into R_{i+1}.*
11		INC1	1	$N - 1$	
12		J1NP	2B	$N - 1$	$2 \le j \le N$. ∎

The running time of this program is $9B + 10N - 3A - 9$ units, where N is the number of records sorted, A is the number of times i decreases to zero in step S4, and B is the number of moves. Clearly A is the number of times $K_j < (K_1, \ldots, K_{j-1})$, for $1 < j \le N$; this is the number of left-to-right minima, namely the quantity which was analyzed carefully in Section 1.2.10. Some reflection shows us that B is also a familiar quantity: The number of moves for fixed j is the number of inversions of K_j, so B is the number of inversions of the permutation $K_1\, K_2 \ldots K_N$. Hence by Eqs. 1.2.10–16 and 5.1.1–12, 13,

$$A = (\min 0,\ \text{ave}\ H_N - 1,\ \max N - 1,\ \text{dev}\ \sqrt{H_n - H_n^{(2)}});$$

$$B = (\min 0,\ \text{ave}\ (N^2 - N)/4,\ \max (N^2 - N)/2,\ \text{dev}\ \sqrt{N(N-1)(N+2.5)/6});$$

and the average running time of Program S, assuming that the input keys are distinct and randomly ordered, is $(2.25N^2 + 7.75N - 3H_N - 6)u$. Exercise 33 explains how to improve this slightly.

The example data in Table 1 involves 16 items; there are two left-to-right minima, namely 087 and 061; and there are 41 inversions, as we have seen in the previous section. Hence $N = 16$, $A = 2$, $B = 41$, and the total sorting time is $514u$.

Table 1

Binary insertion and two-way insertion. While the jth record is being processed during a straight insertion sort, we compare its key with about $\frac{1}{2}j$ of the previously sorted keys, on the average; therefore the total number of comparisons performed comes to about $\frac{1}{2}(1 + 2 + \cdots + N) \approx \frac{1}{4}N^2$, and this gets very large when N is only moderately large. In Section 6.2.1 we shall study "binary search" techniques, which show where to insert the jth item after only about $\log_2 j$ well-chosen comparisons have been made. For example, when inserting the 64th record we can start by comparing K_{64} with K_{32}; if it is less, we compare it with K_{16}, but if it is greater we compare it with K_{48}, etc., so that the proper place to insert R_{64} will be known after making only six comparisons. The total number of comparisons for inserting all N items comes to about $N \log_2 N$, a substantial improvement over $\frac{1}{4}N^2$; and Section 6.2.1 shows that the corresponding program need not be much more complicated than a program for straight insertion. This method is called *binary insertion;* it was mentioned by John Mauchly as early as 1946, in the first published discussion of computer sorting.

The unfortunate difficulty with binary insertion is that it solves only half of the problem; after we have found where record R_j is to be inserted, we still need to move about $\frac{1}{2}j$ of the previously sorted records in order to make room for R_j, so the total running time is still essentially proportional to N^2. Some computers (e.g., the IBM 705) have a built-in "tumble" instruction which does such move operations at high speed, but as N increases the dependence on N^2 eventually takes over. For example, an analysis by H. Nagler [*CACM* **3** (1960), 618–620] indicates that binary insertion should not be recommended for sorting more than about $N = 128$ records on the 705, when each record is 80 characters long, and similar analyses apply to other machines.

Of course, a clever programmer can think of various ways to reduce the amount of moving that is necessary; the first such trick, proposed early in the 1950's, is illustrated in Table 2. Here the first item is placed in the center of

Table 2

TWO-WAY INSERTION

			^503				
			087	503^			
		^087	503	512			
		061	087	503	512^		
		061	087^	503	512	908

	061	087	170^	503	512	897	908
061	087	170	275	503	512	897	908

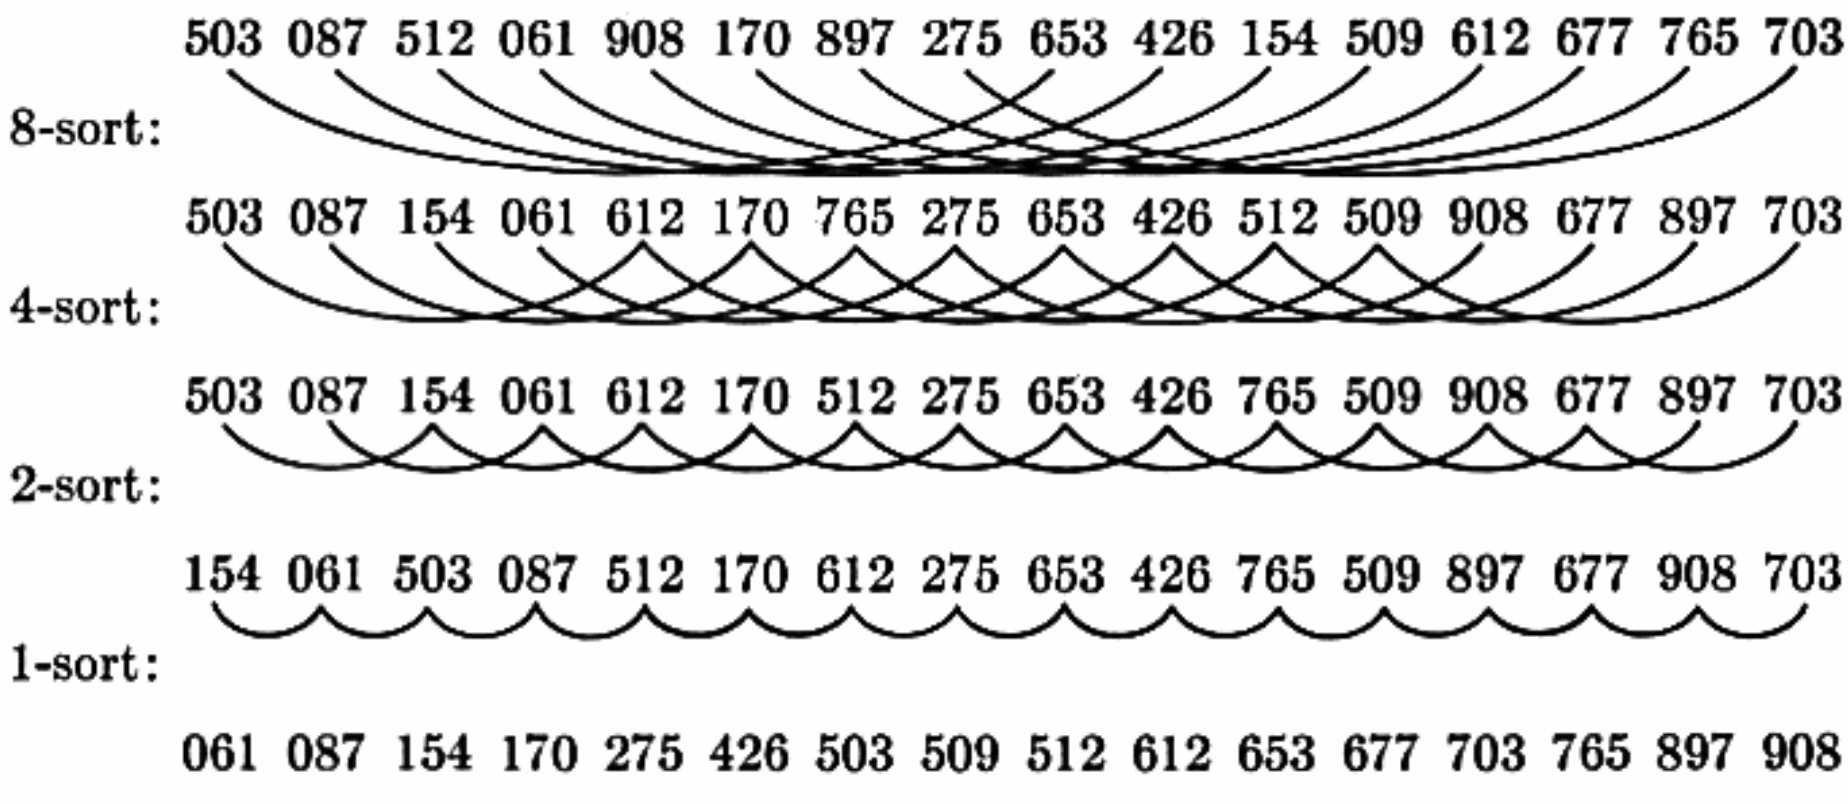
an output area, and space is made for subsequent items by moving to the right or to the left, whichever is most convenient. This saves about half the running time of ordinary binary insertion, at the expense of a somewhat more complicated program. It is possible to use this method without using up more space than required for N records (see exercise 6); but we shall not dwell any longer on this "two-way" method of insertion, since considerably more interesting methods have been developed.

Shell's method. If we have a sorting algorithm which moves items only one position at a time, its average running time will be, at best, proportional to N^2, since each record must travel an average of about $\frac{1}{3}N$ positions during the sorting process (see exercise 7). Therefore, if we want to make substantial improvements over straight insertion, we need some mechanism by which the records can take long leaps instead of short steps.

Such a method was proposed in 1959 by Donald L. Shell [*CACM* **2** (July, 1959), 30–32]; we shall call it the *diminishing increment sort*. Table 3 illustrates the general idea behind his method: First we divide the 16 records into 8 groups of two each, namely (R_1, R_9), (R_2, R_{10}), . . . , (R_8, R_{16}). Sorting each group of records separately takes us to the second line of Table 3; this is called the "first pass." Note that 154 has changed places with 512; 908 and 897 both jump to the right. Now we divide the records into 4 groups of four each, namely (R_1, R_5, R_9, R_{13}), . . . , $(R_4, R_8, R_{12}, R_{16})$, and again each group is sorted separately; this "second pass" takes us to line 3. A third pass sorts two groups of eight records, then a fourth pass completes the job by sorting all 16 records. Each of the intermediate sorting processes involves either a comparatively short file or a file which is comparatively well ordered, so straight insertion can

Table 3

DIMINISHING INCREMENT SORT (8, 4, 2, 1)



be used for each sorting operation; the records tend to converge quickly to their final destination.

The sequence of increments 8, 4, 2, 1 is not sacred; *any* sequence $h_t, h_{t-1}, \ldots, h_1$ can be used, so long as the last increment h_1 equals 1. For example, Table 4 shows the same data sorted with increments 7, 5, 3, 1. Some sequences are much better than others; we will discuss the choice of increments later.

Algorithm D (*Diminishing increment sort*). Records $R_1, \ldots, R_N$ are rearranged in place; after sorting is complete, their keys will be in order, $K_1 \le \cdots \le K_N$. An auxiliary sequence of increments $h_t, h_{t-1}, \ldots, h_1$ is used to control the sorting process, where $h_1 = 1$; proper choice of these increments can significantly decrease the sorting time. This algorithm reduces to Algorithm S when $t = 1$.

D1. [Loop on s.] Perform step D2 for $s = t, t - 1, \ldots, 1$; then terminate the algorithm.

D2. [Loop on j.] Set $h \leftarrow h_s$, and perform steps D3 through D6 for $h < j \le N$. (We will use a straight insertion method to sort elements that are h positions apart, so that $K_i \le K_{i+h}$ for $1 \le i \le N - h$. Steps D3 through D6 are essentially the same as steps S2 through S5, respectively, in Algorithm S.)

D3. [Set up i, K, R.] Set $i \leftarrow j - h$, $K \leftarrow K_j$, $R \leftarrow R_j$.

D4. [Compare K, K_i.] If $K \ge K_i$, go to step D6.

D5. [Move R_i, decrease i.] Set $R_{i+h} \leftarrow R_i$, then $i \leftarrow i - h$. If $i > 0$, go back to step D4.

D6. [R into R_{i+h}.] Set $R_{i+h} \leftarrow R$. ∎

The corresponding MIX program is not much longer than our program for straight insertion. Lines 08–19 of the following code are a direct translation of Program S into the more general framework of Algorithm D.

Program D (*Diminishing increment sort*). We assume that the increments are stored in an auxiliary table, with h_s in location H + s; all increments are less than N. Register assignments: rI1 ≡ $j - N$; rI2 ≡ i; rA ≡ $R \equiv K$; rI3 ≡ s; rI4 ≡ h. Note that this program modifies itself, in order to obtain efficient execution of the inner loop.

***Analysis of Shell's Method.** In order to choose a good sequence of increments $h_t, \ldots, h_1$ for use in Algorithm D, we need to analyze the running time as a function of those increments. This leads to some fascinating mathematical problems, not yet completely resolved; nobody has been able to determine the best possible sequence of increments for large values of N. Yet a good many interesting facts are known about the behavior of Shell's diminishing increment sort, and we will summarize them here; details appear in the exercises below. [Readers who are not mathematically inclined should skim over the next few pages, continuing at the formulas numbered (8) below.]

The frequency counts shown with Program D indicate that five factors determine the execution time: the size of the file, N; the number of passes (i.e., the number of increments), $T = t$; the sum of the increments,

$$S = h_1 + \cdots + h_t;$$

the number of comparisons, $B + NT - S - A$; and the number of moves, B. As in the analysis of Program S, A is the number of left-to-right minima encountered in the intermediate sorting operations, and B is the number of inversions in the subfiles. The factor which governs the running time is B, so we shall devote most of our attention to it. For purposes of analysis we shall assume that the keys are distinct and initially in random order.

Let us call the operation of step D2 "h-sorting," so that Shell's method consists of h_t-sorting, followed by h_{t-1}-sorting, . . . , followed by h_1-sorting. A file in which $K_i \leq K_{i+h}$ for $1 \leq i \leq N - h$ will be called "h-ordered."

Consider first the simplest generalization of straight insertion, when there are just two increments, $h_2 = 2$ and $h_1 = 1$. During the second pass we have a 2-ordered sequence of keys, $K_1\, K_2 \ldots K_N$. It is easy to see that the number of permutations $a_1\, a_2 \ldots a_n$ of $\{1, 2, \ldots, n\}$ such that $a_i \leq a_{i+2}$ for $1 \leq i \leq n - 2$ is

$$\binom{n}{\lfloor n/2 \rfloor},$$

since we obtain exactly one 2-ordered permutation for each choice of $\lfloor n/2 \rfloor$ elements to put in even-numbered positions $a_2\, a_4 \ldots$, with the remaining $\lceil n/2 \rceil$ elements going in odd-numbered positions. Each 2-ordered permutation

is equally likely after a random file has been 2-sorted. What is the average number of inversions among all such permutations?

Let A_n be the total number of inversions among all 2-ordered permutations of $\{1, 2, \ldots, n\}$. Clearly $A_1 = 0$, $A_2 = 1$, $A_3 = 2$; and by considering the six cases

1 3 2 4 1 2 3 4 1 2 4 3 2 1 3 4 2 1 4 3 3 1 4 2

we find that $A_4 = 1 + 0 + 1 + 1 + 2 + 3 = 8$. In order to investigate A_n in general, consider the "lattice diagram" illustrated in Fig. 11 for $n = 15$. A 2-ordered permutation of $\{1, 2, \ldots, n\}$ can be represented as a path from the upper left corner point (0, 0) to the lower right corner point $(\lceil n/2 \rceil, \lfloor n/2 \rfloor)$, if we make the kth step of the path go downwards or to the right, respectively, according as k appears in an odd or an even position in the permutation. This rule defines a one-to-one correspondence between 2-ordered permutations and n-step paths from corner to corner of the lattice diagram; for example, the path shown corresponds to the permutation

$$2\ 1\ 3\ 4\ 6\ 5\ 7\ 10\ 8\ 11\ 9\ 12\ 14\ 13\ 15. \qquad (1)$$

Furthermore, we can attach "weights" to the vertical lines of the path, as the diagram shows; a line from (i, j) to $(i + 1, j)$ gets weight $|i - j|$. A little study will convince the reader that the sum of these weights along each path is equal to the number of inversions of the corresponding permutation. (See exercise 12.) Thus, for example, (1) has $1 + 0 + 1 + 0 + 1 + 2 + 1 + 0 = 6$ inversions.

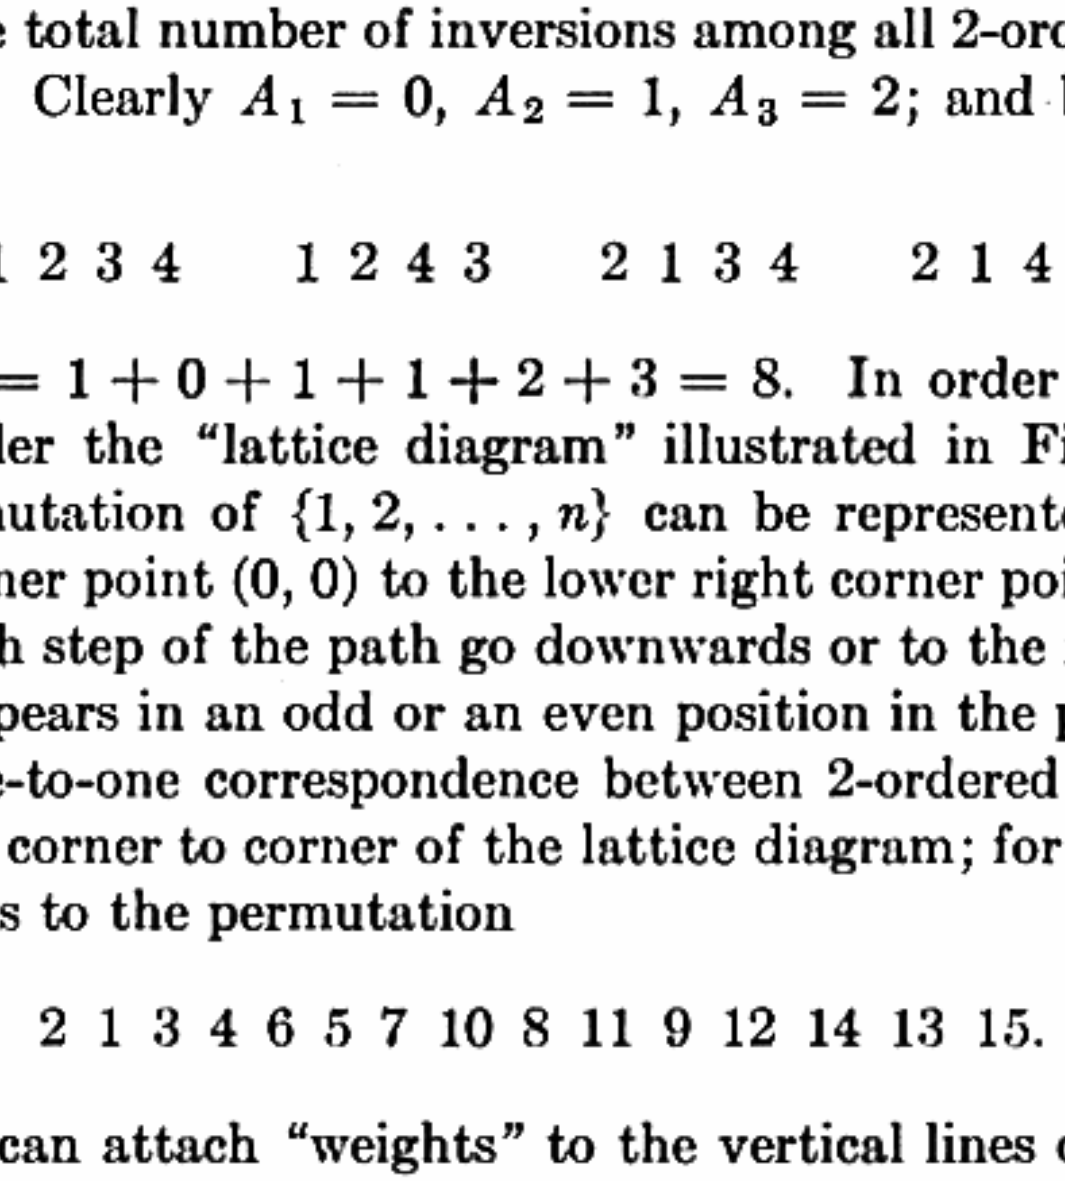

Fig. 11. Correspondence between 2-ordering and paths in a lattice. Italicized numbers are weights which correspond to the number of inversions in the 2-ordered permutation.

When $a \le a'$ and $b \le b'$, the number of relevant paths from (a, b) to (a', b') is the number of ways to mix $a' - a$ vertical lines with $b' - b$ horizontal lines, namely

$$\binom{a' - a + b' - b}{a' - a};$$

hence the number of permutations whose corresponding path traverses the vertical line segment from (i, j) to $(i + 1, j)$ is

$$\binom{i + j}{i}\binom{n - i - j - 1}{\lfloor n/2 \rfloor - j}.$$

Multiplying by the associated weight and summing over all segments gives

$$A_{2n} = \sum_{\substack{0 \le i \le n \\ 0 \le j \le n}} |i - j| \binom{i + j}{i}\binom{2n - i - j - 1}{n - j};$$

$$A_{2n+1} = \sum_{\substack{0 \le i \le n \\ 0 \le j \le n}} |i - j| \binom{i + j}{i}\binom{2n - i - j}{n - j}. \tag{2}$$

The absolute value signs in these sums make the calculations somewhat tricky, but exercise 14 shows that A_n has the surprisingly simple form $\lfloor n/2 \rfloor 2^{n-2}$. Hence the average number of inversions in a random 2-ordered permutation is

$$\lfloor n/2 \rfloor 2^{n-2} \Big/ \binom{n}{\lfloor n/2 \rfloor};$$

by Stirling's approximation this is asymptotically $\sqrt{\pi/128}\, n^{3/2} \approx 0.15n^{3/2}$. The maximum number of inversions is easily seen to be

$$\binom{\lfloor n/2 \rfloor + 1}{2} \approx \frac{1}{8} n^2.$$

It is instructive to study the distribution of inversions more carefully, by examining the generating functions

$$h_1(z) = 1, \qquad h_2(z) = 1 + z,$$
$$h_3(z) = 1 + 2z, \qquad h_4(z) = 1 + 3z + z^2 + z^3, \qquad \ldots, \tag{3}$$

as in exercise 15. In this way we find that the standard deviation is also proportional to $n^{3/2}$, so the distribution is not extremely stable about the mean.

Now let us consider the general two-pass case of Algorithm D, when the increments are h and 1:

Theorem H. *The average number of inversions in an h-ordered permutation of $\{1, 2, \ldots, n\}$ is*

$$f(n, h) = \frac{2^{2q-1}q!q!}{(2q+1)!}\left(\binom{h}{2}q(q+1) + \binom{r}{2}(q+1) - \frac{1}{2}\binom{h-r}{2}q\right), \quad (4)$$

where $q = \lfloor n/h \rfloor$, $r = n \bmod h$.

This theorem is due to Douglas H. Hunt [Bachelor's thesis, Princeton University (April, 1967)]. Note that when $h \geq n$ the formula correctly gives $f(n, h) = \frac{1}{2}\binom{n}{2}$.

Proof. An h-ordered permutation contains r sorted subsequences of length $q+1$, and $h-r$ of length q. Each inversion comes from a pair of distinct subsequences, and a given pair of distinct subsequences in a random h-ordered permutation defines a random 2-ordered permutation. The average number of inversions is therefore the sum of the average numbers of inversions between each pair of distinct subsequences, namely

$$\binom{r}{2}\frac{A_{2q+2}}{\binom{2q+2}{q+1}} + r(h-r)\frac{A_{2q+1}}{\binom{2q+1}{q}} + \binom{h-r}{2}\frac{A_{2q}}{\binom{2q}{q}} = f(n, h). \quad \blacksquare$$

Corollary. *If the sequence of increments $h_t, \ldots, h_1$ satisfies the condition*

$$h_{s+1} \bmod h_s = 0, \qquad \text{for} \qquad t > s \geq 1, \quad (5)$$

then the average number of move operations in Algorithm D is

$$\sum_{t \geq s \geq 1} (r_s f(q_s + 1, h_{s+1}/h_s) + (h_s - r_s)f(q_s, h_{s+1}/h_s)), \quad (6)$$

where $r_s = N \bmod h_s$, $q_s = \lfloor N/h_s \rfloor$, $h_{t+1} = N$, and f is defined in (4).

Proof. The process of h_s-sorting consists of a straight insertion sort on r_s (h_{s+1}/h_s)-ordered subfiles of length $q_s + 1$, and on $(h_s - r_s)$ such subfiles of length q_s. The divisibility condition implies that each of these subfiles is a "random" (h_{s+1}/h_s)-ordered permutation, in the sense that each (h_{s+1}/h_s)-ordered permutation is equally likely, since we are assuming that the original input was a random permutation of distinct elements. $\blacksquare$

Condition (5) in this corollary is always satisfied for *two-pass* Shell sorts when the increments are h and 1, respectively. If $q = \lfloor N/h \rfloor$ and $r = N \bmod h$, the quantity B in Program D will have an average value of

$$rf(q+1, N) + (h-r)f(q, N) + f(N, h) = \frac{r}{2}\binom{q+1}{2} + \frac{h-r}{2}\binom{q}{2} + f(N, h).$$

To a first approximation, the function $f(n, h)$ equals $(\sqrt{\pi}/8)n^{3/2}h^{1/2}$; compare it to the smooth curve in Fig. 12. Hence the running time for a two-pass Pro-

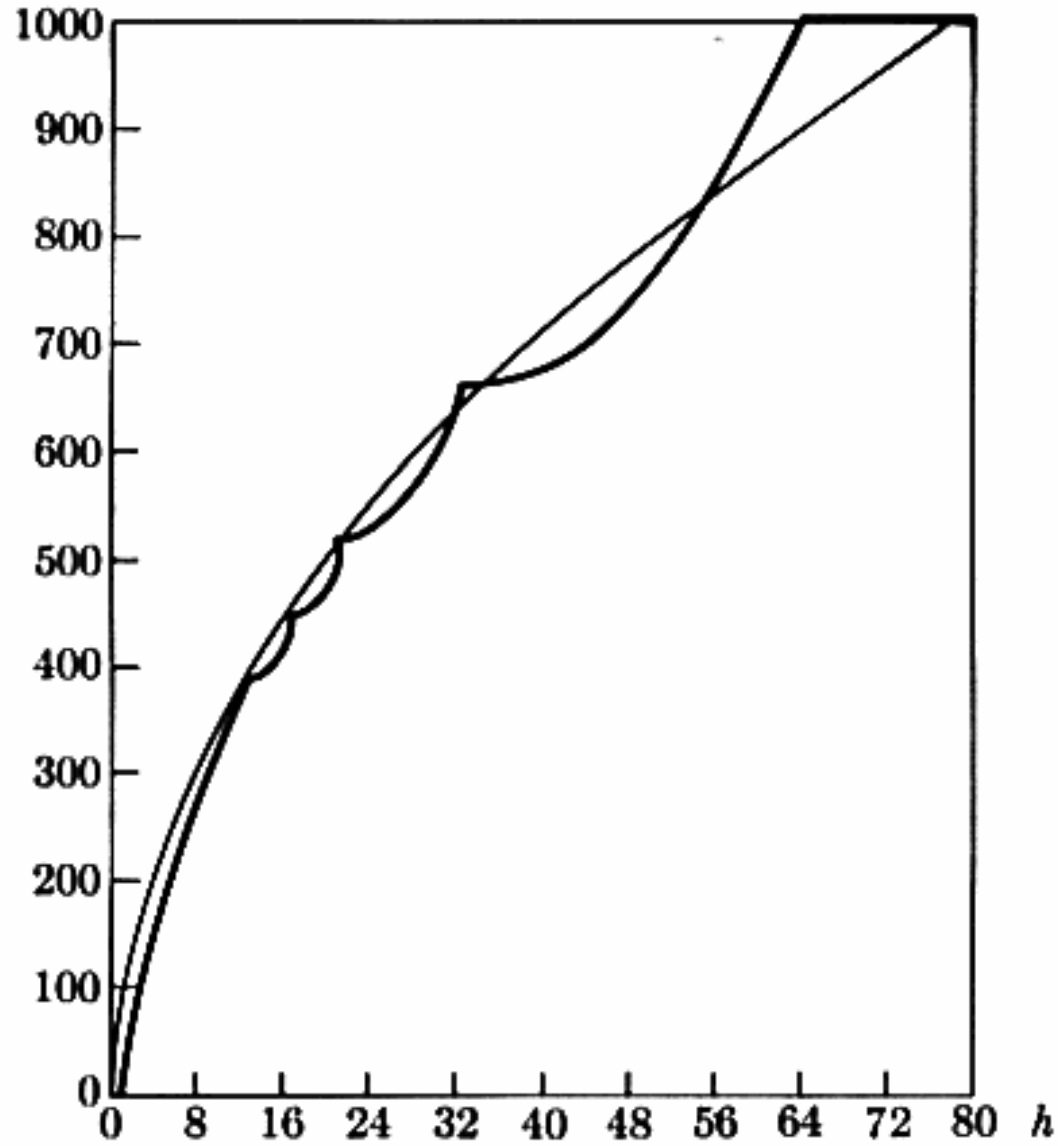

Fig. 12 The average number, $f(n, h)$, of inversions in an h-ordered file of n elements, shown for $n = 64$.

gram D is approximately proportional to $2N^2/h + \sqrt{\pi N^3 h}$. The best choice of h is therefore approximately $\sqrt[3]{16N/\pi} \approx 1.72\sqrt[3]{N}$; and with this choice of h we get an average running time proportional to $N^{5/3}$.

Thus we can make a substantial improvement over straight insertion, from $O(N^2)$ to $O(N^{1.667})$, just by using Shell's method with two increments. Clearly we can do even better when more increments are used. Exercise 18 discusses the optimum choice of $h_t, \ldots, h_1$ when t is fixed and when the h's are constrained by the divisibility condition; the running time decreases to $O(N^{1.5+\epsilon/2})$, where $\epsilon = 1/(2^t - 1)$, for large N. We cannot break the $N^{1.5}$ barrier by using the formulas above, since the last pass always contributes

$$f(N, h_2) \approx (\sqrt{\pi}/8)N^{3/2}h_2^{1/2}$$

inversions to the sum.

But our intuition tells us that we can do even better when the increments $h_t, \ldots, h_1$ do *not* satisfy the divisibility condition (5). For example, 8-sorting followed by 4-sorting followed by 2-sorting does not allow any interaction between keys in even and odd positions; therefore the final 1-sorting pass is faced with $O(N^{3/2})$ inversions. By contrast, 7-sorting followed by 5-sorting followed by 3-sorting jumbles things up in such a way that the final 1-sorting pass cannot encounter more than $2N$ inversions! (See exercise 26.) Indeed, an astonishing phenomenon occurs:

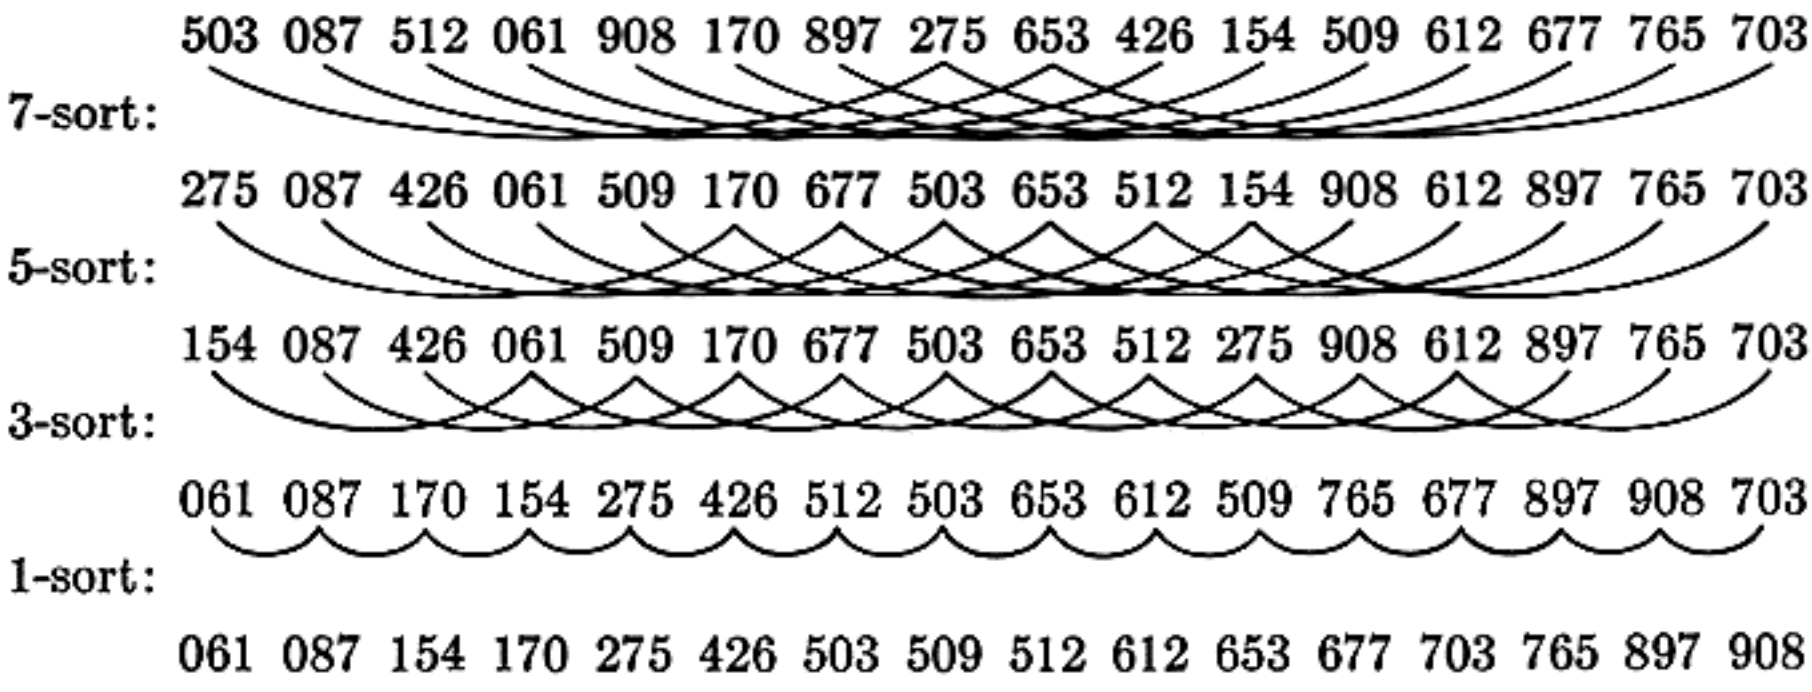
Theorem K. *If a k-ordered file is h-sorted, it remains k-ordered.*

Thus a file which is first 7-sorted, then 5-sorted, becomes both 7-ordered and 5-ordered. And if we 3-sort it, the result is ordered by 7's, 5's, and 3's.

Examples of this remarkable property appear in Table 4.

Table 4

DIMINISHING INCREMENT SORT (7, 5, 3, 1)



Proof. Exercise 20 shows that this theorem comes from the following fact:

Lemma L. *Let m, n, r be nonnegative integers, and let $x_1, \ldots, x_{m+r}$ and $y_1, \ldots, y_{n+r}$ be any sequences of numbers such that*

$$y_1 \le x_{m+1}, \qquad y_2 \le x_{m+2}, \qquad \ldots, \qquad y_r \le x_{m+r}. \tag{7}$$

If the x's and y's are sorted independently, so that $x_1 \le \cdots \le x_{m+r}$ and $y_1 \le \cdots \le y_{n+r}$, the relations (7) will still be valid.

Proof. All but m of the x's are known to dominate (i.e., to be greater than or equal to) some y, where distinct x's dominate distinct y's. Let $1 \le j \le r$. Since x_{m+j} after sorting dominates $m + j$ of the x's, it dominates at least j of the y's; so it dominates the *smallest* j of the y's; hence $x_{m+j} \ge y_j$ after sorting. ∎ ∎

Theorem K shows us that it is desirable to sort with relatively prime increments, but it does not lead directly to exact estimates of the number of moves made in Algorithm D. Since the number of permutations of $\{1, 2, \ldots, n\}$ which are both h-ordered and k-ordered is not always a divisor of $n!$, we can see that Theorem K does not tell the whole story; some k- and h-ordered files are obtained more often than others after k- and h-sorting. Moreover, there is no obvious way to find the "worst case" of Algorithm D for general increments $h_t, \ldots, h_1$. Therefore the analysis of this algorithm in the general case has baffled everyone so far; essentially all that is known is the approximate asymptotic form of the maximum running time in certain cases:

Theorem P. *The running time for Algorithm D is $O(N^{3/2})$ when $h_s = 2^s - 1$, $1 \le s \le t = \lfloor \log_2 N \rfloor$.*

Proof. It suffices to bound B_s, the number of moves in pass s, in such a way that $B_t + \cdots + B_1 = O(N^{3/2})$. During the first $t/2$ passes, for $t \geq s \geq t/2$, we may use the obvious bound $B_s = O(h_s(N/h_s)^2)$, and for subsequent passes we may use the result of exercise 23, $B_s = O(Nh_{s+2}h_{s+1}/h_s)$; hence $B_t + \cdots + B_1 = O(N(2 + 2^2 + \cdots + 2^{t/2} + 2^{t/2} + \cdots + 2)) = O(N^{3/2})$. ∎

This theorem is due to A. A. Papernov and G. V. Stasevich, *Problemy Peredachi Informatsii* **1**, 3 (1965), 81–98. It gives an upper bound on the *maximum* running time of the algorithm, not merely a bound on the *average* running time. The result is not trivial since the maximum running time when the h's satisfy the divisibility constraint (5) is of order N^2; and exercise 24 shows that the exponent 3/2 cannot be lowered.

An interesting improvement of Theorem P was discovered in 1969 by Vaughan Pratt: *If the increments are chosen to be the set of all numbers of the form 2^p3^q which are less than N, the running time of Algorithm D is of order $N(\log N)^2$.* In this case we can also make several important simplifications to the algorithm. Unfortunately, Pratt's method requires a comparatively large number of passes, so it is not the best way to choose the increments unless N is quite large; see exercises 30 and 31.

Let us consider the *total* running time of Program D, namely $(9B + 10NT + 13T - 10S - 3A + 1)u$. Table 5 shows the average running time for various

Table 5

ANALYSIS OF ALGORITHM D WHEN $N = 8$

Increments	A_{ave}	B_{ave}	S	T	MIX time
1	1.718	14.000	1	1	$204.85u$
2 1	2.667	9.657	3	2	$235.91u$
3 1	2.917	9.100	4	2	$220.16u$
4 1	3.083	10.000	5	2	$217.75u$
5 1	2.601	10.000	6	2	$210.00u$
6 1	2.135	10.667	7	2	$206.60u$
7 1	1.718	12.000	8	2	$208.85u$
4 2 1	3.500	8.324	7	3	$272.32u$
5 3 1	3.301	8.167	9	3	$251.60u$
3 2 1	3.320	7.829	6	3	$278.50u$

sequences of increments when $N = 8$; each of the entries in this table can be calculated from the formulas above or in exercise 19, except when the increments are 5 3 1 or 3 2 1; in the latter cases an exhaustive study of all 8! permutations was made. Note that for this small value of N the bookkeeping operations dominate the running time, so that the best results are obtained when $t = 1$; hence for $N = 8$ we are better off using simple straight insertion. (The average

running time of Program S when $N = 8$ is only $191.85u$.) Curiously, the best two-pass algorithm occurs when $h_2 = 6$, since a large value of S is more important here than a small value of B. Similarly, the three increments 3 2 1 minimize the average number of moves, but they do not lead to the best three-pass sequence. It may be of interest to record here some "worst case" permutations which maximize the number of moves, since the general construction of such permutations is still unknown:

$h_3 = 5, \quad h_2 = 3, \quad h_1 = 1:$ 8 5 2 6 3 7 4 1 (19 moves)

$h_3 = 3, \quad h_2 = 2, \quad h_1 = 1:$ 8 3 5 7 2 4 6 1 (17 moves)

As N grows larger we have a slightly different picture. Table 6 shows the approximate number of moves for various sequences of increments when $N = 1000$. The first few entries satisfy the divisibility constraints (5), so that formula (6) can be used; empirical tests were used to get approximate average values for other increment sequences. Five random files of 1000 elements were generated, and they were each sorted with each of the sequences of increments.

Some patterns are evident in this data, but the behavior of Algorithm D still remains very obscure. Shell originally suggested using the increments $\lfloor N/2 \rfloor, \lfloor N/4 \rfloor, \lfloor N/8 \rfloor, \ldots$, but this is undesirable when the binary representation of N contains a long string of zeros. Lazarus and Frank [*CACM* **3** (1960), 20–22] suggested using essentially the same sequence, but adding 1 when necessary, to make all increments odd. Hibbard [*CACM* **6** (1963), 206–213] suggested using increments of the form $2^k - 1$; Papernov and Stasevich suggested the form $2^k + 1$. Other natural sequences investigated in Table 6 involve the numbers $(2^k - (-1)^k)/3$, $(3^k - 1)/2$, and the Fibonacci numbers.

The minimum number of moves, about 6600, was observed for increments of the form $2^k + 1$; but it is important to realize that the number of moves is not the only consideration, even though it asymptotically dominates the running time. Since Program D takes $9B + 10NT + \cdots$ units of time, we see that saving one pass is about as desirable as saving $\frac{10}{9}N$ moves; we are willing to add 1100 moves if we can save one pass. Therefore it seems unwise to start with h_t greater than, say, $\frac{1}{3}N$, since a large increment will not decrease the subsequent number of moves enough to justify the first pass.

A large number of experiments on Algorithm D were conducted by James Peterson and David L. Russell at Stanford University in 1971; they found that the average number of moves, B, can be reasonably well approximated by the following formulas for $100 \leq N \leq 60000$:

$1.09N^{1.27}$ or $.30N(\ln N)^2 - 1.35N \ln N$ for increments $2^k + 1, \ldots, 9, 5, 3, 1$;

$1.22N^{1.26}$ or $.29N(\ln N)^2 - 1.26N \ln N$ for increments $2^k - 1, \ldots, 15, 7, 3, 1$;

$1.12N^{1.28}$ or $.36N(\ln N)^2 - 1.73N \ln N$ for increments $(2^k \pm 1)/3, \ldots, 11, 5, 3, 1$;

$1.66N^{1.25}$ or $.33N(\ln N)^2 - 1.26N \ln N$ for increments $(3^k - 1)/2, \ldots, 40, 13, 4, 1$.

Table 6

ANALYSIS OF ALGORITHM D WHEN $N = 1000$

121 40 13 4 1	275	9900	5

For example when $N = 20000$ we get $B \approx 31000, 33000, 35000, 39000$, with these respective types of increments. Table 7 shows typical breakdowns of

Table 7

MOVES PER PASS; EXAMPLES WITH $N = 20000$

h_s	B_s	h_s	B_s	h_s	B_s

3	24044	5	19961		
1	16789	3	9628		
		1	13277		

moves per pass obtained in three of these experiments. Curiously, *both* of the functional forms $\alpha N(\ln N)^2 + \beta N \ln N$ and βN^α seem to give a pretty good fit to the observed data, although the exponential form was noticeably better than the logarithmic for smaller values of N. Further experiments were made for the increments $2^k - 1$, letting N range as high as 250,000; forty-five trials for $N = 250{,}000$ gave $B \approx 7{,}900{,}000$ with an observed standard deviation of about 50,000. The "best fit" formulas for the range $100 \leq N \leq 250{,}000$ turned out to be $1.21N^{1.26}$ and $.39N(\ln N)^2 - 2.33\ N \ln N$, respectively. Since the coefficients of the exponential form remained about the same, while the coefficients of the logarithmic form changed rather drastically, it is reasonable to conjecture that the exponential form gives the true asymptotic behavior of Shell's method.

This empirical data by no means exhausts the possibilities, and we have found no grounds for making strong assertions about what sequences of increments are best in Algorithm D. Since the increments $(3^k - 1)/2$ do not take substantially more moves, and since they require only about five-eighths as many passes as the increments of other forms, the evidence indicates that *it is reasonable to choose the increments in the following way:*

$$\textit{Let } h_1 = 1,\ h_{s+1} = 3h_s + 1, \textit{ and stop with } h_t \textit{ when } h_{t+2} \geq N. \qquad (8)$$

List insertion. Let us now leave Shell's method and consider other types of improvements over straight insertion. One of the most important general ways

to improve on a given algorithm is to examine its data structures carefully, since a reorganization of data structures to avoid unnecessary operations often leads to substantial improvements. Further discussion of this general idea appears in Section 2.4, where a rather complex algorithm is studied; let us consider how it applies to a very simple algorithm like straight insertion. What is the most appropriate data structure for Algorithm S?

Straight insertion involves two basic operations:

i) scanning an ordered file to find the largest key less than or equal to a given key; and

ii) inserting a new record into a specified part of the ordered file.

The file is obviously a linear list, and Algorithm S handles this list by using sequential allocation (Section 2.2.2); therefore it is necessary to move roughly half of the records in order to accomplish each insertion operation. On the other hand, we know that linked allocation (Section 2.2.3) is ideally suited to insertion, since only a few links need to be changed; and the other operation, sequential scanning, is about as easy with linked allocation as with sequential allocation. Only one-way linkage is needed, since we always scan the list in the same direction. Therefore we conclude that the "right" data structure for straight insertion is a one-way, linked linear list. It also becomes convenient to revise Algorithm S so that the list is scanned in increasing order:

Algorithm L (*List insertion*). Records $R_1, \ldots, R_N$ are assumed to contain keys $K_1, \ldots, K_N$, and "link fields" $L_1, \ldots, L_N$ capable of holding the numbers 0 through N; and there is another link field L_0 in an artificial record R_0 at the beginning of the file. This algorithm sets the link fields so that the records are linked together in ascending order. Thus, if $p(1) \ldots p(N)$ is the "stable" permutation which makes $K_{p(1)} \le \cdots \le K_{p(N)}$, this algorithm will yield

$$L_0 = p(1); \qquad L_{p(i)} = p(i+1), \quad \text{for} \quad 1 \le i \le N; \qquad L_{p(N)} = 0. \tag{9}$$

L1. [Loop on j.] Set $L_0 \leftarrow N$, $L_N \leftarrow 0$. (L_0 acts as the "head" of the list, and 0 acts as a null link; hence the list is essentially circular.) Perform steps L2 through L5 for $j = N-1, N-2, \ldots, 1$; then terminate the algorithm.

L2. [Set up p, q, K.] Set $p \leftarrow L_0$, $q \leftarrow 0$, $K \leftarrow K_j$. (In the following steps we will insert R_j into its proper place in the linked list, by comparing K with the previous keys in ascending order. The variables p and q act as pointers to the current place in the list, with $p = L_q$ so that q is one step behind p.)

L3. [Compare K, K_p.] If $K \le K_p$, go to step L5. (We have found the desired position for record R, between R_q and R_p in the list.)

L4. [Bump p, q.] Set $q \leftarrow p$, $p \leftarrow L_q$. If $p > 0$, go back to step L3. (If $p = 0$, K is the largest key found so far; hence record R belongs at the end of the list, between R_q and R_0.)

L5. [Insert into list.] Set $L_q \leftarrow j$, $L_j \leftarrow p$. ∎

This algorithm is important not only because it is a simple sorting method, but also because it occurs frequently as part of other list-processing algorithms. Table 8 shows the first few steps which occur when our sixteen example numbers are sorted.

```

The running time of this program is $7B + 14N - 3A - 6$ units, where N is the length of the file, A is the number of right-to-left maxima, and B is the number of inversions in the original permutation. (Cf. the analysis of Program S. Note that Program L does not rearrange the records in memory; this can be done as in exercise 5.2–12, at a cost of about $20N$ additional units of time.) Program S requires $(9B + 10N - 3A - 9)u$, and since B is about $\frac{1}{4}N^2$, we can see that the extra memory space used for the link fields has saved about 22 percent of the execution time. Another 22 percent can be saved by careful programming (see exercise 33), but the running time remains proportional to N^2.

To summarize what we have done so far: We started with Algorithm S, a simple and natural sorting algorithm which does about $\frac{1}{4}N^2$ comparisons and $\frac{1}{4}N^2$ moves. We improved it in one direction by considering binary insertion, which does about $N \log_2 N$ comparisons and $\frac{1}{4}N^2$ moves. Changing the data structure slightly with "two-way insertion" cuts the number of moves down to about $\frac{1}{8}N^2$. Shell's "diminishing increment" sorting technique cuts the number of comparisons and moves to about $N^{1.3}$, for N in a practical range; as $N \to \infty$ this number can be lowered to order $N(\log N)^2$. Another way to improve on Algorithm S, using a linked data structure, gave us the list insertion method, which does about $\frac{1}{4}N^2$ comparisons, 0 moves, and $2N$ changes of links.

Is it possible to marry the best features of these methods, reducing the number of comparisons to order $N \log N$ as in binary insertion, yet reducing the number of moves as in list insertion? The answer is yes, by going to a tree-structured arrangement. This possibility was first explored about 1957 by D. J. Wheeler, who suggested using two-way insertion until it becomes necessary to move some data; then instead of moving the data, a pointer to another area of memory is inserted, and the same technique is applied recursively to all items which are to be inserted into this new area of memory. Wheeler's original method [see A. S. Douglas, *Comp. J.* **2** (1959), 5] is a complicated combination of sequential and linked memory, with nodes of varying size; for our 16 example numbers the tree of Fig. 13 would be formed. A similar but simpler tree-insertion

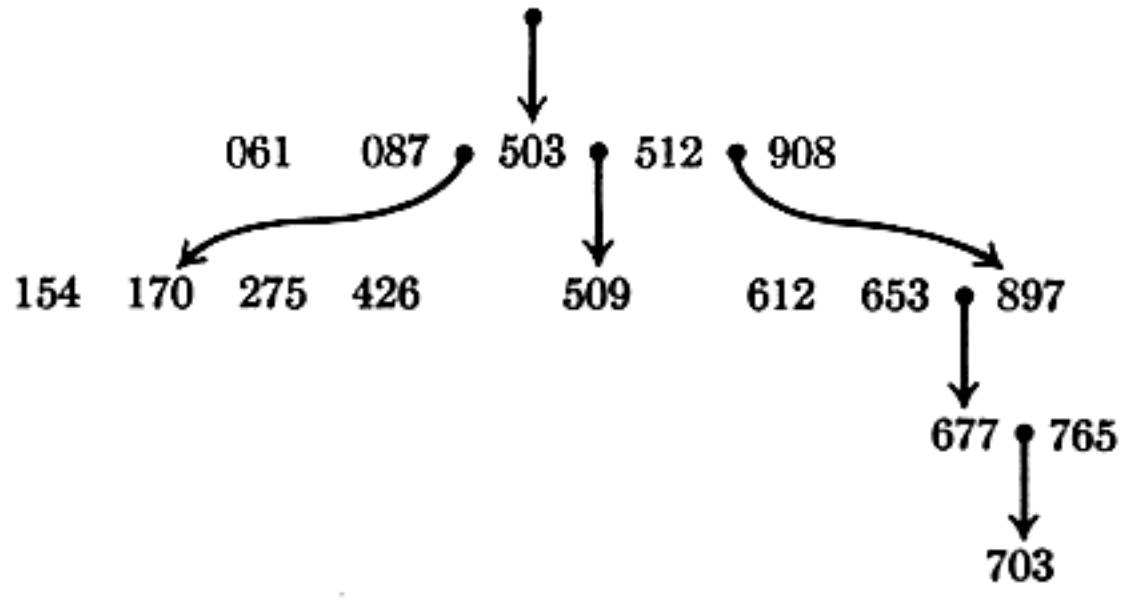

Fig. 13. Example of Wheeler's tree insertion scheme.

scheme, using binary trees, was independently devised by C. M. Berners-Lee about 1958 [see *Comp. J.* **3** (1960), 174, 184]. Since this method and its refinements are quite important for searching as well as sorting, they are discussed at length in Chapter 6.

Still another way to improve on straight insertion is to consider inserting several things at a time. For example, if we have a file of 1000 items, and if 998 of them have already been sorted, Algorithm S makes two more passes through the file (first inserting R_{999}, then R_{1000}). We can obviously save time if we first compare K_{999} with K_{1000}, to see which is larger, then insert them *both* with one look at the file. A combined operation of this kind involves about

$\frac{2}{3}N$ comparisons and moves (cf. exercise 3.4.2–5), instead of two passes each with about $\frac{1}{2}N$ comparisons and moves.

In other words, it is generally a good idea to "batch" operations that require long searches, so that multiple operations can be done together. If we carry this idea to its natural conclusion, we rediscover the method of sorting by merging, which is so important it is discussed below in a separate section.

Address calculation sorting. Surely by now we have exhausted all possible ways to improve on the simple method of straight insertion; but let's look again! Suppose someone gives you a blank sheet of paper and says that he is going to read you some words. Your job is to alphabetize the words, and to give him the sorted list on the paper. Then if he tells you a word starting with A, you will tend to write it near the top of the page, while a word starting with Z will probably be placed near the bottom, and so on. A similar technique is used when putting books into a bookshelf in order by the authors' names, when the books are given to you in random order on the floor: you estimate the final position of each book as you put it in place, thereby reducing the number of comparisons and moves you have to make. (The whole process is somewhat more efficient if you start with a little more shelf space than is absolutely necessary.) This method was first suggested for computer sorting by Isaac and Singleton, *JACM* **3** (1956), 169–174, and it has been further developed by Kronmal and Tartar, *Proc. ACM Nat'l Conf.* **21** (1966), 331–337.

Address calculation sorting usually requires additional storage space proportional to N, either to leave enough room so that excessive moving is not required, or to maintain auxiliary tables which help account for irregularities in the distribution of keys. (See the "distribution counting" sort, Algorithm 5.2D, which is a form of address calculation.) We can probably make best use of this additional memory space if we devote it to link fields, as in the list insertion method. In this way we can also avoid having separate areas for input and output; everything can be done in the same area of memory.

The basic idea is to generalize list insertion so that *several* lists are kept, not just one. Each list is used for certain ranges of keys. We make the important assumption that the keys are pretty evenly distributed, not "bunched up" irregularly: the set of all possible values of the keys is partitioned into M parts, and we assume a probability of $1/M$ that a given key falls into a given part. Then we provide additional storage for M list heads, and each list is maintained as in simple list insertion.

It is not necessary to give the algorithm in great detail here; the method is simply to begin with all list heads set to Λ. As each new item enters, we first decide which of the M parts its key falls into, then we insert it into the corresponding list as in Algorithm L.

To illustrate the method, suppose that the 16 keys used in our examples are divided into the $M = 4$ ranges 0–249, 250–499, 500–749, 750–999. We obtain the following configurations as sorting proceeds:

	4 items entered	8 items entered	12 items entered	Final state
List 1:	061, 087	061, 087, 170	061, 087, 154, 170	061, 087, 154, 170
List 2:		275	275, 426	275, 426
List 3:	503, 512	503, 512	503, 509, 512, 653	503, 509, 512, 612, 653, 677, 703
List 4:		897, 908	897, 908	765, 897, 908

Because linked memory is used, there is no storage allocation problem caused by varying-length lists.

Program M (*Multiple list insertion*). In this program we make the same assumptions as in Program L, except that the keys must be *nonnegative*, thus

$$0 \le \texttt{KEY} < (\texttt{BYTESIZE})^3.$$

The program divides this range into M equal parts by multiplying each key by a suitable constant. The list heads are in locations HEAD+1 through HEAD+M.

```
01    KEY     EQU   1:3
02    LINK    EQU   4:5
03    START   ENT2  M                    1
04            STZ   HEAD,2                M      HEAD[p] ← Λ.
05            DEC2  1                     M
06            J2P   *-2                   M      M ≥ p ≥ 1.
07            ENT1  N                     1      j ← N.
08    2H      LDA   INPUT,1(KEY)          N
09            MUL   =M(1:3)=              N      rA ← ⌊M · K_j/BYTESIZE^3⌋
10            STA   *+1(1:2)              N
11            ENT3  0                     N      q ← rA.
12            INC3  HEAD+1-INPUT          N      q ← LOC(HEAD[q]).
13            LDA   INPUT,1               N      K ← K_j.
14            JMP   4F                    N      To set p.
15    3H      CMPA  INPUT,2(KEY)          B+N-A
16            JLE   5F                    B+N-A  To insert, if K ≤ K_p.
17            ENT3  0,2                   B      q ← p.
18    4H      LD2   INPUT,3(LINK)         B+N    p ← LINK(q).
19            J2P   3B                    B+N    Jump if not end of list.
20    5H      ST1   INPUT,3(LINK)         N      LINK(q) ← LOC(R_j).
21            ST2   INPUT,1(LINK)         N      LINK(LOC(R_j)) ← p.
22    6H      DEC1  1                     N
23            J1P   2B                    N      N ≥ j ≥ 1. ∎
```

This program is written for general M, but it would be better to fix M at some convenient value; for example, we might choose $M = \texttt{BYTESIZE}$, so that the list heads could be cleared with a single MOVE instruction and the multiplication sequence of lines 08–11 could be replaced by the single instruction

`LD3 INPUT,1 (1:1)`. The most notable contrast between Program L and Program M is the fact that Program M must consider the case of an empty list, when no comparisons are to be made.

How much time do we save by having M lists? The total running time of Program M is $7B + 31N - 3A + 4M + 2$ units, where M is the number of lists, N is the number of records sorted, and A, B respectively count the right-to-left maxima and the inversions present among the keys belonging to each list. (In contrast to other time analyses of this section, we are here treating the rightmost element of a nonempty permutation as a "right-to-left maximum," instead of ignoring it.) We have already studied A and B for $M = 1$, when their average values are respectively H_N and $\frac{1}{2}\binom{N}{2}$. By our assumption about the distribution of keys, the probability that a given list contains precisely n items at the conclusion of sorting is the "binomial" probability

$$\binom{N}{n}\left(\frac{1}{M}\right)^n\left(1-\frac{1}{M}\right)^{N-n} \tag{10}$$

Therefore the average values of A and B in the general case are

$$A_{\text{ave}} = M\sum_n \binom{N}{n}\left(\frac{1}{M}\right)^n\left(1-\frac{1}{M}\right)^{N-n} H_n; \tag{11}$$

$$B_{\text{ave}} = M\sum_n \binom{N}{n}\left(\frac{1}{M}\right)^n\left(1-\frac{1}{M}\right)^{N-n} \binom{n}{2}. \tag{12}$$

By Theorem 1.2.7A,

$$\sum_n \binom{N}{n}(M-1)^{-n}H_n = \left(1-\frac{1}{M}\right)^{-N}(H_N - \ln M) + \epsilon,$$

$$0 < \epsilon = \sum_{n>N} \frac{1}{n}\left(1-\frac{1}{M}\right)^{n-N} < \frac{M-1}{N+1};$$

hence

$$A_{\text{ave}} = M(H_N - \ln M) + \delta, \qquad 0 < \delta < \frac{M^2}{N+1}\left(1-\frac{1}{M}\right)^{N+1}. \tag{13}$$

(This formula is practically useless when $M \approx N$. A more detailed discussion of the asymptotic behavior of A_{ave}, when $M = N/\alpha$, appears in exercise 5.2.2–57.) Using the identity

$$\binom{N}{n}\binom{n}{2} = \binom{N}{2}\binom{N-2}{n-2},$$

which is a special case of Eq. 1.2.6–20, the sum in (11) is easily evaluated, and we obtain

$$B_{\text{ave}} = \frac{1}{2M}\binom{N}{2}. \tag{14}$$

(For the standard deviation of B, see exercise 37.) Hence the total running time of Program M, for fixed M as $N \to \infty$, is

$$\begin{aligned} \min &\quad 31N + M + 2, \\ \text{ave} &\quad 1.75N^2/M + 31N - 3MH_N + 3M \ln M + 4M - 3 - 1.75N/M + 2, \\ \max &\quad 3.50N^2 + 24.5N + 4M + 2. \end{aligned} \tag{15}$$

Note that when M is not too large *we are speeding up the average time by a factor of* M; $M = 10$ will sort about ten times as fast as $M = 1$! However, the maximum time is much larger than the average time; this reiterates the assumption we have made about a fairly equal distribution of keys, since the worst case occurs when all records pile onto the same list.

If we set $M = N$, the average running time is approximately $34.36N$; when $M = \frac{1}{2}N$ it is slightly more, approximately $34.52N$; and when $M = \frac{1}{10}N$ it is approximately $48.04N$. (Note that $10N$ of these MIX time units are spent in the multiplication instruction alone!) *We have achieved a sorting method of order* N, *provided only that the keys are reasonably well spread out over their range.*

EXERCISES

1. [*10*] Is Algorithm S a "stable" sorting algorithm?

2. [*11*] Would Algorithm S still sort numbers correctly if the relation "$K \geq K_i$" in step S3 were replaced by "$K > K_i$"?

▶ **3.** [*30*] Is Program S the shortest possible sorting program that can be written for MIX, or is there a shorter program which achieves the same effect?

▶ **4.** [*M20*] Find the minimum and maximum running times for Program S, as a function of N.

▶ **5.** [*M27*] Find the generating function $g_N(z) = \sum_{k\geq 0} p_{Nk}z^k$ for the total running time of Program S, where p_{Nk} is the probability that Program S takes exactly k units of time, given a random permutation of $\{1, 2, \ldots, N\}$ as input. Also calculate the standard deviation of the running time, given N.

6. [*23*] The two-way insertion method illustrated in Table 2 seems to imply that there is an output area capable of holding up to $2N + 1$ records, in addition to the input area containing N records. Show that two-way insertion can be done using only enough space for $N + 1$ records, including both input and output.

7. [*M20*] If $a_1\, a_2 \ldots a_n$ is a random permutation of $\{1, 2, \ldots, n\}$, what is the average value of $|a_1 - 1| + |a_2 - 2| + \cdots + |a_n - n|$? (This is n times the average net distance traveled by a record during a sorting process.)

8. [*10*] Is Algorithm D a "stable" sorting algorithm?

9. [*20*] What are the quantities A and B, and the total running time of Program D, corresponding to Tables 3 and 4? Discuss the relative merits of Shell's method versus straight insertion in this case.

▶ **10.** [*22*] If $K_j \geq K_{j-h}$ in step D3, Algorithm D specifies a lot of actions that accomplish nothing. Show how to modify Program D so that this redundant computation can be avoided, and discuss the merits of such a modification.

11. [*M10*] What path in a lattice like Fig. 11 corresponds to the permutation 1 2 5 3 7 4 8 6 9 11 10 12?

12. [*M20*] Prove that the sum of the vertical weights on a lattice path equals the number of inversions in the corresponding 2-ordered permutation.

▸ **13.** [*M22*] Explain how to put weights on the *horizontal* line segments of a lattice, instead of the vertical segments, so that the sum of the horizontal weights on a lattice path is the number of inversions in the corresponding 2-ordered permutation.

14. [*M24*] (a) Show that, in the sums defined by Eq. (2), $A_{2n+1} = 2A_{2n}$. (b) The general identity of exercise 1.2.6–26 simplifies to

$$\sum_k \binom{2k+s}{k} z^k = \frac{1}{\sqrt{1-4z}} \left(\frac{1-\sqrt{1-4z}}{2z} \right)^s$$

if we set $r = -s-1$, $t = 1$. By considering the sum $\sum_n A_{2n} z^n$, show that

$$A_{2n} = n \cdot 4^{n-1}.$$

▸ **15.** [*HM33*] Let $g_n(z)$, $\bar{g}_n(z)$, $h_n(z)$, $\bar{h}_n(z)$ be $\sum z^{\text{total weight of path}}$ summed over all lattice paths of length $2n$ from $(0, 0)$ to (n, n), subject to certain restrictions on the vertices on the paths: For $h_n(z)$, there is no restriction, but for $g_n(z)$ the path must avoid all vertices (i, j) with $i > j$; $\bar{h}_n(z)$ and $\bar{g}_n(z)$ are defined similarly, except that all vertices (i, i) are also excluded, for $0 < i < n$. Thus

$$g_0(z) = 1, \quad g_1(z) = z, \quad g_2(z) = z^3 + z^2; \quad \bar{g}_1(z) = z, \quad \bar{g}_2(z) = z^3;$$
$$h_0(z) = 1, \quad h_1(z) = z+1, \quad h_2(z) = z^3 + z^2 + 3z + 1;$$
$$\bar{h}_1(z) = z+1, \quad \bar{h}_2(z) = z^3 + z.$$

Find recurrence relations defining these functions, and use the recurrence relations to prove that

$$h_n''(1) + h_n'(1) = \frac{7n^3 + 4n^2 + 4n}{30} \binom{2n}{n}.$$

(The exact formula for the variance of the number of inversions in a random 2-ordered permutation of $\{1, 2, \ldots, 2n\}$ is therefore easily found; it is asymptotically $(\frac{7}{30} - \frac{\pi}{16})n^3$.)

16. [*M24*] Find a formula for the maximum number of inversions in an h-ordered permutation of $\{1, 2, \ldots, n\}$. What is the maximum possible number of moves in Algorithm D when the increments satisfy the divisibility condition (5)?

17. [*M21*] Show that, when $N = 2^t$ and $h_s = 2^{s-1}$ for $t \geq s \geq 1$, there is a unique permutation of $\{1, 2, \ldots, N\}$ which maximizes the number of move operations performed by Algorithm D. Find a simple way to describe this permutation.

18. [*HM24*] For large N the sum (6) can be estimated as

$$\frac{1}{4} \frac{N^2}{h_t} + \frac{\sqrt{\pi}}{8} \left(\frac{N^{3/2} h_t^{1/2}}{h_{t-1}} + \cdots + \frac{N^{3/2} h_2^{1/2}}{h_1} \right).$$

What real values of $h_t, \ldots, h_1$ minimize this expression when N and t are fixed and $h_1 = 1$?

▸ **19.** [*M25*] What is the average value of the quantity A in the timing analysis of Program D, when the increments satisfy the divisibility condition (5)?

20. [*M20*] Show that Theorem K follows from Lemma L.

21. [*M25*] Let h and k be relatively prime positive integers. Show that the largest integer which cannot be represented in the form $ah + bk$, when a and b are *nonnegative* integers, is $hk - h - k$. Hence if a file is both h-ordered and k-ordered, we have $K_i \leq K_j$ whenever $j - i \geq (h - 1)(k - 1)$.

22. [*M30*] Prove that all integers $\geq 2^h(2^h - 1)$ can be represented in the form $a_0(2^h - 1) + a_1(2^{h+1} - 1) + a_2(2^{h+2} - 1) + \cdots$, where the a_j's are nonnegative integers; but $2^h(2^h - 1) - 1$ cannot be so represented. Furthermore, exactly $2^{h-1}(2^h + h - 3)$ positive integers are unrepresentable in this form.

Find analogous formulas when the quantities $2^k - 1$ are replaced by $2^k + 1$ in the representations.

▸ **23.** [*M22*] Prove that if h_{s+2} and h_{s+1} are relatively prime, the number of moves which occur while Algorithm D is using the increment h_s is $O(Nh_{s+2}h_{s+1}/h_s)$. *Hint:* See exercise 21.

24. [*M42*] Prove that Theorem P is best possible, in the sense that the exponent 3/2 cannot be lowered.

▸ **25.** [*M22*] How many permutations of $\{1, 2, \ldots, n\}$ are both 3-ordered and 2-ordered? What is the maximum number of inversions in such a permutation? What is the total number of inversions among all such permutations?

26. [*M35*] Can a file of N elements have more than N inversions if it is 3-, 5-, and 7-ordered?

27. [*M50*] Find an efficient algorithm to construct permutations which maximize the number of moves in Algorithm D, given N, h_t, h_{t-1}, $\ldots$, h_1.

28. [*15*] Which sequence of increments shown in Table 6 is best from the standpoint of Program D, considering the total running time?

29. [*M42*] For $N = 1000$ and various values of t, find empirical values of $h_t, \ldots, h_1$ which seem to minimize the average number of moves made by Algorithm D, in the sense that, if any one of the h's is varied while the others are fixed, the average number of moves increases.

30. [*M23*] (V. Pratt.) If the set of increments is $\{2^p3^q \mid 2^p3^q < N\}$, show that the number of passes is approximately $\frac{1}{2}(\log_2 N)(\log_3 N)$, and the number of moves per pass is at most $N/2$. In fact, if $K_{j-h} > K_j$ on any pass, we will always have K_{j-3h}, $K_{j-2h} \leq K_j < K_{j-h} \leq K_{j+h}$, K_{j+2h}; so we may simply interchange K_{j-h} and K_j and increase j by $2h$, saving two of the comparisons of Algorithm D. *Hint:* See exercise 25.

▸ **31.** [*25*] Write a MIX program for Pratt's sorting algorithm (exercise 30). Express its running time in terms of quantities A, B, S, T, N analogous to those in Program D.

32. [*10*] What would be the final contents of $L_0\, L_1 \ldots L_{16}$ if the list insertion sort in Table 8 were carried through to completion?

▸ **33.** [*25*] Find a way to improve on Program L so that its running time is dominated by $5B$ instead of $7B$, where B is the number of inversions.

34. [*M10*] Verify formula (10).

35. [*18*] Assume that the byte size of MIX is 100, and that the sixteen example keys in Table 8 are actually 503000, 087000, 512000, . . . , 703000. Determine the running time of Programs L and M on this data, when $M = 4$.

36. [*HM16*] If a program runs in approximately $A/M + B$ units of time and uses $C + M$ locations in memory, what choice of M gives the optimum product of space times time?

37. [*M25*] Let $g_n(z)$ be the generating function for inversions in a random permutation of n objects (cf. Eq. 5.1.1–11). Let $g_{NM}(z)$ be the corresponding generating function for the quantity B in Program M. Show that

$$\sum_{N\geq 0} g_{NM}(z)M^N w^N/N! = \left(\sum_{n\geq 0} g_n(z)w^n/n!\right)^M,$$

and use this formula to derive the variance of B.

38. [*HM23*] (R. M. Karp.) Let $F(x)$ be a distribution function for a probability distribution, with $F(0) = 0$ and $F(1) = 1$. Given that the keys $K_1, K_2, \ldots, K_N$ are independently chosen at random from this distribution, and that $M = cN$, where c is constant and $N \to \infty$, prove that the running time of Program M is $O(N)$ when F is sufficiently smooth. (A key K is inserted into list j when $\lfloor MK \rfloor = j - 1$; this occurs with probability $F(j/M) - F((j-1)/M)$. Only the case $F(x) = x, 0 \leq x \leq 1$, is treated in the text.)

39. [*M25*] (*Disorder in a library.*) Casual users of a library often put books back on the shelves in the wrong place. One way to measure the amount of disorder present in a library is to consider the minimum number of times we would have to take a book out of one place and insert it in another, before all books are restored to the correct order.

Thus let $\pi = a_1\, a_2 \ldots a_n$ be a permutation of $\{1, 2, \ldots, n\}$. A "deletion-insertion operation" changes π to

$$a_1 \ldots a_{i-1} a_{i+1} \ldots a_j\, a_i\, a_{j+1} \ldots a_n \quad \text{or to} \quad a_1 \ldots a_j\, a_i\, a_{j+1} \ldots a_{i-1}\, a_{i+1} \ldots a_n,$$

for some i and j. Let dis (π) be the minimum number of deletion-insertion operations which will sort π into order. Can dis (π) be expressed in terms of simpler characteristics of π?

40. [*40*] Experiment with the following variation of the diminishing increment sort, intended to speed up the "inner loop": For $s = t, t-1, \ldots, 2$, and for $j = h_s + 1, h_s + 2, \ldots, N$, interchange $R_{j-h_s} \leftrightarrow R_j$ if $K_{j-h_s} > K_j$. (Thus, the result of interchanges is not propagated; no comparison of K_{j-h_s}: K_{j-2h_s} is made. The records will not always be h_s-sorted, but these preliminary passes will help to decrease the number of inversions.) Finally apply straight insertion to complete the sort.

5.2.2. Sorting by Exchanging

We come now to the second family of sorting algorithms mentioned near the beginning of Section 5.2: "exchange" or "transposition" methods which systematically interchange pairs of elements that are out of order until no more such pairs exist.

The process of straight insertion, Algorithm 5.2.1S, can be viewed as an exchange method: We take each new record R_j and essentially exchange it with its neighbors to the left until it has been inserted into the proper place. So the classification of sorting methods into various families such as "insertion," "exchange," "selection," etc., is not always clear-cut. In this section, we shall discuss four types of sorting methods for which exchanging is a dominant characteristic: *exchange selection* (the "bubble sort"); *merge exchange* (Batcher's parallel sort); *partition exchange* (Hoare's "quicksort"); and *radix exchange*.

The bubble sort. Perhaps the most obvious way to sort by exchanges is to compare K_1 with K_2, interchanging R_1 and R_2 if the keys are out of order; then do the same to records R_2 and R_3, R_3 and R_4, etc. During this sequence of operations, records with large keys tend to move to the right, and in fact the record with the largest key will move up to become R_N. Repetitions of the process will get the appropriate records into positions R_{N-1}, R_{N-2}, etc., so that all records will ultimately be sorted.

Figure 14 shows this sorting method in action on the sixteen keys 503 087 512 . . . 703; it is convenient to represent the file of numbers vertically instead of horizontally, with R_N at the top and R_1 at the bottom. The method is called

	Pass 1	Pass 2	Pass 3	Pass 4	Pass 5	Pass 6	Pass 7	Pass 8	Pass 9
703	908	908	908	908	908	908	908	908	908
765	703	897	897	897	897	897	897	897	897
677	765	703	765	765	765	765	765	765	765
612	677	765	703	703	703	703	703	703	703
509	612	677	677	677	677	677	677	677	677
154	509	612	653	653	653	653	653	653	653
426	154	509	612	612	612	612	612	612	612
653	426	154	509	512	512	512	512	512	512
275	653	426	154	509	509	509	509	509	509

Fig. 14. The bubble sort in action.

"bubble sorting" because large elements "bubble up" to their proper position, by contrast with the "sinking sort" (i.e., straight insertion) in which elements sink down to an appropriate level. The bubble sort is also known by more prosaic names such as "exchange selection" or "propagation."

After each pass through the file, it is not hard to see that all records above and including the last one to be exchanged must be in their final position, so they need not be examined on subsequent passes. Horizontal lines in Fig. 14 show the progress of the sorting from this standpoint; note, for example, that five more elements are known to be in final position as a result of Pass 4. On the final pass, no exchanges are performed at all. With these observations we are ready to formulate the algorithm.

Algorithm B (*Bubble sort*). Records $R_1, \ldots, R_N$ are rearranged in place; after sorting is complete their keys will be in order, $K_1 \le \cdots \le K_N$.

B1. [Initialize BOUND.] Set BOUND $\leftarrow N$. (BOUND is the highest index for which the record is not known to be in its final position; thus we are indicating that nothing is known at this point.)

B2. [Loop on j.] Set $t \leftarrow 0$. Perform step B3 for $j = 1, 2, \ldots,$ BOUND-1, and then go to step B4.

B3. [Compare/exchange R_j: R_{j+1}.] If $K_j > K_{j+1}$, interchange $R_j \leftrightarrow R_{j+1}$ and set $t \leftarrow j$.

B4. [Any exchanges?] If $t = 0$, the algorithm terminates. Otherwise set BOUND $\leftarrow t$ and return to step B2. ∎

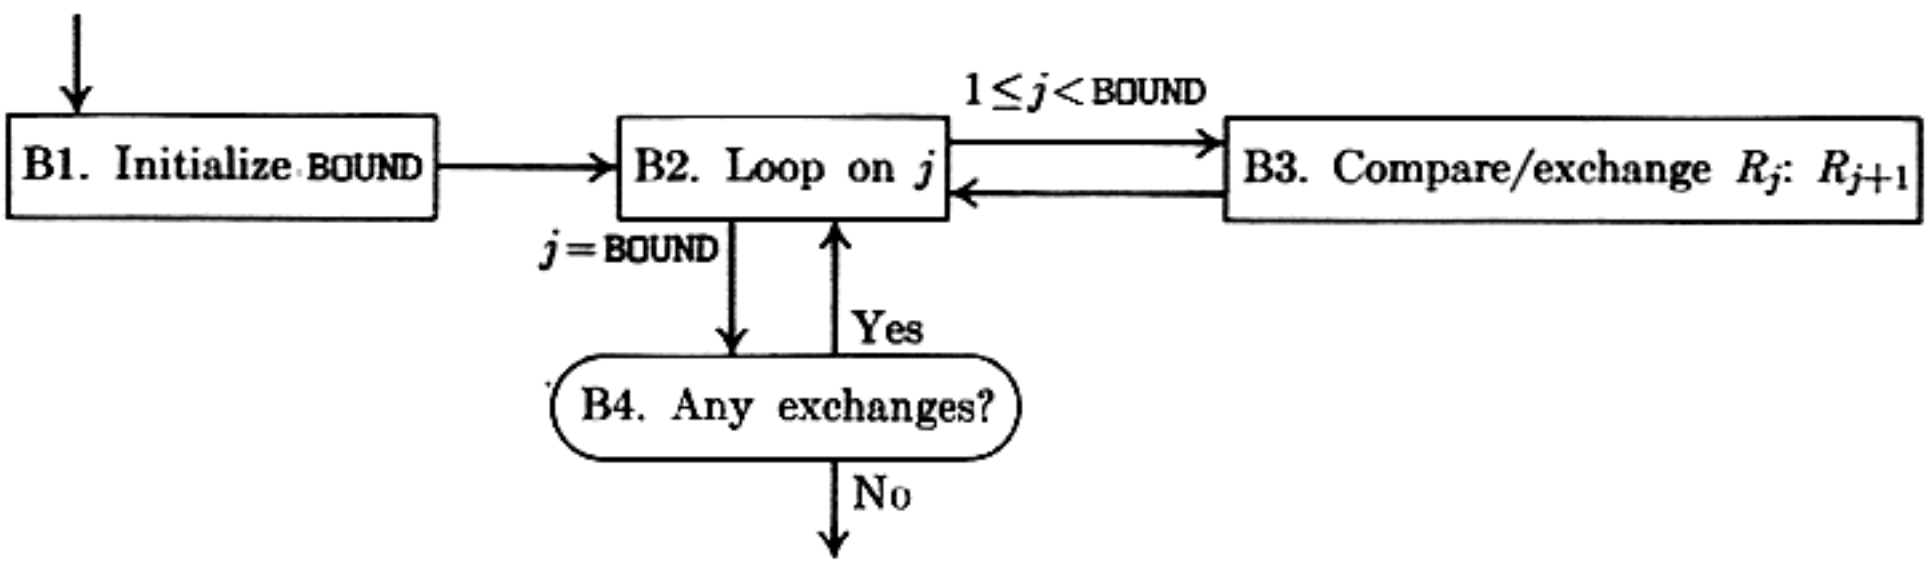

Fig. 15. Flowchart for bubble sorting.

Program B (*Bubble sort*). As in previous MIX programs of this chapter, we assume that the items to be sorted are in locations INPUT+1 through INPUT+N. rI1 $\equiv t$; rI2 $\equiv j$.

```
01  START  ENT1  N              1   B1. Initialize BOUND. t ← N.
02  1H     ST1   BOUND(1:2)     A   BOUND ← t.
03         ENT2  1              A   B2. Loop on j.
04         ENT1  0              A   t ← 0.
05         JMP   BOUND          A   Exit if j ≥ BOUND.
```

16	4H	J1P	1B	A	*B4. Any exchanges?* To B2 if $t > 0$. ∎

Analysis of the bubble sort. It is quite instructive to analyze the running time of Algorithm B. Three quantities are involved in the timing: the number of passes, A; the number of exchanges, B; and the number of comparisons, C. If the input keys are distinct and in random order, we may assume that they form a random permutation of $1, 2, \ldots, n$. The idea of *inversion tables* (Section 5.1.1) leads to an easy way to describe the effect of each pass in a bubble sort.

Theorem I. *Let $a_1\ a_2 \ldots a_n$ be a permutation of $\{1, 2, \ldots, n\}$, and let $b_1\ b_2 \ldots b_n$ be the corresponding inversion table. If one pass of the bubble sort, Algorithm B, changes $a_1\ a_2 \ldots a_n$ to the permutation $a'_1\ a'_2 \ldots a'_n$, the corresponding inversion table $b'_1\ b'_2 \ldots b'_n$ is obtained from $b_1\ b_2 \ldots b_n$ by decreasing each nonzero entry by* 1.

Proof. If a_i is preceded by a larger element, the largest preceding element is exchanged with it, so b_{a_i} decreases by 1. On the other hand if a_i is not preceded by a larger element, it is never exchanged with a larger element, so b_{a_i} remains 0. ∎

Thus we can see what happens during a bubble sort by studying the sequence of inversion tables betweeen passes. For example, the successive inversion tables corresponding to Fig. 14 are

	3	1	8	3	4	5	0	4	0	3	2	2	3	2	1	0	
Pass 1																	
	2	0	7	2	3	4	0	3	0	2	1	1	2	1	0	0	
Pass 2																	
	1	0	6	1	2	3	0	2	0	1	0	0	1	0	0	0	
Pass 3																	
	0	0	5	0	1	2	0	1	0	0	0	0	0	0	0	0	(1)

and so on. If $b_1\ b_2 \ldots b_n$ is the inversion table of the input permutation, we must therefore have

$$A = 1 + \max(b_1, b_2, \ldots, b_n); \tag{2}$$

$$B = b_1 + b_2 + \cdots + b_n; \tag{3}$$

$$C = c_1 + c_2 + \cdots + c_A, \tag{4}$$

where c_j is the value of BOUND–1 at the beginning of pass j. In terms of the inversion table,

$$c_j = \max \{b_i + i \mid b_i \geq j - 1\} - j \tag{5}$$

(see exercise 5). In example (1) we therefore have $A = 9$, $B = 41$, $C = 15 + 14 + 13 + 12 + 7 + 5 + 4 + 3 + 2 = 75$. The total MIX sorting time for Fig. 14 is $1030u$.

The distribution of B (the total number of inversions in a random permutation) is very well-known to us by now; so we are left with A and C to be analyzed.

The probability that $A \leq k$ is $1/n!$ times the number of inversion tables having no components $\geq k$, namely $k^{n-k}k!$, when $1 \leq k \leq n$. Hence the probability that exactly k passes are required is

$$A_k = \frac{1}{n!}(k^{n-k}k! - (k-1)^{n-k+1}(k-1)!). \tag{6}$$

The mean value $\sum kA_k$ can therefore be calculated; summing by parts, it is

$$A_{\text{ave}} = n + 1 - \sum_{0 \leq k \leq n} \frac{k^{n-k}k!}{n!} = n + 1 - P(n), \tag{7}$$

where $P(n)$ is the function whose asymptotic value was found to be $\sqrt{\pi n/2} - \frac{2}{3} + O(1/\sqrt{n})$ in Section 1.2.11, Eq. (24). Formula (7) was stated without proof by E. H. Friend in *JACM* **3** (1956), 150; a proof was given by Howard B. Demuth [Ph. D. thesis (Stanford University: October, 1956), 64–68]. For the standard deviation of A, see exercise 7.

The total number of comparisons, C, is somewhat harder to handle, and we will consider only C_{ave}. For fixed n, let $f_j(k)$ be the number of inversion tables $b_1 \ldots b_n$ such that for $1 \leq i \leq n$ we have either $b_i < j - 1$ or $b_i + i - j \leq k$; then

$$f_j(k) = (j + k)!(j - 1)^{n-j-k}, \qquad \text{for} \qquad 0 \leq k \leq n - j. \tag{8}$$

(See exercise 8.) The average value of c_j in (5) is $(\sum k(f_j(k) - f_j(k-1)))/n!$; summing by parts and then summing on j leads to the formula

$$C_{\text{ave}} = \binom{n+1}{2} - \frac{1}{n!} \sum_{\substack{1 \leq j \leq n \\ 0 \leq k \leq n-j}} f_j(k) = \binom{n+1}{2} - \frac{1}{n!} \sum_{0 \leq r < s \leq n} s!r^{n-s}. \tag{9}$$

Here the asymptotic value is not easy to determine, and we shall return to it at the end of this section.

To summarize our analysis of the bubble sort, the formulas derived above and below may be written as follows:

$$A = (\min 1, \quad \text{ave } N - \sqrt{\pi N/2} + O(1), \quad \max N); \tag{10}$$

$$B = (\min 0, \quad \text{ave } \tfrac{1}{4}(N^2 - N), \quad \max \tfrac{1}{2}(N^2 - N)); \tag{11}$$

$$C = (\min N - 1, \quad \text{ave } \tfrac{1}{2}(N^2 - N \ln N - (\gamma + \ln 2 - 1)N) + O(\sqrt{N}), \quad \max \tfrac{1}{2}(N^2 - N)). \tag{12}$$

In each case the minimum occurs when the input is already in order, and the maximum occurs when it is in reverse order; so the MIX running time is $8A + 7B + 8C + 1 = (\min 8N + 1, \text{ave } 5.75N^2 + O(N \ln N), \max 7.5N^2 + 0.5N + 1)$.

Refinements of the bubble sort. It took a good deal of work to analyze the bubble sort; and although the techniques used in the calculations are instructive, the results are disappointing since they tell us that the bubble sort isn't really very good at all. Compared to straight insertion (Algorithm 5.2.1S), bubble sorting requires a more complicated program and takes about twice as long!

Some suggestions can be given for improving the bubble sort. For example, in Fig. 14, the first comparison in Pass 4 is redundant, as are the first two in Pass 5 and the first three in Passes 6 and 7. Note also that elements can never move to the left more than one step per pass; so if the smallest item happens to be initially at the far right we are forced to make the maximum number of comparisons. This suggests the "cocktail shaker sort," in which alternate passes go in opposite directions (see Fig. 16). The average number of comparisons is slightly reduced by this approach. K. E. Iverson [*A Programming Language* (Wiley, 1962), 218–219] has made an interesting observation in this regard: If j is an index such that R_j and R_{j+1} are not exchanged with each

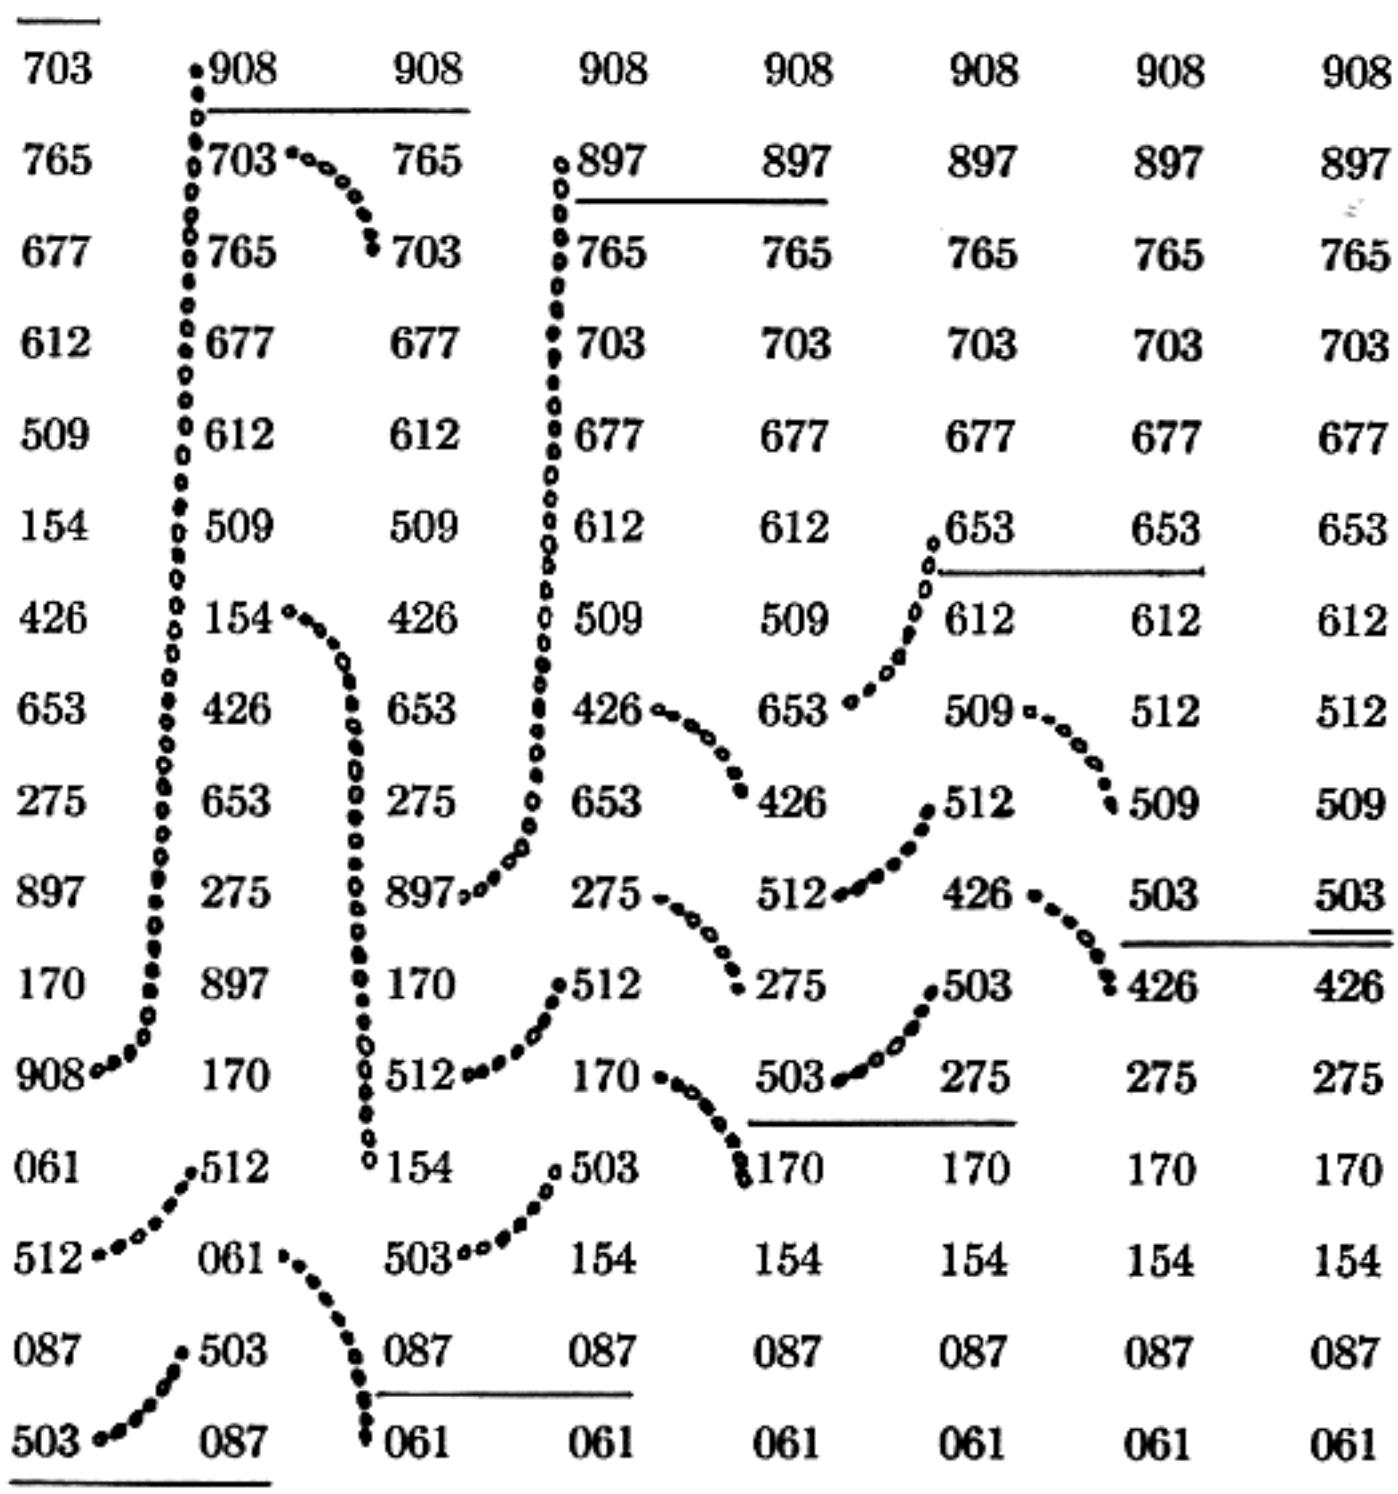

Fig. 16. The "cocktail-shaker sort."

other on two consecutive passes in opposite directions, then R_j and R_{j+1} must be in their final position, and they need not enter into any subsequent comparisons. For example, traversing 4 3 2 1 8 6 9 7 5 from left to right yields 3 2 1 4 6 8 7 5 9; no interchange occurred between R_4 and R_5. Traversing the latter permutation from right to left, R_4 is still less than (the new) R_5, so we may immediately conclude that R_4 and R_5 need not participate in any further comparisons.

But none of these refinements lead to an algorithm better than straight insertion (and we already know that straight insertion isn't suitable for large N). Another idea is to eliminate most of the exchanges; since most elements simply shift left one step during an exchange, we could achieve the same effect by viewing the array differently, shifting the origin of indexing! But the resulting algorithm is no better than straight *selection*, Algorithm 5.2.3S, which we shall study later.

In short, the bubble sort seems to have nothing to recommend it, except a catchy name and the fact that it leads to some interesting theoretical problems.

Batcher's parallel method. If we are going to have an exchange algorithm whose running time is faster than order N^2, we need to select some *nonadjacent* pairs of keys (K_i, K_j) for comparisons; otherwise we will need as many exchanges as the original permutation has inversions, and the average number of inversions is $\frac{1}{4}(N^2 - N)$. An ingenious way to program a sequence of comparisons, looking for potential exchanges, was discovered in 1964 by K. E. Batcher [*Proc. AFIPS Spring Joint Computer Conference* **32** (1968), 307–314]. His method is not at all obvious; in fact, it requires a fairly intricate proof just to show that it is valid, since comparatively few comparisons are made. We shall discuss two proofs, one in this section and another in Section 5.3.4.

Batcher's sorting scheme is somewhat like Shell's sort, but the comparisons are done in a novel way so that no propagation of exchanges is necessary. Thus we can compare Table 1 to Table 5.2.1–3; Batcher's method achieves the

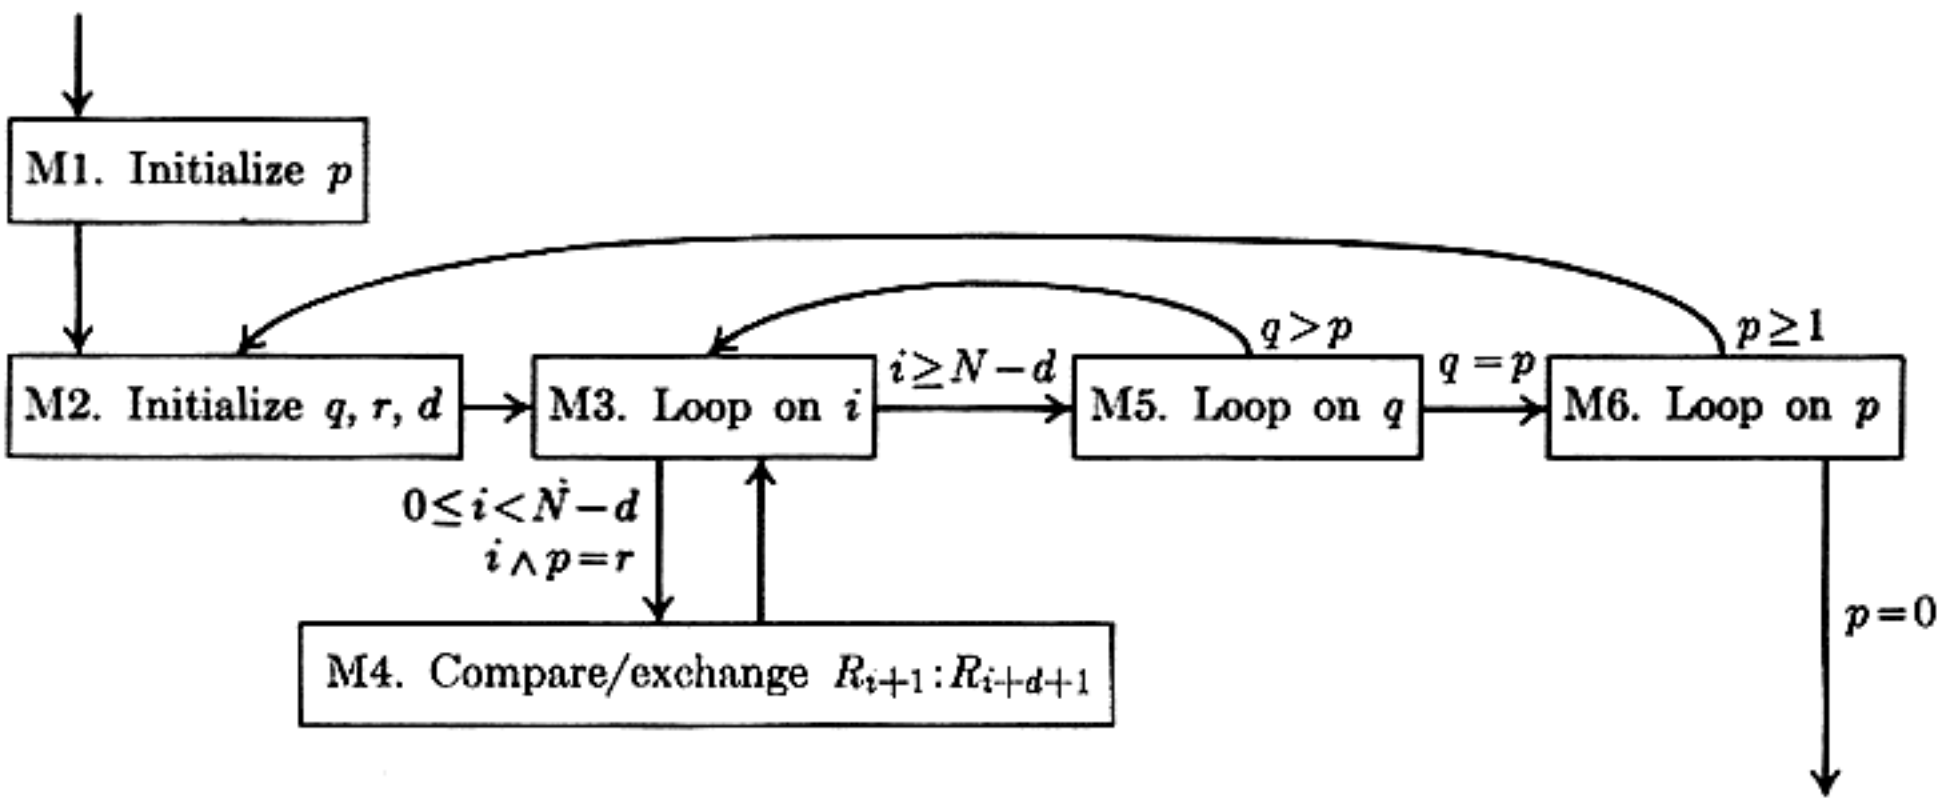

Fig 17. Algorithm M.

effect of 8-sorting, 4-sorting, 2-sorting, and 1-sorting, but the comparisons do not overlap. Since Batcher's algorithm essentially merges pairs of sorted subsequences, it may be called the "merge exchange sort."

Algorithm M (*Merge exchange*). Records $R_1, \ldots, R_N$ are rearranged in place; after sorting is complete their keys will be in order, $K_1 \le \cdots \le K_N$. We assume that $N \ge 2$.

M1. [Initialize p.] Set $p \leftarrow 2^{t-1}$, where $t = \lceil \log_2 N \rceil$ is the least integer such that $2^t \ge N$. (Steps M2 through M5 will be performed for $p = 2^{t-1}$, $2^{t-2}, \ldots, 1$.)

M2. [Initialize q, r, d.] Set $q \leftarrow 2^{t-1}$, $r \leftarrow 0$, $d \leftarrow p$.

M3. [Loop on i.] For all i such that $0 \le i < N - d$ and $i \wedge p = r$, do step M4. Then go to step M5. (Here $i \wedge p$ means the "logical and" of the binary representations of i and p; each bit of the result is zero except where both i and p have 1 bits in corresponding positions. Thus $13 \wedge 21 = (1101)_2 \wedge (10101)_2 = (00101)_2 = 5$. At this point, d is an odd multiple of p, and p is a power of 2, so that $i \wedge p \ne (i + d) \wedge p$; it follows that the actions of step M4 can be done for all relevant i in any order, even simultaneously.)

M4. [Compare/exchange $R_{i+1} : R_{i+d+1}$.] If $K_{i+1} > K_{i+d+1}$, interchange $R_{i+1} \leftrightarrow R_{i+d+1}$.

M5. [Loop on q.] If $q \ne p$, set $d \leftarrow q - p$, $q \leftarrow q/2$, $r \leftarrow p$, and return to M3.

M6. [Loop on p.] (At this point the permutation $K_1\, K_2 \ldots K_N$ is p-ordered.) Set $p \leftarrow \lfloor p/2 \rfloor$. If $p > 0$, go back to M2. ∎

Table 1 illustrates the method for $N = 16$. Note that the algorithm sorts N elements essentially by sorting R_1, R_3, $R_5, \ldots$ and R_2, R_4, $R_6, \ldots$ independently; then we perform steps M2 through M5 for $p = 1$, in order to merge the two sorted sequences together.

In order to prove that the magic sequence of comparison/exchanges specified in Algorithm M actually will sort all possible input files $R_1\, R_2 \ldots R_N$, we must show only that steps M2 through M5 will merge all 2-ordered files $R_1\, R_2 \ldots R_N$ when $p = 1$. For this purpose we can use the lattice-path method of Section 5.2.1 (cf. Fig. 11); each 2-ordered permutation of $\{1, 2, \ldots, N\}$ corresponds uniquely to a path from $(0, 0)$ to $(\lceil N/2 \rceil, \lfloor N/2 \rfloor)$ in a lattice diagram. Figure 18(a) shows an example for $N = 16$, corresponding to the permutation 1 3 2 4 10 5 11 6 13 7 14 8 15 9 16 12. When we perform step M3 with $p = 1$, $q = 2^{t-1}$, $r = 0$, $d = 1$, the effect is to compare (and possibly exchange) $R_1 : R_2$, $R_3 : R_4$, etc. This operation corresponds to a simple transformation of the lattice path, "folding" it about the diagonal if necessary so that it never goes above the diagonal. (See Fig. 18(b) and the proof in exercise 10.) The next iterations of step M3 have $p = r = 1$, and $d = 2^{t-1} - 1, 2^{t-2} - 1, \ldots, 1$; their effect is to compare/exchange $R_2 : R_{2+d}$, $R_4 : R_{4+d}$, etc., and again there is a simple lattice interpretation: the path is "folded" about a line $\frac{1}{2}(d + 1)$ units below the diagonal. See Fig. 18(c) and (d); eventually we get to the path

in Fig. 18(e), which corresponds to a completely sorted permutation. This completes a "geometric proof" that Batcher's algorithm is valid; we might call it sorting by folding!

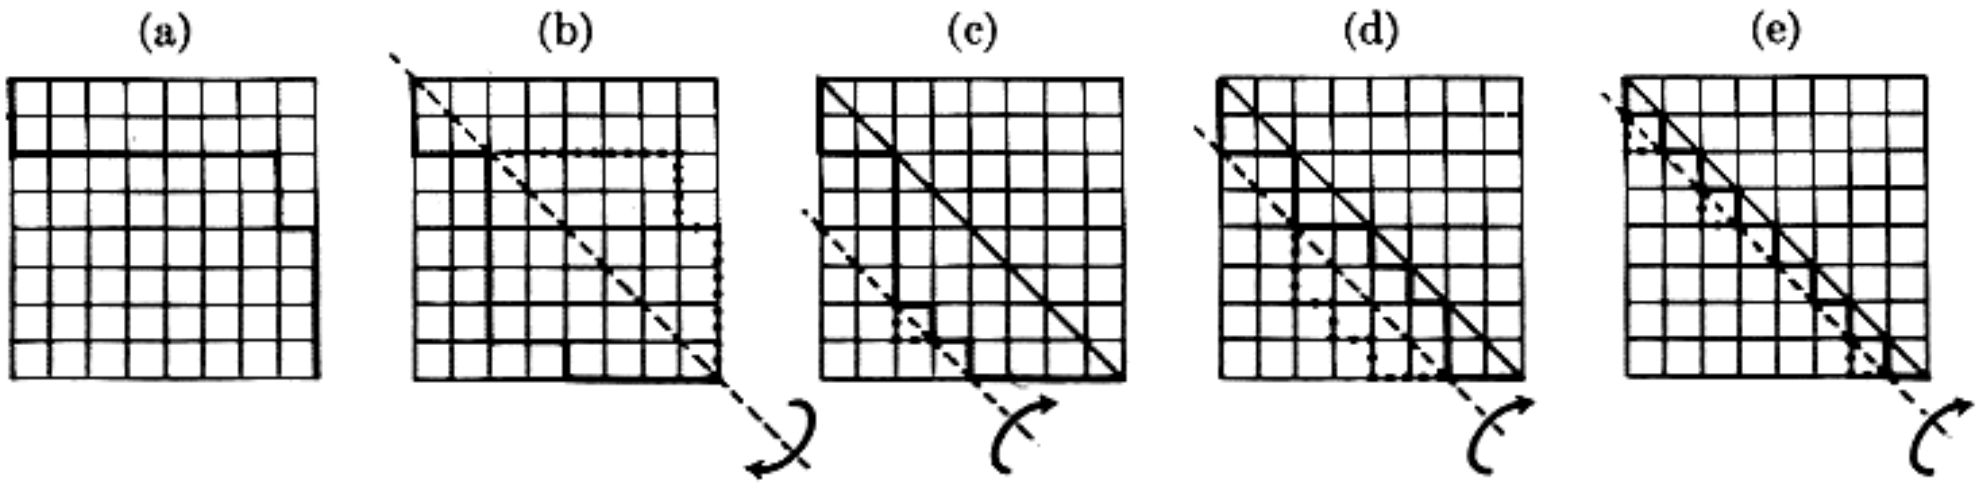

Fig. 18. A geometric interpretation of Batcher's method, $N = 16$.

A MIX program for Algorithm M appears in exercise 12. Unfortunately the amount of bookkeeping needed to control the sequence of comparisons is rather large, so the program is less efficient than other methods we have seen. But it has one important redeeming feature: All comparison/exchanges specified by a given iteration of step M3 can be done *simultaneously*, on computers or logical networks which allow parallel computations. With such parallel operations, sorting is completed in $\frac{1}{2}\lceil \log_2 N \rceil (\lceil \log_2 N \rceil + 1)$ steps, and this is about as fast as any general method known. For example, *1024 elements can be sorted in only 55 parallel steps by Batcher's method.* The nearest competitor is Pratt's method (see exercise 5.2.1–30), which uses either 40 or 73 steps, depending on how we count; if we are willing to allow overlapping comparisons as long as no overlapping exchanges are necessary, Pratt's method requires only 40 comparison/exchange cycles to sort 1024 elements. For further comments, see Section 5.3.4.

"Quicksort." The sequence of comparisons in Batcher's method is predetermined; we compare the same pairs of keys each time, regardless of what we may have learned about the file from previous comparisons. The same is largely true of the bubble sort, although Algorithm B does make limited use of previous knowledge in order to reduce its work at the right end of the file. Let us now turn to a quite different strategy, which uses the result of each comparison to determine what keys are to be compared next. Such a strategy is inappropriate for parallel computations, but on computers which work serially it can be quite fruitful.

Consider therefore the following comparison/exchange scheme: Keep two pointers, i and j, with $i = 1$ and $j = N$ initially. Compare $K_i{:}K_j$, and if no exchange is necessary decrease j by 1 and repeat the process. After an exchange first occurs, increase i by 1, and continue comparing and increasing i until another exchange occurs. Then decrease j again, and so on, "burning the candle at both ends," until $i = j$. For example, consider what happens to our file of sixteen numbers.

Given:	**503** 087 512 061 908 170 897 275 653 426 154 509 612 677 765 **703**	
		Decrease j
1st exchange:	**154** 087 512 061 908 170 897 275 653 426 **503** 509 612 677 765 703	
		Increase i

		Decrease j

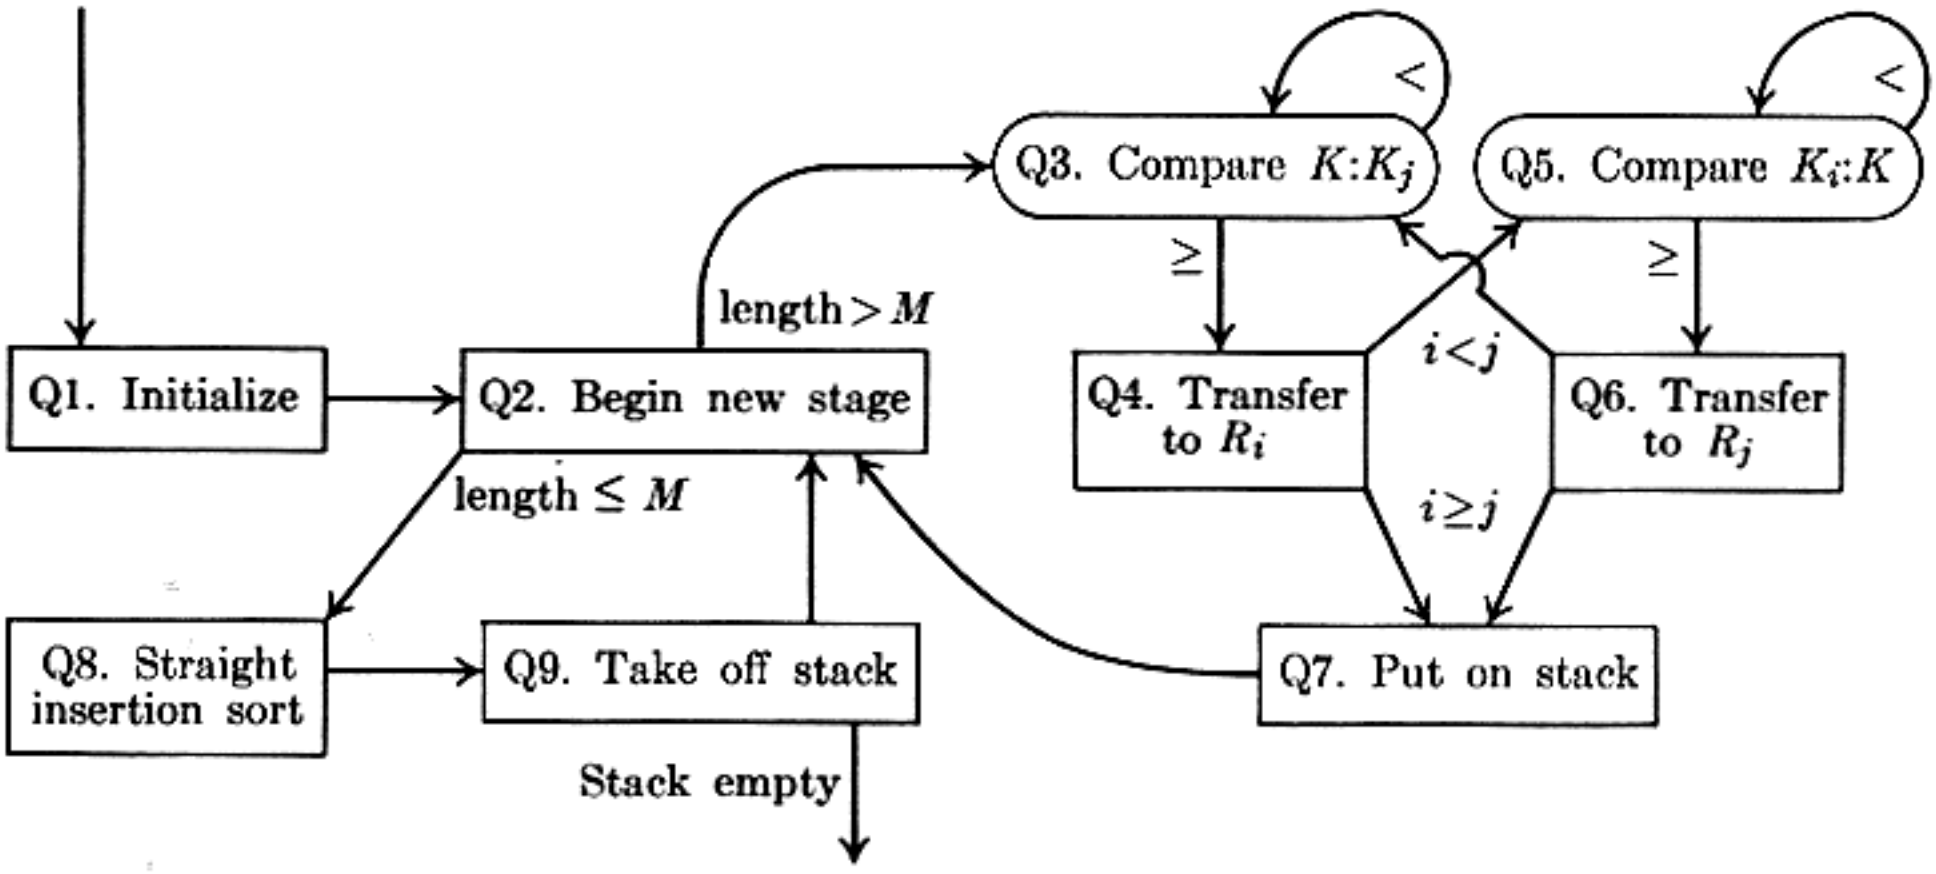

Fig. 19. Partition-exchange sorting ("quicksort").

(In order to indicate the position of i and j, K_i and K_j have been shown in boldface type.) Note that each of the comparisons in this example involves the key 503; in general, each comparison will involve the original value of K_1, because it keeps getting exchanged every time we switch directions. By the time that $i = j$, the original record R_1 will have moved into its final position, since it is easy to see that there will be no greater keys to its left and no smaller keys to its right. The original file will have been partitioned in such a way that the original problem is reduced to two simpler problems, sorting $R_1 \ldots R_{i-1}$ and (independently) sorting $R_{i+1} \ldots R_N$. We can apply the same technique to each of these subfiles.

Table 2 shows how our example file gets completely sorted by this approach, in 11 stages. Brackets indicate subfiles which still need to be sorted; inside a computer, these subfiles can be represented by two variables l and r (the

boundaries of the subfile currently under examination) and a stack of additional pairs (l_k, r_k). Each time the file is subdivided, we put the *largest* subfile on the stack and commence work on the other one, until we reach trivially short files; this procedure assures that the stack will never contain more than about $\log_2 N$ entries, as shown in exercise 20.

The sorting procedure just described may be called *partition-exchange sorting;* it is due to C. A. R. Hoare, whose interesting paper [*Comp. J.* **5** (1962), 10–15] contains one of the most comprehensive accounts of a sorting method that has ever been published. Hoare dubbed his method "quicksort"; such a name is not inappropriate, since, for example, the entire sorting process in Table 2 requires only 48 comparisons (the least we have seen so far, except for binary insertion which takes 47). All comparisons in a given stage are made against the same key, so this key may be kept in a register. Furthermore, the amount of data movement is quite reasonable; the computation in Table 2 makes only 17 exchanges, most of which are simply "half-exchanges" (simple transfers) because one key stays in the register and it need not be stored until the end of a stage.

The extra bookkeeping (required to control i, j, and the stack) is not difficult, but it makes the quicksort partitioning procedure most suitable for large N; therefore it is desirable to sort short subfiles in a special manner as in the following algorithm.

Algorithm Q (*Partition-exchange sort*). Records $R_1, \ldots, R_N$ are rearranged in place; after sorting is complete their keys will be in order, $K_1 \le \cdots \le K_N$. An auxiliary stack with at most $\log_2 N$ entries is needed for temporary storage. This algorithm follows the "quicksort" partitioning procedure described in the text above, with slight modifications for extra efficiency:

a) We assume the presence of artificial keys $K_0 = -\infty$ and $K_{N+1} = +\infty$ such that

$$K_0 \le K_i \le K_{N+1} \quad \text{for} \quad 1 \le i \le N. \tag{13}$$

(Equality is allowed.)

b) Subfiles of M or fewer elements are sorted by straight insertion, where $M \ge 1$ is a parameter which should be chosen as described in the text below.

c) One or two extra comparisons are made during particular stages (allowing the pointers i, j to cross), so that the main comparison loops can be as fast as possible.

d) Records with equal keys are exchanged, although it is not strictly necessary to do so. (This idea, due to R. C. Singleton, helps to split subfiles nearly in half when equal elements are present; see exercise 18.)

Q1. [Initialize.] Set the stack empty, and set $l \leftarrow 1$, $r \leftarrow N$.

Q2. [Begin new stage.] (We now wish to sort the subfile $R_l \ldots R_r$; from the nature of the algorithm, we have $r \geq l-1$, and $K_{l-1} \leq K_i \leq K_{r+1}$ for $l \leq i \leq r$.) If $r - l < M$, go to step Q8. Otherwise set $i \leftarrow l$, $j \leftarrow r$, $K \leftarrow K_l$, $R \leftarrow R_l$. (For a discussion of better choices for R and K, see the text below.)

Q3. [Compare K:K_j.] If $K < K_j$, decrease j by 1 and repeat this step.

Q4. [Transfer to R_i.] (At this point K_i is an irrelevant key $\geq K$, and $K \geq K_j$.) If $j \leq i$, set $R_i \leftarrow R$ and go to Q7. Otherwise set $R_i \leftarrow R_j$ and increase i by 1.

Q5. [Compare K_i:K.] If $K_i < K$, increase i by 1 and repeat this step.

Q6. [Transfer to R_j.] (At this point K_j is an irrelevant key $\leq K$, and $K \leq K_i$.] If $j \leq i$, set $R_j \leftarrow R$ and $i \leftarrow j$. Otherwise set $R_j \leftarrow R_i$, decrease j by 1, and go to Q3.

Q7. [Put on stack.] (Now the subfile $R_l \ldots R_i \ldots R_r$ has been partitioned so that $K_k \leq K_i$ for $l \leq k \leq i$ and $K_i \leq K_k$ for $i \leq k \leq r$.) If $r - i \geq i - l$, insert $(i+1, r)$ on top of the stack and set $r \leftarrow i-1$. Otherwise insert $(l, i-1)$ on top of the stack and set $l \leftarrow i+1$. (Each entry (a, b) on the stack is a request to sort the subfile $R_a \ldots R_b$ at some future time.) Now go back to step Q2.

Q8. [Straight insertion sort.] For $j = l+1, l+2, \ldots$ until $j > r$ do the following operations: Set $K \leftarrow K_j$, $R \leftarrow R_j$, $i \leftarrow j-1$; then set $R_{i+1} \leftarrow R_i$, $i \leftarrow i-1$ zero or more times until $K_i \leq K$; then set $R_{i+1} \leftarrow R$. (This is essentially Algorithm 5.2.1S, applied to a subfile of M or fewer elements.)

Q9. [Take off stack.] If the stack is empty, we are done sorting; otherwise remove its top entry (l', r'), set $l \leftarrow l'$, $r \leftarrow r'$, and return to step Q2. ∎

The corresponding MIX program is rather long, but not complicated; in fact, a large part of the coding is devoted to step Q7, which just fools around with the variables in a very straightforward way.

Program Q (*Partition-exchange sort*). Records to be sorted appear in locations INPUT+1 through INPUT+N; assume that locations INPUT and INPUT+N+1 contain, respectively, the smallest and largest values possible in MIX. The stack is kept in locations STACK+1, STACK+2, . . . ; see exercise 20 for the exact number of locations to set aside for the stack. rI1 $\equiv l$, rI2 $\equiv r$, rI3 $\equiv i$, rI4 $\equiv j$, rI6 $\equiv$ size of stack, rA $\equiv K \equiv R$.

Analysis of "quicksort." The timing information shown with Program Q is not hard to derive using Kirchhoff's conservation law (cf. Section 1.3.3) and the fact that everything put on the stack is eventually removed again. The total running time depends on the following quantities:

$$\begin{aligned}
A &= \text{number of stages in which the given subfile has more than } M \text{ elements;}\\
B &= \text{number of times } R_j \leftarrow R_i \text{ in step Q6;}\\
C' &= \text{number of times step Q3 is performed;}\\
C'' &= \text{number of times step Q5 is performed;}\\
D &= \text{number of times } R \leftarrow R_j \text{ in step Q8;}\\
E &= \text{number of times } R_{i+1} \leftarrow R_i \text{ in step Q8;}\\
L &= \text{number of times } r \le l \text{ in step Q8;}\\
X &= \text{number of times } i \leftarrow j \text{ in step Q6.}
\end{aligned} \tag{14}$$

Instead of analyzing C' and C'' independently, we shall consider only

$$C = C' + C'' = \text{ total number of comparisons,} \tag{15}$$

since the running time for C' and C'' is identical. By analyzing these seven quantities A, B, C, D, E, L, and X, we will be able to make an intelligent choice of the parameter M which specifies the "threshold" between straight insertion sorting and partitioning. (Nonmathematical readers, please skip to Eq. (25).)

As in most other analyses of this chapter, we shall assume that the keys to be sorted are distinct; exercise 18 indicates that equalities between keys do not seriously harm the efficiency of Algorithm Q, and in fact they seem to help it. Since the method depends only on the relative order of the keys, we may as well assume that they are simply $\{1, 2, \ldots, N\}$ in some order.

When we first get to step Q2, the sorting reduces to straight insertion if $N \le M$, and we have already analyzed straight insertion; so let us assume that $N > M$. We need to study only the computations which take us to step Q7

for the first time; once the partitioning has been achieved, it is easy to see that both subfiles $R_1 \ldots R_{i-1}$ and $R_{i+1} \ldots R_N$ are in random order if the original file was in random order, so the contribution of subsequent computations can be determined by induction on N.

Let s be the value of the first key, K_1, and assume that exactly t of the keys $K_1, \ldots, K_s$ are greater than s. Let

$$h = \begin{cases} 1, & \text{if } K_s < s; \\ 0, & \text{if } K_s \geq s. \end{cases} \tag{16}$$

In other words, h is 1 if the key which initially occupies position s (where K_1 will be placed) will be moved to the left. Remember that the keys being sorted are the integers $\{1, 2, \ldots, N\}$.

If $s = 1$, it is easy to see what happens during the first stage of partitioning: Step Q3 is performed N times, and then step Q4 takes us to Q7. So the contributions of the first stage in this case are $A = 1$, $B = 0$, $C = N$, $X = 0$. A similar but slightly more complicated argument when $s > 1$ (see exercise 21) shows that the contributions of the first stage to the total running time are, in general,

$$A = 1, B = t, C = N + 1 - \delta_{s1}, X = h, \qquad \text{for} \qquad 1 \leq s \leq N. \tag{17}$$

To this we must add the contributions of the later stages, which sort subfiles of $s - 1$ and $N - s$ elements, respectively.

If we assume that the original file is in random order, it is now possible to write down formulas which define the generating functions for the probability distributions of $A, B, \ldots, X$ (see exercise 22). But for simplicity we shall consider here only the *average* values of these quantities, $A_N, B_N, \ldots, X_N$, as functions of N. Consider, for example, the average number of comparisons, C_N, which occur during the partitioning process. When $N \leq M$, $C_N = 0$. Since any given value of s occurs with probability $1/N$, we have

$$\begin{aligned} C_N &= \frac{1}{N} \sum_{1 \leq s \leq N} (N + 1 - \delta_{s1} + C_{s-1} + C_{N-s}) \\ &= N + 1 - \frac{1}{N} + \frac{2}{N} \sum_{0 \leq k < N} C_k, \qquad \text{for} \qquad N > M. \end{aligned} \tag{18}$$

Similar formulas hold for the other quantities $A_N, B_N, \ldots, X_N$ (see exercise 23).

There is a simple way to solve recurrence relations of the form

$$x_n = f_n + \frac{2}{n} \sum_{0 \leq k < n} x_k, \qquad \text{for} \qquad n \geq m. \tag{19}$$

The first step is to get rid of the summation sign: Since

$$(n+1)x_{n+1} = (n+1)f_{n+1} + 2\sum_{0\le k\le n} x_k,$$

$$nx_n = nf_n + 2\sum_{0\le k<n} x_k,$$

we may subtract, obtaining

$$(n+1)x_{n+1} - nx_n = g_n + 2x_n, \qquad \text{where} \qquad g_n = (n+1)f_{n+1} - nf_n.$$

Now the recurrence takes the much simpler form

$$(n+1)x_{n+1} = (n+2)x_n + g_n, \qquad \text{for} \qquad n \ge m. \tag{20}$$

Any recurrence relation which has the general form

$$a_n x_{n+1} = b_n x_n + g_n \tag{21}$$

can be reduced to a summation if we multiply both sides by the "summing factor" $a_0\, a_1 \ldots a_{n-1}/b_0\, b_1 \ldots b_n$; we obtain

$$y_{n+1} = y_n + c_n, \quad \text{where} \quad y_n = \frac{a_0 \ldots a_{n-1}}{b_0 \ldots b_{n-1}}\, x_n, \quad c_n = \frac{a_0 \ldots a_{n-1}}{b_0\, b_1 \ldots b_n}\, g_n. \tag{22}$$

In our case (20), the summing factor is simply $n!/(n+2)! = 1/(n+1)(n+2)$, so we find that the simple relation

$$\frac{x_{n+1}}{n+2} = \frac{x_n}{n+1} + \frac{(n+1)f_{n+1} - nf_n}{(n+1)(n+2)}, \qquad n \ge m, \tag{23}$$

is a consequence of (19).

For example, if we set $f_n = 1/n$, we get the unexpected result $x_n/(n+1) = x_m/(m+1)$ for all $n \ge m$. If we set $f_n = n+1$, we get

$$\begin{aligned} x_n/(n+1) &= 2/(n+1) + 2/n + \cdots + 2/(m+2) + x_m/(m+1) \\ &= 2(H_{n+1} - H_{m+1}) + x_m/(m+1), \end{aligned}$$

for all $n \ge m$. Combining these two solutions, and setting $m = M+1$ and $x_n = 0$ for $n \le M$, gives the formula

$$\begin{aligned} C_N &= (N+1)\left(2H_{N+1} - 2H_{M+2} + 1 - \frac{1}{(M+1)(M+2)}\right) \\ &\approx 2(N+1)\ln\left(\frac{N+1}{M+2}\right), \qquad \text{for} \qquad N > M. \end{aligned} \tag{24}$$

In Section 6.2.2, we shall prove that the standard deviation of C_N is asymptotically $\sqrt{(21 - 2\pi^2)/3}\, N$; this is reasonably small compared to (24).

The other quantities can be found in a similar way (see exercise 23); we have

$$\begin{aligned}
A_N &= 2(N+1)/(M+2) - 1,\\
B_N &= \frac{1}{6}(N+1)\left(2H_{N+1} - 2H_{M+2} + 1 - \frac{6}{M+2}\right) + \frac{1}{2},\\
D_N &= (N+1)M(M-1)/(M+2)(M+1),\\
E_N &= \tfrac{1}{6}(N+1)M(M-1)/(M+2),\\
L_N &= 4(N+1)/(M+2)(M+1),\\
X_N &= (N+1)/(M+2) - \tfrac{1}{2}, \qquad \text{for} \qquad N > M.
\end{aligned} \tag{25}$$

The above discussion shows that it is possible to carry out an exact analysis of the average running time of a fairly complex program, by using techniques that we have previously applied only to simpler cases.

Formulas (24) and (25) can be used to determine the "best" value of M on a particular computer. In MIX's case, Program Q requires $37A + 14B + 4C + 12D + 8E - L + 8X + 15$ units of time; this comes to $\frac{1}{3}\,(38(N+1)H_N + (N+1)f(M)) - 19$ units on the average, for $N > M$, where

$$f(M) = 4M - 38H_{M+2} + 43 + \frac{84}{M+2} + \frac{48}{(M+2)(M+1)}. \tag{26}$$

We want to choose M so that $f(M)$ is a minimum. In this case

$$f(M) - f(M-1) = 4 - \frac{38}{M+2} - \frac{84}{(M+2)(M+1)} - \frac{96}{(M+2)(M+1)M},$$

and we want to find M such that $f(M) - f(M-1) \le 0$, $f(M+1) - f(M) \ge 0$; the solution, $M = 9$, is easily found. When $M = 9$ the average running time of Program Q is approximately $12.67(N+1)\ln N - 1.92N - 14.59$ for large N.

So Program Q is quite fast, on the average, considering that it requires very little memory space. But what is the *worst* case of Algorithm Q? Are there some inputs which it does not handle efficiently? The answer to this question is quite embarrassing: If the original file is already in order, with $K_1 < K_2 < \cdots < K_N$, each "partitioning" operation is almost useless, since it reduces the size of the subfile by only one element! So this situation (which ought to be easiest of all to sort) makes quicksort anything but quick; its running time becomes proportional to N^2 instead of $N \log N$. (See exercise 25.) Unlike the other sorting methods we have seen, Algorithm Q likes a disordered file!

Hoare suggested two ways to remedy the situation, in his original paper, by choosing a better value of the test key K which governs the partitioning. One of his recommendations is to choose a *random* integer q between l and r in the last part of step Q2; we can change the instructions "$K \leftarrow K_l$, $R \leftarrow R_l$" to

$$K \leftarrow K_q, \qquad R \leftarrow R_q, \qquad R_q \leftarrow R_l \tag{27}$$

in that step. According to Eqs. (25), such random integers need to be calculated only $2(N+1)/(M+2) - 1$ times on the average, so the additional running

time is not substantial; and the random choice gives good protection against the occurrence of the worst case.

Hoare's second suggestion is to look at a small sample of the file and to choose a median value of the sample. This approach has been followed by R. C. Singleton [*CACM* **12** (1969), 185–187], who suggests letting K_q be the median of the three values

$$K_l, \qquad K_{\lfloor (l+r)/2 \rfloor}, \qquad K_r. \tag{28}$$

Singleton's procedure cuts the number of comparisons down from $2N \ln N$ to about $\frac{12}{7}N \ln N$ (see exercise 29). It can be shown that B_N is asymptotically $C_N/5$ instead of $C_N/6$ in this case, so the median method slightly increases the amount of time spent in transferring the data; the total running time therefore decreases by roughly 8 percent. (See exercise 56 for a detailed analysis.) The worst case is still of order N^2, but such slow behavior will hardly ever occur.

W. D. Frazer and A. C. McKellar [*JACM* **17** (1970), 496–507] have suggested taking a much larger sample consisting of $2^k - 1$ records, where k is chosen so that $2^k \approx N/\ln N$. The sample can be sorted by the usual quicksort method, then inserted among the remaining records by taking k passes over the file (partitioning it into 2^k subfiles, bounded by the elements of the sample). Finally the subfiles are sorted. The average number of comparisons required by such a "samplesort" procedure is about the same as in Singleton's median method, when N is in a practical range, but it decreases to the asymptotic value $N \log_2 N$ as $N \to \infty$.

Radix exchange. We come now to a method which is quite different from any of the sorting schemes we have seen before; it makes use of the *binary representation* of the keys, so it is intended only for binary computers. Instead of comparing two keys with each other, this method inspects individual bits of the keys, to see if they are 0 or 1. In other respects it has the characteristics of exchange sorting, and, in fact, it is rather similar to quicksort. Since it depends on radix 2 representations, we call it "radix exchange sorting." The algorithm can be described roughly as follows:

1) Sort the sequence on its *most significant binary bit*, so that all keys which have a leading 0 come before all keys which have a leading 1. This sorting is done by finding the leftmost key K_i which has a leading 1, and the rightmost key K_j with a leading 0. Then R_i and R_j are exchanged and the process is repeated until $i > j$.

2) Let F_0 be the elements with leading bit 0, and let F_1 be the others. Apply the radix exchange sorting method to F_0 (starting now at the *second* bit from the left instead of the most significant bit), until F_0 is completely sorted; then do the same for F_1.

For example, Table 3 shows how the radix exchange sort acts on our 16 random numbers, which have been converted to octal notation. Stage 1 in the table shows the initial input, and after exchanging on the first bit we get to

Table 3

RADIX-EXCHANGE SORTING

Stage																	l	r	b	Stack

stage 2. Stage 2 sorts the first group on bit 2, and stage 3 works on bit 3. (The reader should mentally convert the octal notation to 10-bit binary numbers.) When we reach stage 5, after sorting on bit 4, we find that each group remaining has but a single element, so this part of the file need not be further examined. The notation "$^4[0232\ 0252]$" means that the subfile *0232 0252* is waiting to be sorted on bit 4 from the left. In this particular case, no progress occurs when sorting on bit 4; we need to go to bit 5 before the items are separated.

The complete sorting process shown in Table 3 takes 22 stages, somewhat more than the comparable number for quicksort (Table 2). Similarly, the number of bit inspections, 82, is rather high; but we shall see that the number of bit inspections for large N is actually less than the number of comparisons made by quicksort, assuming a uniform distribution of keys. The total number of exchanges in Table 3 is 17, which is quite reasonable. Note that bit inspections never have to go past bit 7 here, although 10-bit numbers are being sorted.

As in quicksort, we can use a stack to keep track of the "boundary line information" for waiting subfiles. Instead of sorting the smallest subfile first, it is convenient simply to go from left to right, since the stack size in this case can never exceed the number of bits in the keys being sorted. In the following algorithm the stack entry (r, b) is used to indicate the right boundary r of a subfile waiting to be sorted on bit b; the left boundary need not be recorded in the stack, it is implicit because of the left-to-right nature of the procedure.

Algorithm R (*Radix-exchange sort*). Records $R_1, \ldots, R_N$ are rearranged in place; after sorting is complete, their keys will be in order, $K_1 \le \cdots \le K_N$. Each key is assumed to be an m-bit binary number, e.g. $(a_1\, a_2 \ldots a_m)_2$; the ith most significant bit, a_i, is called "bit i" of the key. An auxiliary stack with room for at most $m - 1$ entries is needed for temporary storage. This algorithm essentially follows the radix-exchange partitioning procedure described in the text above; certain improvements in its efficiency are possible, as described in the text and exercises below.

R1. [Initialize.] Set the stack empty, and set $l \leftarrow 1$, $r \leftarrow N$, $b \leftarrow 1$.

R2. [Begin new stage.] (We now wish to sort the subfile $R_l \le \cdots \le R_r$ on bit b; from the nature of the algorithm, we have $l \le r$.) If $l = r$, go to step R10 (since a one-word file is already sorted). Otherwise set $i \leftarrow l$, $j \leftarrow r$.

R3. [Inspect K_i for 1.] Examine bit b of K_i. If it is a 1, go to step R6.

R4. [Increase i.] Increase i by 1. If $i \le j$, return to step R3; otherwise go to step R8.

R5. [Inspect K_{j+1} for 0.] Examine bit b of K_{j+1}. If it is a 0, go to step R7.

R6. [Decrease j.] Decrease j by 1. If $i \le j$, go to step R5; otherwise go to step R8.

R7. [Exchange R_i, R_{j+1}.] Interchange records $R_i \leftrightarrow R_{j+1}$; then go to step R4.

R8. [Test special cases.] (At this point a partitioning stage has been completed; $i = j + 1$, bit b of keys $K_l, \ldots, K_j$ is 0, and bit b of keys $K_i, \ldots, K_r$ is 1.) Increase b by 1. If $b > m$, where m is the total number of bits in the keys, go to step R10. (In such a case, the subfile $R_l \ldots R_r$ has been sorted. This test need not be made if there is no chance of having equal keys present in the file.) Otherwise if $j < l$ or $j = r$, go back to step R2 (all bits examined were 1 or 0, respectively). Otherwise if $j = l$, increase l by 1 and go to step R2 (there was only one 0 bit).

R9. [Put on stack.] Insert the entry (r, b) on top of the stack; then set $r \leftarrow j$ and go to step R2.

R10. [Take off stack.] If the stack is empty, we are done sorting; otherwise set $l \leftarrow r + 1$, remove the top entry (r', b') of the stack, set $r \leftarrow r'$, $b \leftarrow b'$, and return to step R2. ∎

Program R (*Radix-exchange sort*). The following MIX code uses essentially the same conventions as Program Q. We have rI1 $\equiv l - r$, rI2 $\equiv r$, rI3 $\equiv i$, rI4 $\equiv j$, rI5 $\equiv m - b$, rI6 $\equiv$ size of stack, except that it proves convenient for certain instructions (designated below) to leave $rI3 = i - j$ or $rI4 = j - i$. Because of the binary nature of radix-exchange, this program uses the operations SRB (shift right AX binary), JAE (jump A even), and JAO (jump A odd) which are defined in Section 4.5.2. We assume that $N \geq 2$.

```

```

The running time of this radix exchange program depends on

$$\begin{aligned}
A &= \text{number of stages encountered with } l < r;\\
B &= \text{number of exchanges;}\\
C &= C' + C'' = \text{number of bit inspections;}\\
G &= \text{number of times } b > m \text{ in step R8;}\\
K &= \text{number of times } b \le m,\ j = l \text{ in step R8;}\\
L &= \text{number of times } b \le m,\ j < l \text{ in step R8;}\\
R &= \text{number of times } b \le m,\ j = r \text{ in step R8;}\\
S &= \text{number of times things are entered onto the stack;}\\
X &= \text{number of times } j < i \text{ in step R6.}
\end{aligned} \tag{29}$$

By Kirchhoff's law, $S = A - G - K - L - R$; so the total running time comes to $27A + 8B + 8C - 23G - 14K - 17L - 19R - X + 13$ units. The bit-inspection loops can be made somewhat faster, as shown in exercise 34, at the expense of a more complicated program. It is also possible to increase the speed of radix exchange by using straight insertion whenever $r - l$ is sufficiently small, as we did in Algorithm Q; but we shall not dwell on these refinements.

In order to analyze the running time of radix exchange, two kinds of input data suggest themselves:

i) Assume that $N = 2^m$ and that the keys to be sorted are simply the integers $0, 1, 2, \ldots, 2^m - 1$ in random order; or

ii) Assume that $m = \infty$ (unlimited precision) and that the keys to be sorted are independent uniformly distributed real numbers in $[0, 1)$.

The analysis of case (i) is relatively easy, so it has been left as an exercise for the reader (see exercise 35). Case (ii) is comparatively difficult, so it has *also* been left as an exercise. The following table shows crude approximations to the results of these analyses:

Quantity	Case (i)	Case (ii)
A	N	αN
B	$\frac{1}{4}N \log_2 N$	$\frac{1}{4}N \log_2 N$
C	$N \log_2 N$	$N \log_2 N$
G	$\frac{1}{2}N$	0
K	0	$\frac{1}{2}N$
L	0	$\frac{1}{2}(\alpha - 1)N$
R	0	$\frac{1}{2}(\alpha - 1)N$
S	$\frac{1}{2}N$	$\frac{1}{2}N$
X	$\frac{1}{2}N$	$\frac{1}{4}(\alpha + 1)N$

(30)

Here $\alpha = 1/(\ln 2) = 1.4427$. Note that the average number of exchanges, bit inspections, and stack accesses is essentially the same for both cases, even though case (ii) takes about 44 percent more stages. Our MIX program takes approximately $14.4\, N \ln N$ units of time, on the average, to sort N items in case (ii), and this could be cut to about $11.5\, N \ln N$ using the suggestion of exercise 34; the corresponding figure for Program Q is $12.7\, N \ln N$, which can be decreased to about $11.7\, N \ln N$ using Singleton's median-of-three suggestion.

Thus radix exchange sorting takes about as long as quicksort, on the average, when sorting uniformly distributed data; on MIX it is actually a little quicker than quicksort. Exercise 53 indicates to what extent the process slows down for a nonuniform distribution. It is important to note that our entire analysis is predicated on the assumption that keys are distinct; *radix exchange as defined above is not especially efficient when equal keys are present*, since it goes through several time-consuming stages trying to separate sets of identical keys before b becomes $> m$. One plausible way to remedy this defect is suggested in the answer to exercise 40.

Both radix exchange and quicksort are essentially based on the idea of partitioning. Records are exchanged until the file is split into two parts: a left-hand subfile, in which all keys are $\leq K$, for some K, and a right-hand subfile in which all keys are $\geq K$. Quicksort chooses K to be an actual key in the file, while radix exchange essentially chooses an artificial key K based on binary representations. From a historical standpoint, radix exchange was discovered by P. Hildebrandt, H. Isbitz, H. Rising, and J. Schwartz [*JACM* **6** (1959), 156–163], about a year earlier than quicksort. Other partitioning schemes are also possible; for example, John McCarthy has suggested setting $K \approx \frac{1}{2}(u + v)$, if all keys are known to lie between u and v.

Still another partitioning strategy has been proposed by M. H. van Emden [*CACM* **13** (1970), 563–567]: Instead of choosing K in advance, we "learn"

what a good K might be, by keeping track of $K' = \max(K_l, \ldots, K_i)$ and $K'' = \min(K_j, \ldots, K_r)$ as partitioning proceeds. We may increase i until encountering a key greater than K', then decrease j until encountering a key less than K'', then exchange and/or adjust K' and K''. Empirical tests on this "interval-exchange sort" method indicate that it requires about $1.64\,N \ln N = 1.14\,N \log_2 N$ comparisons; it is the only sorting method discussed in this book for which no adequate theoretical explanation of the behavior has yet been found.

A generalization of radix exchange to radices higher than 2 is discussed in Section 5.2.5.

***Asymptotic methods.** The analysis of exchange sorting algorithms leads to some particularly instructive mathematical problems which enable us to learn more about how to find the asymptotic behavior of functions. For example, we came across the function

$$W_n = \frac{1}{n!} \sum_{0 \le r < s \le n} s! r^{n-s} \tag{31}$$

in our analysis of the bubble sort (Eq. 9); what is its asymptotic value?

We can proceed as in our study of the number of involutions, Eq. 5.1.4–41; the reader will find it helpful to review the discussion at the end of Section 5.1.4 before reading further.

Inspection of (31) shows that the contribution for $s = n$ is larger than that for $s = n - 1$, etc; this suggests replacing s by $n - s$. In fact, we soon discover that it is most convenient to use the substitutions $t = n - s + 1$, $m = n + 1$, so that (31) becomes

$$\frac{1}{m} W_{m-1} = \frac{1}{m!} \sum_{1 \le t < m} (m-t)! \sum_{0 \le r < m-t} r^{t-1}. \tag{32}$$

The inner sum has a well-known asymptotic series obtained from Euler's summation formula,

$$\begin{aligned} \sum_{0 \le r < N} r^{t-1} &= \frac{N^t}{t} - \frac{1}{2}(N^{t-1} - \delta_{t1}) + \frac{B_2}{2!}(t-1)(N^{t-2} - \delta_{t2}) + \cdots \\ &= \frac{1}{t} \sum_{0 \le j \le k} \binom{t}{j} B_j (N^{t-j} - \delta_{tj}) + O(N^{t-k}) \end{aligned} \tag{33}$$

(see exercise 1.2.11.2–4), hence our problem reduces to studying sums of the form

$$\frac{1}{m!} \sum_{1 \le t < m} (m-t)!(m-t)^t t^k, \qquad k \ge -1. \tag{34}$$

As in Section 5.1.4 we can show that the value of this summand is negligible, $O(\exp(-n^\delta))$, whenever t is greater than $m^{1/2+\epsilon}$; hence we may put $t =$

$O(m^{1/2+\epsilon})$ and replace the factorials by Stirling's approximation:

$$\frac{(m-t)!(m-t)^t}{m!}$$
$$= \sqrt{1-\frac{t}{m}}\exp\left(\frac{t}{12m^2}-\left(\frac{t^2}{2m}+\frac{t^3}{3m^2}+\frac{t^4}{4m^3}+\frac{t^5}{5m^4}\right)+O(m^{-2+6\epsilon})\right).$$

We are therefore interested in the asymptotic value of

$$r_k(m)=\sum_{1\le t<m} e^{-t^2/2m}t^k, \qquad k\ge -1. \tag{35}$$

(The sum could also be extended to the full range $1\le t<\infty$ without changing its asymptotic value, since the values for $t>m^{1/2+\epsilon}$ are negligible as stated above.)

Let $g_k(x)=x^ke^{-x^2}$ and $f_k(x)=g_k(x/\sqrt{2m})$. When $k\ge 0$, Euler's summation formula tells us that

$$\sum_{0\le t<m} f_k(t)=\int_0^m f_k(x)\,dx+\sum_{1\le j\le p}\frac{B_j}{j!}\left(f_k^{(j-1)}(m)-f_k^{(j-1)}(0)\right)+R_p,$$

$$R_p=\frac{(-1)^{p+1}}{p!}\int_0^m B_p(\{x\})f_k^{(p)}(x)\,dx$$
$$=\left(\frac{1}{\sqrt{2m}}\right)^p O\left(\int_0^\infty |g_k^{(p)}(y)|\,dy\right)=O(m^{-p/2}); \tag{36}$$

hence we can get an asymptotic series for $r_k(m)$ whenever $k\ge 0$ by using essentially the same ideas we have used before. But when $k=-1$ the method breaks down, since $f_{-1}(0)$ is undefined; we can't merely sum from 1 to m either, because the remainders don't give smaller and smaller powers of m when the lower limit is 1. (This is the crux of the matter, and the reader should make sure he appreciates the problem before reading further.)

To resolve the dilemma we can define $g_{-1}(x)=(e^{-x^2}-1)/x$, $f_{-1}(x)=g_{-1}(x/\sqrt{2m})$; then $f_{-1}(0)=0$ and $r_{-1}(m)$ can be obtained from $\sum_{0\le t<m}f_{-1}(t)$ in a simple way. Equation (36) is now valid for $k=-1$, and the remaining integral is "well known,"

$$\frac{2}{\sqrt{2m}}\int_0^m f_{-1}(x)\,dx=2\int_0^m\frac{e^{-x^2/2m}-1}{x}\,dx=\int_0^{m/2}\frac{e^{-y}-1}{y}\,dy$$
$$=\int_0^1\frac{e^{-y}-1}{y}\,dy+\int_1^{m/2}\frac{e^{-y}}{y}\,dy-\ln(m/2)$$
$$=-\gamma-\ln(m/2)+O(e^{-m/2})$$

by exercise 43.

Now we have enough facts and formulas to grind out the answer,

$$W_n = \tfrac{1}{2}m \ln m + \tfrac{1}{2}(\gamma + \ln 2)m - \tfrac{2}{3}\sqrt{2\pi m} + \tfrac{31}{36} + O(n^{-1/2}), \qquad m = n + 1, \tag{37}$$

as shown in exercise 44. This completes our analysis of the bubble sort.

For the analysis of radix exchange sorting, we need to know the asymptotic value of the finite sum

$$U_n = \sum_{k\ge 2} \binom{n}{k} (-1)^k \frac{1}{2^{k-1} - 1} \tag{38}$$

as $n \to \infty$. This question turns out to be harder than any of the other asymptotic problems we have met so far; the elementary methods of power series expansions, Euler's summation formula, etc., turn out to be inadequate. The following derivation has been suggested by N. G. de Bruijn.

To get rid of the cancellation effects of the large factors $\binom{n}{k}(-1)^k$ in (38), we start by rewriting the sum as an infinite series

$$U_n = \sum_{k\ge 2} \binom{n}{k} (-1)^k \sum_{j\ge 1} \left(\frac{1}{2^{k-1}}\right)^j = \sum_{j\ge 1} (2^j(1 - 2^{-j})^n - 2^j + n). \tag{39}$$

If we set $x = n/2^j$, the summand is

$$2^j(1 - 2^{-j})^n - 2^j + n = \frac{n}{x}\left(\left(1 - \frac{x}{n}\right)^n - 1 + x\right).$$

When $x \le n^\epsilon$, we have

$$\left(1 - \frac{x}{n}\right)^n = \exp\left(n \ln\left(1 - \frac{x}{n}\right)\right) = \exp\left(-x + x^2 O(n^{-1})\right), \tag{40}$$

and this suggests approximating (39) by

$$T_n = \sum_{j\ge 1} (2^j e^{-n/2^j} - 2^j + n). \tag{41}$$

To justify this approximation, we have $U_n - T_n = X_n + Y_n$, where

$$X_n = \sum_{\substack{j\ge 1 \\ 2^j < n^{1-\epsilon}}} (2^j(1 - 2^{-j})^n - 2^j e^{-n/2^j}) \qquad \text{[i.e., the terms for } x > n^\epsilon\text{]}$$

$$= \sum_{\substack{j\ge 1 \\ 2^j < n^{1-\epsilon}}} O(ne^{-n/2^j}) \qquad \text{[since } 0 < 1 - 2^{-j} < e^{-2^{-j}}\text{]}$$

$$= O(n \log n\, e^{-n^\epsilon}) \qquad \text{[since there are } O(\log n) \text{ terms]};$$

and

$$Y_n = \sum_{\substack{j\ge 1\\ 2^j\ge n^{1-\epsilon}}} (2^j(1-2^{-j})^n - 2^j e^{-n/2^j}) \qquad \text{[the terms for } x \le n^{-\epsilon}\text{]}$$

$$= \sum_{\substack{j\ge 1\\ 2^j\ge n^{1-\epsilon}}} \left(e^{-n/2^j}\left(\frac{n}{2^j}\right)O(1)\right) \qquad \text{[by (40)].}$$

Our discussion below will demonstrate that the latter sum is $O(1)$; hence $U_n - T_n = O(1)$. (See exercise 47.)

So far we haven't applied any techniques that are really different from those we have used before; but the study of T_n requires a new idea, based on simple principles of complex variable theory. If x is any positive number, we have

$$e^{-x} = \frac{1}{2\pi i}\int_{1/2-i\infty}^{1/2+i\infty} \Gamma(z)x^{-z}\,dz = \frac{1}{2\pi}\int_{-\infty}^{\infty} \Gamma(\tfrac{1}{2}+it)x^{-(1/2+it)}\,dt. \qquad (42)$$

To prove this identity, consider the path of integration shown in Fig 20(a), where N, N', and M are large. The value of the integral along this contour is the sum of the residues inside, namely,

$$\sum_{0\le k<M} x^{-k} \lim_{z\to -k}(z+k)\Gamma(z) = \sum_{0\le k<M} x^{-k}\frac{(-1)^k}{k!}.$$

The integral on the top line is $O(\int_{-\infty}^{1/2} |\Gamma(t+iN)|x^{-t}\,dt)$, and we have the well-known bound

$$\Gamma(t+iN) = O(N^{t-1/2}e^{-\pi N/2}) \qquad \text{as} \qquad N\to\infty.$$

[For properties of the gamma function see, for example, A. Erdélyi et al., *Higher Transcendental Functions* **1** (New York: McGraw-Hill, 1953), Chapter 1.] Therefore the top line integral is quite negligible, $O(e^{-\pi N/2}\int_{-\infty}^{1/2}(N/x)^t\,dt)$. The bottom line integral has a similar innocuous behavior. For the integral along the left line we use the fact that

$$\Gamma(\tfrac{1}{2}+it-M) = \Gamma(\tfrac{1}{2}+it)/(-M+\tfrac{1}{2}+it)\ldots(-1+\tfrac{1}{2}+it)$$
$$= \Gamma(\tfrac{1}{2}+it)O(1/(M-1)!);$$

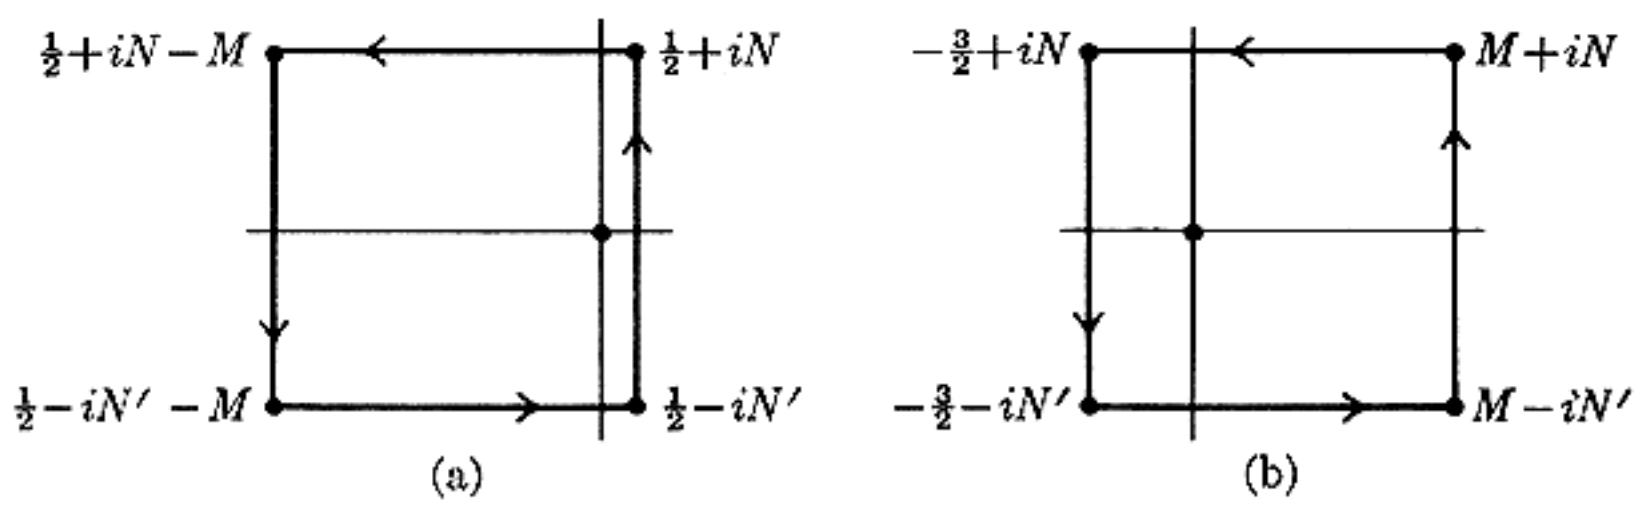

Fig. 20. Contours of integration for gamma-function identities.

hence the left-hand integral is $O(x^{M-1/2}/(M-1)!)\int_{-\infty}^{\infty}|\Gamma(\frac{1}{2}+it)|\,dt$. Therefore as $M, N, N' \to \infty$, only the right-hand integral survives, and this proves (42). In fact, (42) remains valid if we replace "$\frac{1}{2}$" by any positive number.

The same argument can be used to derive many other useful relations involving the gamma function. We can replace x^{-z} by other functions of z; or we can replace the constant $\frac{1}{2}$ by other quantities. For example,

$$\frac{1}{2\pi i}\int_{-3/2-i\infty}^{-3/2+i\infty}\Gamma(z)x^{-z}\,dz = e^{-x} - 1 + x, \tag{43}$$

and this is the critical quantity in our formula (41) for T_n:

$$T_n = n\sum_{j\geq 1}\frac{1}{2\pi i}\int_{-3/2-i\infty}^{-3/2+i\infty}\Gamma(z)(n/2^j)^{-1-z}\,dz. \tag{44}$$

The sum may be placed inside the integrals, since convergence is absolutely well-behaved; we have

$$\sum_{j\leq 1}(n/2^j)^w = n^w\sum_{j\leq 1}(1/2^w)^j = n^w/(2^w-1), \qquad \text{when} \qquad \Re(w) > 0,$$

since $|2^w| = 2^{\Re(w)} > 1$. Therefore

$$T_n = \frac{n}{2\pi i}\int_{-3/2-i\infty}^{-3/2+i\infty}\frac{\Gamma(z)n^{-1-z}}{2^{-1-z}-1}\,dz, \tag{45}$$

and it remains to evaluate the latter integral.

This time we integrate along a path which extends far to the *right*, as in Fig. 20(b). The top line integral is $O(n^{1/2}e^{-\pi M/2}\int_{-3/2}^{M}N^t\,dt)$, if $2^{iN} \neq 1$, and the bottom line integral is equally negligible. The right-hand line integral is $O(n^{-1-M}\int_{-\infty}^{\infty}|\Gamma(M+it)|\,dt)$. Fixing M and letting $N, N' \to \infty$ shows that $-T_n/n$ is $O(n^{-1-M})$ plus the sum of the residues in the region $-3/2 < \mathrm{Re}\,(z) < M$. Let $M \to \infty$; $\Gamma(z)$ has simple poles at $z = -1$ and 0, n^{-1-z} has no poles, and $1/(2^{-1-z}-1)$ has simple poles when $z = -1 + 2\pi ik/\ln 2$.

The double pole at $z = -1$ is the hardest to handle. We can use the well-known relation

$$\Gamma(z+1) = \exp\left(-\gamma z + \zeta(2)z^2/2 - \zeta(3)z^3/3 + \zeta(4)z^4/4 - \cdots\right),$$

where $\zeta(s) = 1^{-s} + 2^{-s} + 3^{-s} + \cdots = H_\infty^{(s)}$,

to deduce the following expansions when $w = z + 1$ is small:

$$\Gamma(z) = \frac{\Gamma(w+1)}{w(w-1)} = -w^{-1} + (\gamma - 1) + O(w),$$

$$n^{-1-z} = 1 - (\ln n)w + O(w^2),$$

$$1/(2^{-1-z}-1) = -w^{-1}/\ln 2 - \tfrac{1}{2} + O(w).$$

The residue at $z = -1$ is the coefficient of w^{-1} in the product of these three formulas, namely $\frac{1}{2} - (\ln n + \gamma - 1)/\ln 2$. Adding the other residues gives the formula

$$T_n/n = \frac{\ln n + \gamma - 1}{\ln 2} - \frac{1}{2} + f(n) + \frac{2}{n}, \tag{46}$$

where $f(n)$ is a rather strange function,

$$f(n) = \frac{2}{\ln 2} \sum_{k \geq 1} \Re\left(\Gamma(-1 - 2\pi ik/\ln 2) \exp\left(2\pi ik \log_2 n\right)\right). \tag{47}$$

Note that $f(n) = f(2n)$. The average value of $f(n)$ is zero, since the average value of each term is zero. (We may assume that $(\log_2 n) \bmod 1$ is uniformly distributed, in view of the results about floating-point numbers in Section 4.2.4.) Furthermore since $|\Gamma(-1 + it)| = |\pi/(t(1 + t^2) \sinh \pi t)|^{1/2}$, it is not difficult to show that

$$f(n) < 0.0000001725;$$

thus we may safely ignore $f(n)$ for practical purposes. For theoretical purposes, however, we can't obtain an asymptotic expansion of U_n without it; that is why U_n is a comparatively difficult function to analyze.

In summary, we have proved that

$$U_n = n \log_2 n + n\left(\frac{\gamma - 1}{\ln 2} - \frac{1}{2} + f(n)\right) + O(1). \tag{48}$$

Other examples of this gamma-function method appear in exercises 51–53 and in Section 6.3.

EXERCISES

1. [*M20*] Let $a_1 \ldots a_n$ be a permutation of $\{1, \ldots, n\}$, and let i and j be indices such that $i < j$ and $a_i > a_j$. Let $a'_1 \ldots a'_n$ be the permutation obtained from $a_1 \ldots a_n$ by interchanging a_i and a_j. Can $a'_1 \ldots a'_n$ have more inversions than $a_1 \ldots a_n$?

▶ **2.** [*M25*] (a) What is the minimum number of exchanges which will sort the permutation 3 7 6 9 8 1 4 5 2? (b) In general, given any permutation $\pi = a_1 \ldots a_n$ of $\{1, \ldots, n\}$, let xch (π) be the minimum number of exchanges which will sort π into increasing order. Express xch (π) in terms of "simpler" characteristics of π. (Cf. exercise 5.2.1–39.)

3. [*10*] Is the bubble sort Algorithm B a "stable" sorting algorithm?

4. [*M23*] If $t = 1$ in step B4, we could actually terminate Algorithm B immediately, because the subsequent step B2 will do nothing useful. What is the probability that $t = 1$ will occur in step B4 when sorting a random permutation?

5. [*M25*] Let $b_1\, b_2 \ldots b_n$ be the inversion table for the permutation $a_1\, a_2 \ldots a_n$. Show that the value of BOUND after r passes of the bubble sort is $\max \{b_i + i \mid b_i \geq r\} - r$, for $0 \leq r \leq \max (b_1, \ldots, b_n)$.

6. [*M22*] Let $a_1 \ldots a_n$ be a permutation of $\{1, \ldots, n\}$ and let $a'_1 \ldots a'_n$ be its inverse. Show that the number of passes to bubble-sort $a_1 \ldots a_n$ is $1 + \max(a'_1 - 1, a'_2 - 2, \ldots, a'_n - n)$.

7. [*M28*] Calculate the standard deviation of the number of passes for the bubble sort, and express it in terms of n and the function $P(n)$. [Cf. Eqs. (6) and (7).]

8. [*M24*] Derive Eq. (8).

9. [*M48*] Analyze the number of passes and the number of comparisons in the cocktail-shaker shorting [shic] algorithm. *Note:* See exercise 5.4.8–9 for partial information.

10. [*M26*] Let $a_1\, a_2 \ldots a_n$ be a 2-ordered permutation of $\{1, 2, \ldots, n\}$. (a) What are the coordinates of the endpoints of the a_i-th step of the corresponding lattice path? (Cf. Fig. 11.) (b) Prove that comparison/exchange of $a_1{:}a_2$, $a_3{:}a_4$, ..., corresponds to folding the path about the diagonal, as in Fig. 18(b). (c) Prove that comparison/exchange of $a_2{:}a_{2+d}$, $a_4{:}a_{4+d}$, ..., corresponds to folding the path about a line m units below the diagonal, as in Figs. 18(c), (d), and (e), when $d = 2m - 1$.

▸ **11.** [*M25*] What permutation of $\{1, 2, \ldots, 16\}$ maximizes the number of exchanges done by Batcher's algorithm?

12. [*24*] Write a MIX program for Algorithm M, assuming that MIX is a binary computer with the operations AND, SRB. How much time does your program take to sort the sixteen records in Table 1?

13. [*10*] Is Batcher's method a "stable" sorting algorithm?

14. [*M21*] Let $c(N)$ be the number of key comparisons used to sort N elements by Batcher's method; this is the number of times step M4 is performed. (a) Show that $c(2^t) = 2c(2^{t-1}) + (t-1)2^{t-1} + 1$, for $t \geq 1$. (b) Find a simple expression for $c(2^t)$ as a function of t. *Hint:* Consider the sequence $x_t = c(2^t)/2^t$.

15. [*M38*] The object of this exercise is to analyze the function $c(N)$ of exercise 13, and to find a formula for $c(N)$ when $N = 2^{e_1} + 2^{e_2} + \cdots + 2^{e_r}$, $e_1 > e_2 > \cdots > e_r \geq 0$. (a) Let $a(N) = c(N+1) - c(N)$. Prove that $a(2n) = a(n) + \lfloor \log_2 (2n) \rfloor$, and $a(2n+1) = a(n) + 1$; hence

$$a(N) = \binom{e_1 + 1}{2} - r(e_1 - 1) + (e_1 + e_2 + \cdots + e_r).$$

(b) Let $x(n) = a(n) - a(\lfloor n/2 \rfloor)$, so that $a(n) = x(n) + x(\lfloor n/2 \rfloor) + x(\lfloor n/4 \rfloor) + \cdots$. Let $y(n) = x(1) + x(2) + \cdots + x(n)$; and let $z(2n) = y(2n) - a(n)$, $z(2n+1) = y(2n+1)$. Prove that $c(N+1) = z(N) + 2z(\lfloor N/2 \rfloor) + 4z(\lfloor N/4 \rfloor) + \cdots$. (c) Prove that $y(N) = N + (\lfloor N/2 \rfloor + 1)(e_1 - 1) - 2^{e_1} + 2$. (d) Now put everything together and find a formula for $c(N)$ in terms of the exponents e_j, holding r fixed.

16. [*HM46*] Find the asymptotic value of the *average* number of exchanges occurring when Batcher's method is applied to $N = 2^t$ distinct elements, randomly ordered.

▸ **17.** [*20*] Where in Algorithm Q do we use the fact that K_0 and K_{N+1} have the values postulated in (13)?

▸ **18.** [*20*] Explain how the computation proceeds in Algorithm Q when all of the input keys are equal. What would happen if the "$<$" signs in steps Q3 and Q5 were changed to "$\leq$" instead?

19. [*15*] Would Algorithm Q still work properly if a queue (first-in-first-out) were used instead of a stack (last-in-first-out)?

20. [*M20*] What is the largest possible number of elements that will ever be on the stack at once in Algorithm Q, as a function of M and N?

21. [*20*] Explain why the partitioning phase of Algorithm Q takes the number of comparisons, transfers, etc., specified in (17).

22. [*M25*] Let p_{kN} be the probability that the quantity A in (14) will equal k, when Algorithm Q is applied to a random permutation of $\{1, 2, \ldots, N\}$, and let $A_N(z) = \sum_k p_{kN} z^k$ be the corresponding generating function. Prove that $A_N(z) = 1$ for $N \leq M$, and $A_N(z) = z\bigl(\sum_{1\leq s\leq N} A_{s-1}(z) A_{N-s}(z)\bigr)/N$ for $N > M$. Find similar recurrence relations defining the other probability distributions $B_N(z)$, $C_N(z)$, $D_N(z)$, $E_N(z)$, $L_N(z)$, $X_N(z)$.

23. [*M24*] Let A_N, B_N, D_N, E_N, L_N, X_N be the average values of the corresponding quantities in (14), when sorting a random permutation of $\{1, 2, \ldots, N\}$. Find recurrence relations for these quantities, analogous to (18); and solve these recurrences to obtain (25).

24. [*M21*] Algorithm Q obviously does a few more comparisons than it needs to, since we can have $i = j$ and even $i > j$ in steps Q3 and Q5. How many comparisons C_N would be done on the average if we avoided all comparisons when $i \geq j$?

25. [*M20*] When the input keys are the numbers $1\ 2 \ldots N$ in order, what are the exact values of the quantities A, B, C, D, E, L, and X in the timing of Program Q? (Assume that $N > M$.)

▸ **26.** [*M21*] Construct an input file which makes Program Q go even more slowly than it does in exercise 25. (Try to find a really bad case.)

27. [*M23*] What input leads to the *best* case of Algorithm Q? Give approximate values of A, B, C, D, E, X in this case.

28. [*M26*] Find the recurrence relation analogous to (20) which is satisfied by the average number of comparisons in Singleton's modification of Algorithm Q (choosing s as the median of $\{K_1, K_{\lfloor (N+1)/2 \rfloor}, K_N\}$ instead of $s = K_1$).

29. [*HM40*] Find the asymptotic value of the number of comparisons in Singleton's "median of three" method (cf. exercise 28).

30. [*25*] (P. Shackleton.) When *multiword keys* are being sorted, many sorting methods become progressively slower as the file gets closer to its final order, since equal and nearly-equal keys require an inspection of several words to determine the proper lexicographic order. (See exercise 5–5.) Files which arise in practice often involve nearly-equal keys, so this phenomenon can have a significant impact on the sorting time. Algorithm Q has this difficulty; Algorithm R does not, since it inspects only one bit each time (although the presence of equal and nearly-equal keys can greatly increase the running time of Algorithm R for other reasons).

Explain how Algorithm Q can be extended to avoid this difficulty; within a subfile in which the leading k words are known to have constant values for all keys, only the $(k + 1)$st words of the keys should be inspected.

▸ **31.** [*20*] (C. A. R. Hoare.) Suppose that, instead of sorting an entire file, we only want to determine the mth smallest of a given set of n elements. Show that "quicksort" can be adapted to this purpose, avoiding many of the computations required to do a complete sort.

32. [*M40*] Find a simple "closed form" expression for C_{nm}, the average number of key comparisons required to find the mth smallest of n elements by the method of

exercise 31. (For simplicity, avoid all comparisons with $i \geq j$ as in exercise 24.) What is the asymptotic behavior of $C_{(2m-1)m}$, the average number of comparisons needed to find the median of $2m - 1$ elements by Hoare's method?

▶ **33.** [*20*] Design an algorithm which rearranges all the numbers in a given table so that all *negative* values precede all positive ones. (The items need not be sorted completely, just separated between negative and nonnegative.) Your algorithm should use the minimum possible number of exchanges.

34. [*20*] How can the bit-inspection loops of radix exchange (in steps R3 through R6) be speeded up?

35. [*M23*] Analyze the values of the frequencies A, B, C, G, K, L, R, S, and X which arise in radix exchange sorting using "case (i) input."

36. [*M27*] Given a sequence of numbers $\langle a_n \rangle = a_0, a_1, a_2, \ldots$, define its *binomial transform* $\langle \hat{a}_n \rangle = \hat{a}_0, \hat{a}_1, \hat{a}_2, \ldots$ by the rule

$$\hat{a}_n = \sum_k \binom{n}{k} (-1)^k a_k.$$

(a) Prove that $\langle \hat{\hat{a}}_n \rangle = \langle a_n \rangle$. (b) Find the binomial transform of the sequences $\langle 1 \rangle$; $\langle n \rangle$; $\langle \binom{n}{m} \rangle$, for fixed m; $\langle a^n \rangle$, for fixed a; $\langle \binom{n}{m} a^n \rangle$, for fixed a and m. (c) Given that a sequence $\langle x_n \rangle$ satisfies the relation

$$x_n = a_n + 2^{1-n} \sum_{k \geq 2} \binom{n}{k} x_k, \qquad \text{for} \qquad n \geq 2; \qquad x_0 = x_1 = a_0 = a_1 = 0;$$

prove that

$$x_n = \sum_{k \geq 2} \binom{n}{k} (-1)^k \frac{2^{k-1} \hat{a}_k}{2^{k-1} - 1} = a_n + \sum_{k \geq 2} \binom{n}{k} (-1)^k \frac{\hat{a}_k}{2^{k-1} - 1}.$$

37. [*M28*] Determine all sequences $\langle a_n \rangle$ such that $\langle \hat{a}_n \rangle = \langle a_n \rangle$, in the sense of exercise 36.

▶ **38.** [*M30*] Find A_N, B_N, C_N, G_N, K_N, L_N, R_N, and X_N, the average values of the quantities in (29) when radix exchange is applied to "case (ii) input." Express your answers in terms of N and the functions

$$U_n = \sum_{k \geq 2} \binom{n}{k} \frac{(-1)^k}{2^{k-1} - 1} \qquad V_n = \sum_{k \geq 2} \binom{n}{k} \frac{(-1)^k k}{2^{k-1} - 1} = n(U_n - U_{n-1}).$$

[*Hint:* See exercise 36.]

39. [*20*] The results shown in (30) indicate that radix exchange takes about $1.44N$ stages when it is applied to random input. Prove that quicksort will never require more than N stages; and explain why radix exchange often does.

40. [*21*] Explain how to modify Algorithm R so that it works with reasonable efficiency when sorting files containing numerous equal keys.

41. [*23*] Formulate van Emden's "interval exchange sort," obtaining a precise description of an algorithm.

42. [*M43*] Analyze the interval exchange algorithm of exercise 41.

43. [*HM21*] Prove that $\int_0^1 y^{-1}(e^{-y} - 1)\,dy + \int_1^\infty y^{-1}e^{-y}\,dy = -\gamma$. [*Hint:* Consider $\lim_{a\to 0+} y^{a-1}$.]

44. [*HM24*] Derive (37) as suggested in the text.

45. [*HM20*] Explain why (43) is true, when $x > 0$.

46. [*HM20*] What is the value of $(1/2\pi i)\int_{a+i\infty}^{a+i\infty} \Gamma(z)n^{s-z}\,dz/(2^{s-z} - 1)$, given that s is a positive integer and $0 < a < s$?

47. [*HM21*] Prove that $\sum_{j\geq 1} (n/2^j)e^{-n/2^j}$ is a bounded function of n.

48. [*HM24*] Find the asymptotic value of the quantity V_n defined in exercise 38, using a method analogous to the text's study of U_n, obtaining terms up to $O(1)$.

49. [*HM24*] Extend the asymptotic formula (47) for U_n to $O(n^{-1})$.

50. [*HM24*] Find the asymptotic value of the function

$$U_{mn} = \sum_{k\geq 2} \binom{n}{k} (-1)^k \frac{1}{m^{k-1} - 1},$$

when m is any fixed number greater than 1. (When m is an integer greater than 2, this quantity arises in the study of generalizations of radix exchange, as well as the "trie memory" search algorithms of Section 6.3.)

▸ **51.** [*HM28*] Show that the gamma-function approach to asymptotic problems can be used instead of Euler's summation formula to derive the asymptotic expansion of $r_k(m)$. (Cf. Eq. 35). This gives us a uniform method for studying $r_k(m)$ for all k, without relying on "tricks" such as the text's introduction of $g_{-1}(x) = (e^{-x^2} - 1)/x$.)

52. [*HM35*] (N. G. de Bruijn.) What is the asymptotic behavior of the sum

$$S_n = \sum_{t\geq 1} \left(\frac{2n}{n+t}\right) d(t),$$

where $d(t)$ is the number of divisors of t? (Thus, $d(1) = 1$, $d(2) = d(3) = 2$, $d(4) = 3$, $d(5) = 2$, etc. This question arises in connection with the analysis of a tree traversal algorithm, exercise 2.3.1–11.) Find the value of $S_n/\binom{2n}{n}$ to terms of $O(n^{-1})$.

53. [*HM42*] Analyze the average number of bit inspections and exchanges done by radix exchange when the input data consists of infinite-precision binary numbers in [0, 1), each of whose bits is independently equal to 1 with probability p. (Only the case $p = \frac{1}{2}$ is discussed in the text; the methods we have used can be generalized to arbitrary p.) Consider in particular the case $p = 1/\phi = .61803\ldots$.

54. [*HM24*] (S. O. Rice.) Show that U_n can be written

$$U_n = (-1)^n \frac{n!}{2\pi i} \oint_C \frac{dz}{z(z-1)\ldots(z-n)} \frac{1}{2^{z-1} - 1},$$

where C is a skinny closed curve encircling the points $2, 3, \ldots, n$. Changing C to an arbitrarily large circle centered at the origin, derive the convergent series

$$U_n = n(H_{n-1} - 1)/(\ln 2) - \tfrac{1}{2}n + 2 + \frac{2}{\ln 2} \sum_{m\geq 1} \Re\,(B(n+1, -1 + ibm)),$$

where $b = 2\pi/(\ln 2)$, and $B(n+1, -1+ibm) = \Gamma(n+1)\Gamma(-1+ibm)/\Gamma(n+ibm) = n!/\Pi_{0\leq k\leq n}(k - 1 + ibm)$.

▸ **55.** [*22*] Show how Program Q should be modified so that the partitioning element is the median of the three keys (28).

56. [*M44*] Analyze the average behavior of the quantities which occur in the running time of Algorithm Q when the program has been modified to take the median of three elements as in exercise 55. [Cf. exercise 29.]

▸ **57.** [*HM24*] Find the asymptotic value of the number of right-to-left maxima occurring in multiple list insertion, Eq. 5.2.1–11, when $M = N/\alpha$, for fixed α as $N \to \infty$. Carry out the expansion to terms of $O(N^{-1})$, expressing your answer in terms of the "exponential integral" function $E_1(z) = \int_z^\infty e^{-t}\, dt/t$.

5.2.3. Sorting by Selection

Another important family of sorting techniques is based on the idea of repeated selection. The simplest selection method is perhaps the following:

i) Find the smallest key; transfer the corresponding record to the output area; then replace the key by the value "∞" (which is assumed to be higher than any actual key).
ii) Repeat step (i). This time the second smallest key will be selected, since the smallest key has been replaced by ∞.
iii) Continue repeating step (i) until N records have been selected.

Note that such a selection method requires all the input items to be present before sorting may proceed, and it generates the final outputs one by one in sequence. This is essentially the opposite of insertion, where the inputs are received sequentially but we do not know any of the final outputs until sorting is completed.

Some computers (e.g., those with a cyclic drum memory) have a built-in "find the smallest" instruction which operates at high speed. This makes selection sorting by the above method especially attractive when N is not too large.

The above method involves $N - 1$ comparisons each time a new record is selected, and it also requires a separate output area in memory. There is an obvious way to improve upon the situation, avoiding the use of ∞: We can take the selected value and move it into its proper position by exchanging it with the record currently occupying that position. Then we need not consider that position again in future selections. This idea yields our first selection sorting algorithm.

Algorithm S (*Straight selection sort*). Records $R_1, \ldots, R_N$ are rearranged in place; after sorting is complete, their keys will be in order, $K_1 \le \cdots \le K_N$. Sorting is based on the method indicated above, except that it proves to be more convenient to select the *largest* element first, then the second largest, etc.

S1. [Loop on j.] Perform steps S2 and S3 for $j = N, N - 1, \ldots, 2$.

S2. [Find max $(K_1, \ldots, K_j)$.] Search through keys $K_j, K_{j-1}, \ldots, K_1$ to find a maximal one; let it be K_i.

S3. [Exchange with R_j.] Interchange records $R_i \leftrightarrow R_j$. (Now records $R_j, \ldots, R_N$ are in their final position.) ∎

Table 1 shows this algorithm in action on our sixteen example keys; elements which are candidates for the maximum during the search in step S2 are shown in boldface type.

Table 1

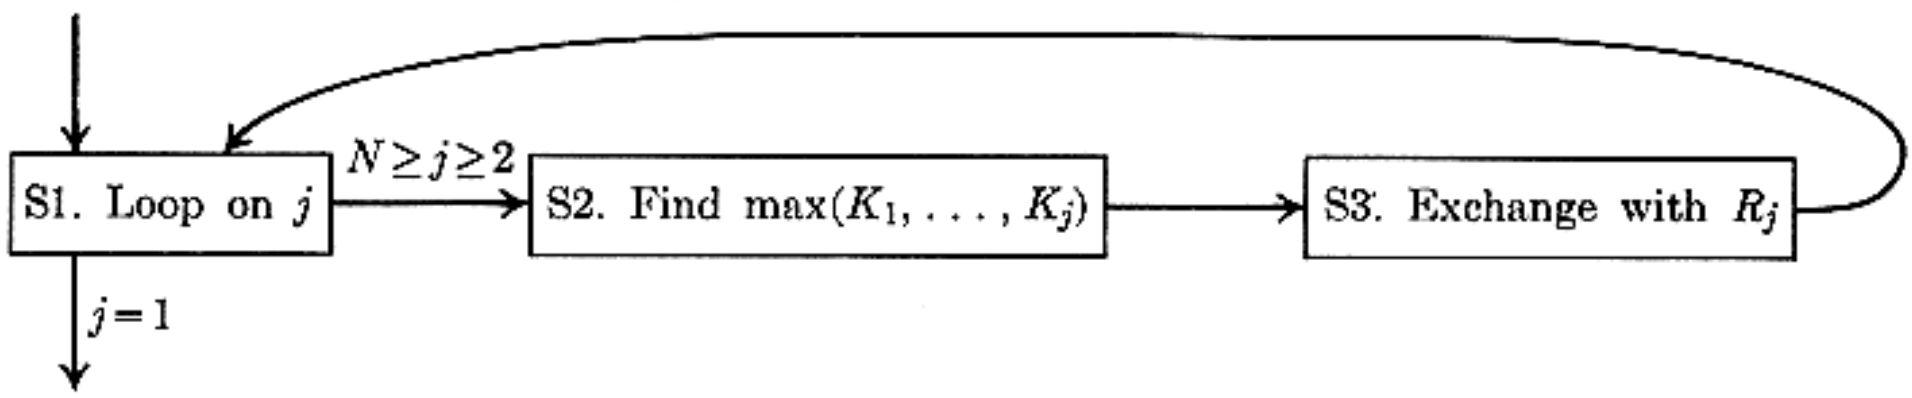

Fig. 21. Straight selection sorting.

The corresponding MIX program is quite simple:

Program 5.2.3S (*Straight selection sort*). As in previous programs of this chapter, the records in locations INPUT+1 through INPUT+N are sorted in place, on a full-word key. rA ≡ current maximum, rI1 ≡ $j - 1$, rI2 ≡ k (index for searching), rI3 ≡ i. Assume that $N \geq 2$.

```
01     START  ENT1  N-1          1        S1. Loop on j. j ← N.
02     2H     ENT2  0,1          N - 1    S2. Find max (K_1, ..., K_j). k ← j - 1.
03            ENT3  1,1          N - 1    i ← j.
04            LDA   INPUT,3      N - 1    rA ← K_i.
05     8H     CMPA  INPUT,2      A
06            JGE   *+3          A        Jump if K_i ≥ K_k.
07            ENT3  0,2          B        Otherwise set i ← k,
08            LDA   INPUT,3      B        rA ← K_i.
09            DEC2  1            A        k ← k - 1.
10            J2P   8B           A        Repeat if k > 0.
11            LDX   INPUT+1,1    N - 1    S3. Exchange with R_j.
12            STX   INPUT,3      N - 1    R_i ← R_j.
13            STA   INPUT+1,1    N - 1    R_j ← rA.
14            DEC1  1            N - 1
15            J1P   2B           N - 1    N ≥ j ≥ 2. ∎
```

The running time of this program depends on the number of items; N; the number of comparisons, A; and the number of "right-to-left maxima," B. It is easy to see that

$$A = \binom{N}{2} = \frac{1}{2}N(N-1), \tag{1}$$

regardless of the values of the input keys; hence only B is variable. In spite of the simplicity of straight selection, this quantity B is not easy to analyze precisely. Exercises 3 through 6 show that

$$B = (\min 0,\ \text{ave}\ (N+1)H_N - 2N,\ \max \lfloor N^2/4 \rfloor); \tag{2}$$

in this case the maximum value turns out to be particularly interesting. (The standard deviation of B has not yet been determined.)

Thus the average running time of Program S is $2.5N^2 + 3(N+1)H_N + 3.5N - 11$ units, just slightly slower than straight insertion (Program 5.2.1S). It is interesting to compare Algorithm S to the bubble sort (Algorithm 5.2.2B), since bubble sorting may be regarded as a selection algorithm which sometimes selects more than one element at a time. For this reason bubble sorting usually does less comparisons than straight selection and it may seem to be preferable; but in fact Program 5.2.2B is more than twice as slow as Program S! Bubble sorting is handicapped by the fact that it does so many exchanges, while straight selection involves very little data movement.

Refinements of straight selection. Is there any way to improve on the selection method used in Algorithm S? For example, take the search for a maximum in step S2; is there a substantially faster way to find a maximum? The answer to the latter question is *no*!

Lemma M. *Every algorithm for finding the maximum of n elements, based on comparing pairs of elements, must make at least $n - 1$ comparisons.*

Proof. If we have made less than $n - 1$ comparisons, there will be at least two elements which have never been found to be less than any others. Therefore we will not know which of these two elements is larger, and we cannot have determined the maximum. ∎

Thus a selection process which finds the largest element must take at least $n - 1$ steps; perhaps all sorting methods based on n repeated selections are doomed to require order n^2 steps? Fortunately Lemma M applies only to the *first* selection step; subsequent selections can make use of previously-gained information. For example, exercise 8 shows that a comparatively simple change to Algorithm S cuts the average number of comparisons in half.

Consider the 16 numbers in Table 1; one way to save time on repeated selections is to regard them as four groups of four. We can start by determining the largest of each group, namely the respective keys

512, 908, 653, 765;

the largest of these four elements, 908, is then the largest of the entire file. To get the second largest we need only look at the other three elements of the group containing 908; the largest of {170, 897, 275} is 897, and the largest of

512, 897, 653, 765

is 897. Similarly to get the third largest element we determine the largest of {170, 275} and then the largest of

512, 275, 653, 765,

and so on. Each selection after the first takes at most 6 additional comparisons. In general, if N is a perfect square, we can divide the file into $\sqrt{N}$ groups of $\sqrt{N}$ elements each; each selection after the first takes at most $\sqrt{N} - 1$ comparisons within the group of the previously selected item, plus $\sqrt{N} - 1$ comparisons among the "group-leaders." This idea is called *quadratic selection*; its total execution time is $O(N\sqrt{N})$, which is substantially better than order N^2.

Quadratic selection was first published by E. H. Friend [*JACM* **3** (1956), 152–154], who pointed out that the same idea can be generalized to cubic, quartic, etc. selection. For example, cubic selection divides the file into $\sqrt[3]{N}$ large groups, each containing $\sqrt[3]{N}$ small groups, each containing $\sqrt[3]{N}$ records; the execution time is proportional to $N\sqrt[3]{N}$. If we carry this idea to its ultimate conclusion we arrive at what Friend called "nth degree selecting," based on a binary tree structure. This method has an execution time proportional to $N \log N$; we shall call it *tree selection*.

Tree selection. The principles of tree selection sorting are easy to understand in terms of matches in a typical "knock-out tournament." Consider, for example, the results of the ping-pong contest shown in Fig. 22; Jim beats Don and Joe beats Jack, then in the next round Joe beats Jim, etc.

Figure 22 shows that Joe is the champion of the eight players, and $8 - 1 = 7$ matches (i.e., comparisons) were required to determine this fact. Dick is not necessarily the second-best player; any of the people defeated by Joe, including the first-round loser Jack, might possibly be second best. We can determine the second-best player by having Jack play Jim, and the winner of that match plays Dick; only two additional matches are required to find the second-best man, because of the structure we have remembered from the earlier games.

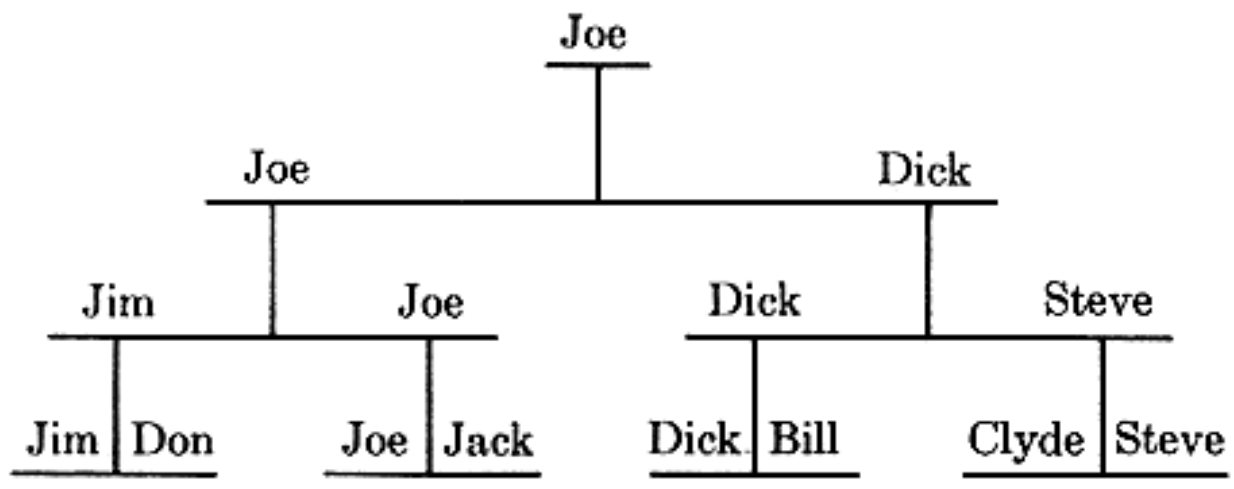

Fig. 22. A ping-pong tournament.

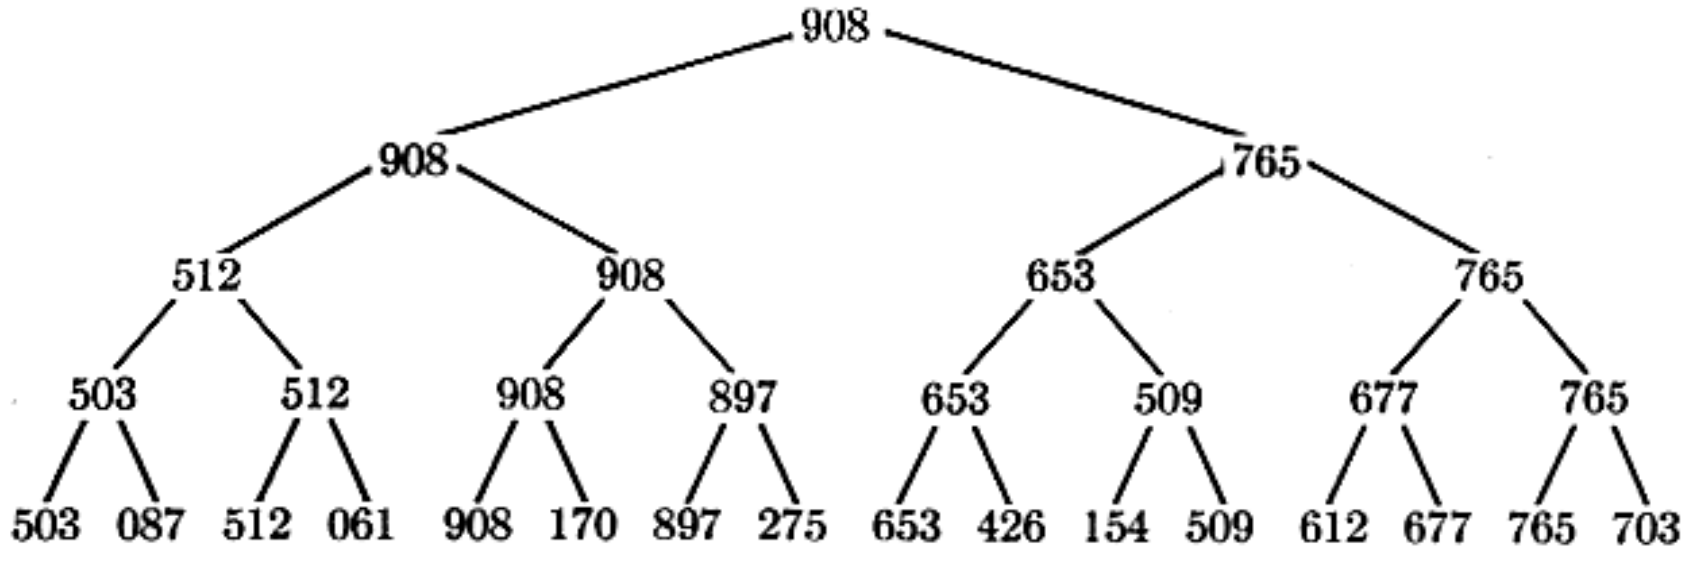
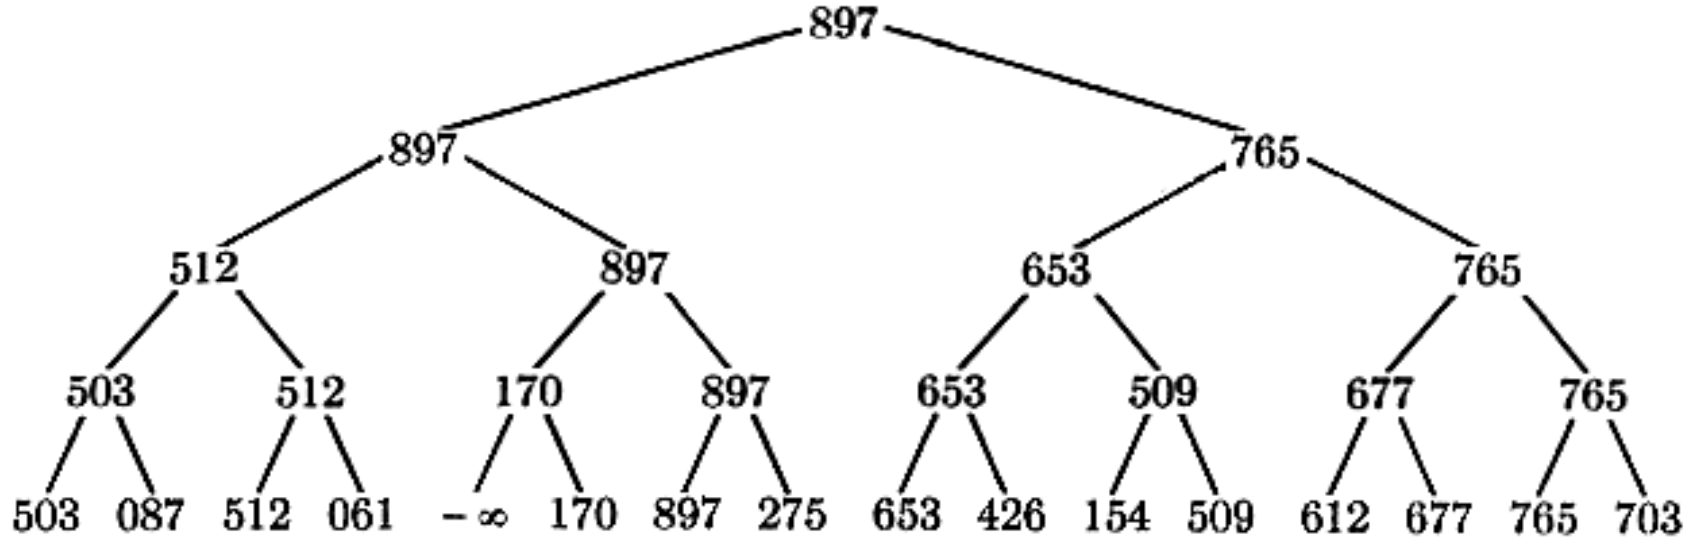
In general, we can "output" the player at the root of the tree, and replace him by an extremely weak player. Substituting this weak player means that the original second-best player will now be best, so he will appear at the root if we recalculate the winners in upper levels of the tree. For this purpose only one path in the tree must be changed, so that less than $\lceil \log_2 N \rceil$ further comparisons are needed to select the next-best player. The total time for such a selection sort is roughly proportional to $N \log N$.

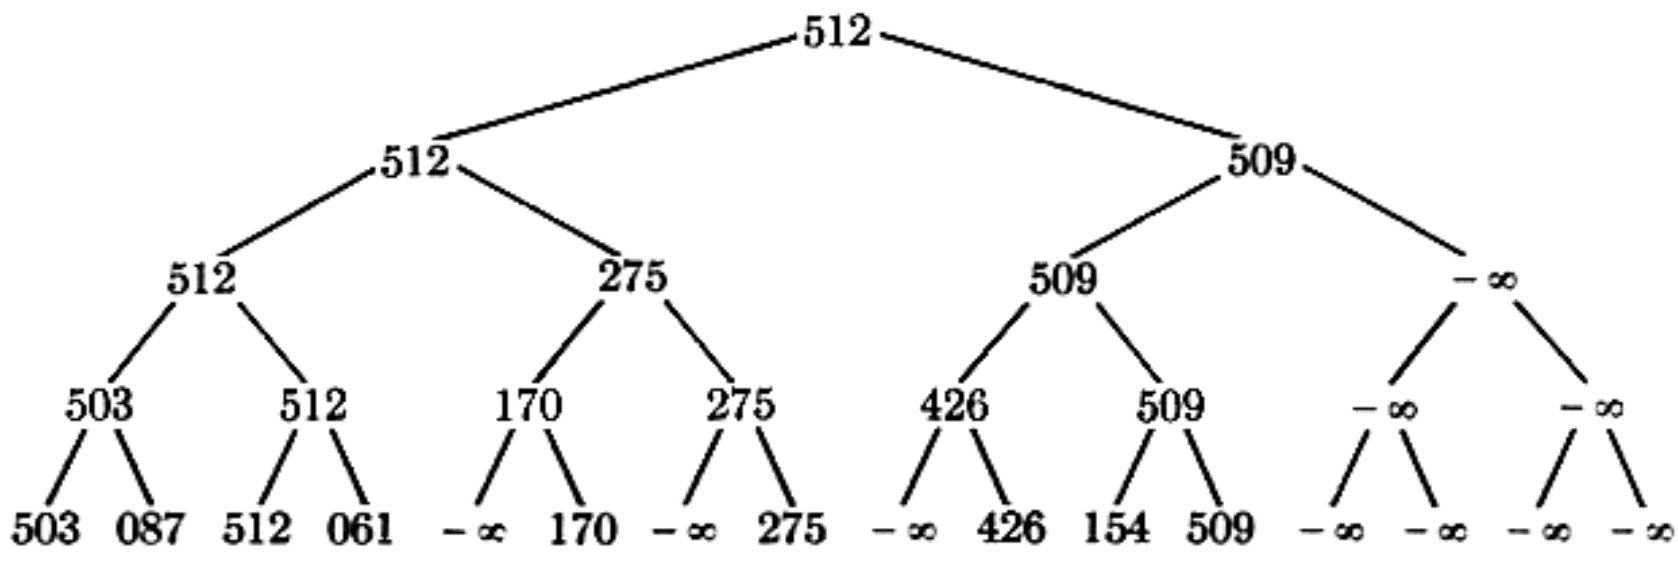
Figure 23 shows tree selection sorting in action, on our 16 example numbers. Note that it is necessary to know where the key at the root came from, in order to know where to insert the next "$-\infty$". Therefore the branch nodes



(a) Initial configuration.



(b) 908 is replaced by $-\infty$, and the second highest element moves up to the root.



(c) Configuration after 908, 897, 765, 703, 677, 653, 612 have been output.

Fig. 23. An example of tree selection sorting.

of the tree actually contain a pointer or index specifying the position of the relevant key, instead of the key itself. It follows that we need memory space for N input records, $N - 1$ pointer words, and N output records. (If the output goes to tape or disk, of course, we don't need to retain the output records in high-speed memory.)

The reader should pause at this point until he understands tree selection, in order to appreciate the remarkable improvements we are about to discuss. For example, it should now be easy to work exercise 10.

One way to modify tree selection, essentially introduced by K. E. Iverson [*A Programming Language*, (Wiley, 1962), 223–227], does away with the need for pointers by "looking ahead" in the following way: When the winner of a match in the bottom level of the tree is moved up, he can be replaced immediately by "$-\infty$" at the bottom level; and when a winner moves up from one branch to another, we can replace him by the one which eventually should move up into his former place (namely the larger of the two keys below). Repeating this operation as often as possible converts Fig. 23(a) into Fig. 24.

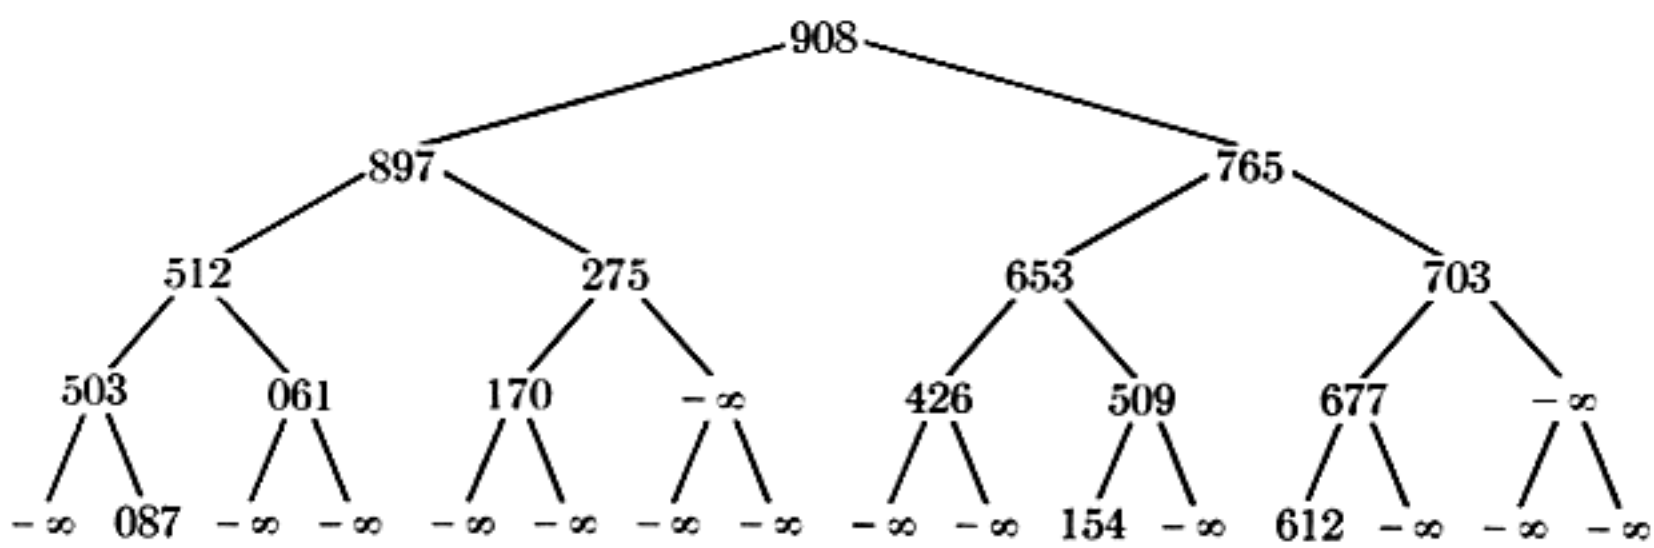


Fig. 24. The Peter Principle applied to sorting. Everyone rises to his level of incompetence in the hierarchy.

Once the tree has been set up in this way we can proceed to sort by a "top-down" method, instead of the "bottom up" method of Fig. 23; we output the root, move up his largest descendant, move up the latter's largest descendant, etc. The process begins to look less like a ping-pong tournament and more like a corporate system of promotions.

The reader should be able to see that this top-down method has the advantage that redundant comparisons of $-\infty$ with $-\infty$ can be avoided. (The bottom-up approach finds $-\infty$ omnipresent in the latter stages of sorting, but the top-down approach can stop modifying the tree during each stage as soon as a $-\infty$ has been stored.)

Figures 23 and 24 are *complete binary trees* with 16 terminal nodes (cf. Section 2.3.4.5), and it is convenient to represent such a tree in consecutive locations as shown in Fig. 25. Note that the father of node number k is node $\lfloor k/2 \rfloor$, and its sons are nodes $2k$ and $2k + 1$. This leads to another advantage of the top-down approach, since it is often considerably simpler to go top-down from node k

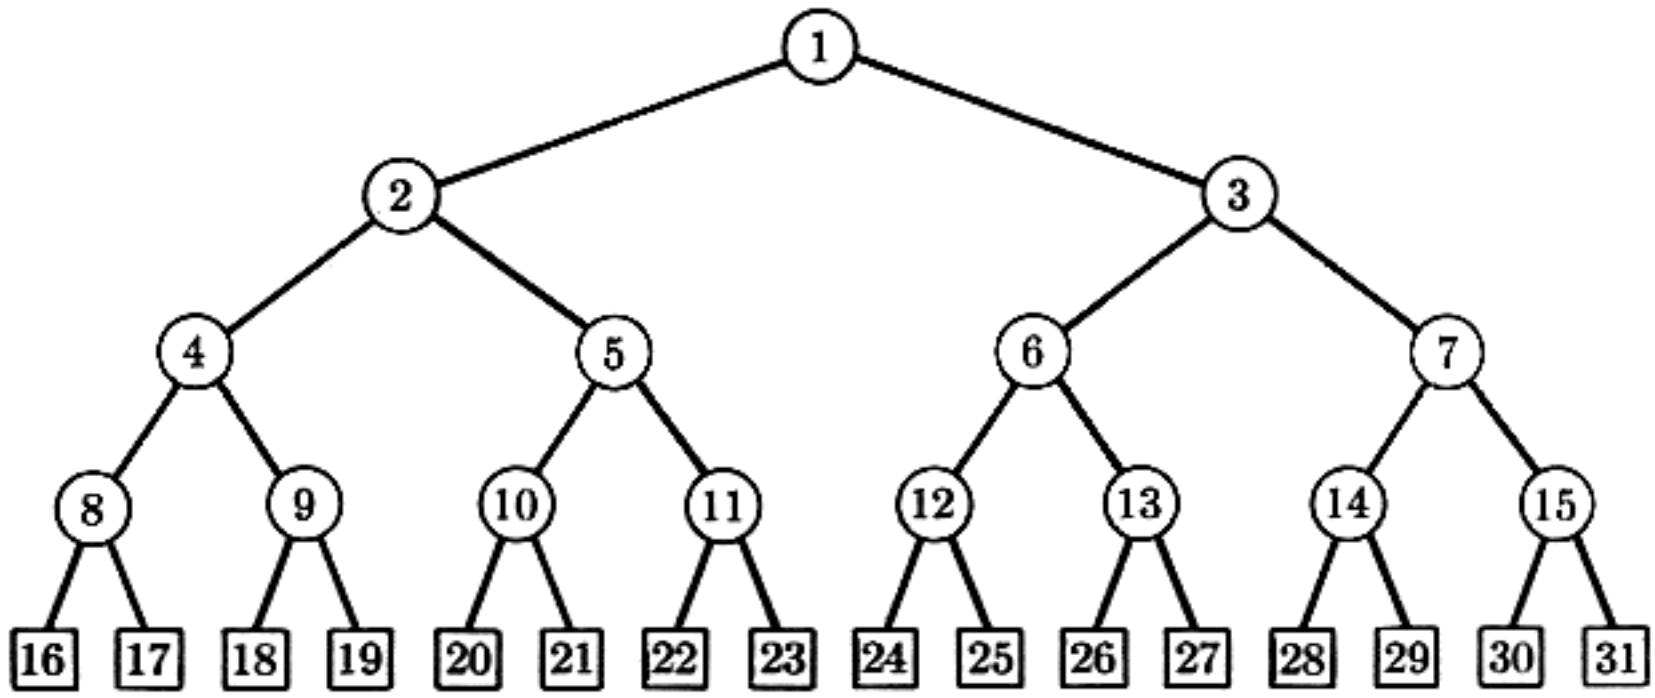

Fig. 25. Sequential storage allocation for a complete binary tree.

to nodes $2k$ and $2k+1$ than bottom-up from node k to nodes $k \oplus 1$ and $\lfloor k/2 \rfloor$. (Here $k \oplus 1$ stands for $k+1$ or $k-1$, according as k is even or odd.)

Our examples of tree selection so far have more or less assumed that N is a power of 2; but actually we can work with arbitrary N, since the complete binary tree with N terminal nodes is readily constructed for any N.

Now we come to the crucial question: Can't we do the top-down method without using "$-\infty$" at all? Wouldn't it be nice if the important information of Fig. 24 were all in locations 1 through 16 of the complete binary tree, without the useless "holes" containing $-\infty$? Some reflection shows that it is indeed possible to achieve this goal, not only eliminating $-\infty$ but also making it possible to sort N records in place without an auxiliary output area. This brings us to an important sorting algorithm which was christened "heapsort" by its discoverer J. W. J. Williams [*CACM* **7** (1964), 347–348].

Heapsort. Let us say that a file of keys $K_1, K_2, \ldots, K_N$ is a "heap" if

$$K_{\lfloor j/2 \rfloor} \geq K_j \qquad \text{for} \qquad 1 \leq \lfloor j/2 \rfloor < j \leq N. \tag{3}$$

Thus, $K_1 \geq K_2$, $K_1 \geq K_3$, $K_2 \geq K_4$, etc.; this is exactly the condition which holds in Fig. 24, and it implies in particular that the largest key appears "on top of the heap,"

$$K_1 = \max(K_1, K_2, \ldots, K_N). \tag{4}$$

If we can somehow transform an arbitrary input file into a heap, we can use a "top-down" selection procedure like that described above to obtain an efficient sorting algorithm.

An efficient approach to heap creation has been suggested by R. W. Floyd [*CACM* **7** (1964), 701]. Let us assume that we have been able to arrange the file so that

$$K_{\lfloor j/2 \rfloor} \geq K_j \qquad \text{for} \qquad l < \lfloor j/2 \rfloor < j \leq N, \tag{5}$$

where l is some number ≥ 1. (In the original file this condition holds "vacu-

ously" for $l = \lfloor N/2 \rfloor$, since no subscript j satisfies the condition $\lfloor N/2 \rfloor < \lfloor j/2 \rfloor < j \leq N$.) It is not difficult to see how to transform the file so that the inequalities in (5) are extended to the case $\lfloor j/2 \rfloor = l$, working entirely in the subtree whose root is node l. Therefore we can decrease l by 1, until condition (3) is finally achieved. These ideas of Williams and Floyd lead to the following elegant algorithm which merits careful study:

Algorithm H (*Heapsort*). Records $R_1, \ldots, R_N$ are rearranged in place; after sorting is complete, their keys will be in order, $K_1 \leq \cdots \leq K_N$. First we rearrange the file so that it forms a heap, then we repeatedly remove the top of the heap and transfer it to its proper final position. Assume that N ≥ 2.

H1. [Initialize.] Set $l \leftarrow \lfloor N/2 \rfloor + 1$, $r \leftarrow N$.

H2. [Decrease l or r.] If $l > 1$, set $l \leftarrow l - 1$, $R \leftarrow R_l$, $K \leftarrow K_l$. (If $l > 1$, we are in the process of transforming the input file into a heap; on the other hand if $l = 1$, the keys $K_1 K_2 \ldots K_r$ presently constitute a heap.) Otherwise set $R \leftarrow R_r$, $K \leftarrow K_r$, $R_r \leftarrow R_1$, and $r \leftarrow r - 1$; if this makes $r = 1$, set $R_1 \leftarrow R$ and terminate the algorithm.

H3. [Prepare for "sift-up."] Set $j \leftarrow l$. (At this point we have

$$K_{\lfloor j/2 \rfloor} \geq K_j \qquad \text{for} \qquad l < \lfloor j/2 \rfloor < j \leq r; \tag{6}$$

and record R_k is in its final position for $r < k \leq N$. Steps H3–H8 are called the "sift-up" algorithm; their effect is equivalent to setting $R_l \leftarrow R$ and then rearranging $R_l, \ldots, R_r$ so that condition (6) holds also for $\lfloor j/2 \rfloor = l$.)

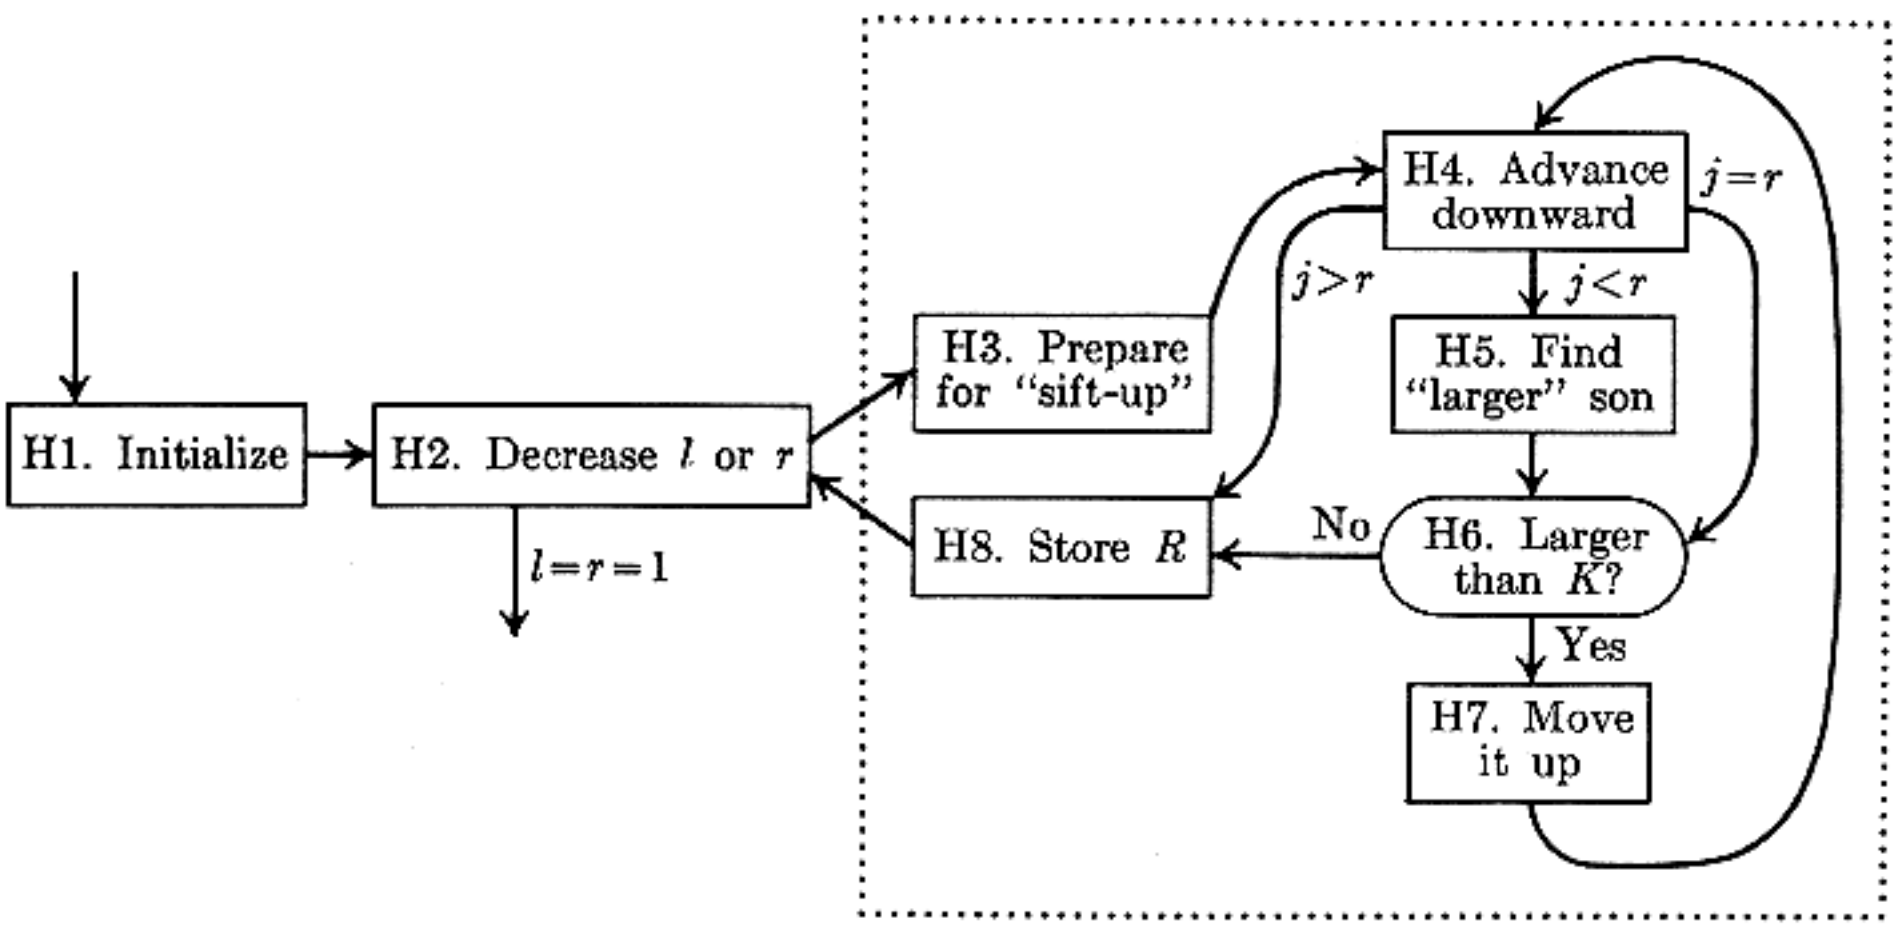

Fig. 26. Heapsort; dotted lines enclose the "sift-up" algorithm.

H4. [Advance downward.] Set $i \leftarrow j$ and $j \leftarrow 2j$. (In the following steps we have $i = \lfloor j/2 \rfloor$.) If $j < r$, go right on to step H5; if $j = r$, go to step H6; and if $j > r$, go to H8.

H5. [Find "larger" son.] If $K_j < K_{j+1}$, then set $j \leftarrow j + 1$.

H6. [Larger than K?] If $K \geq K_j$, then go to step H8.

H7. [Move it up.] Set $R_i \leftarrow R_j$, and go back to step H4.

H8. [Store R.] Set $R_i \leftarrow R$. (This terminates the "sift-up" algorithm initiated in step H3.) Return to step H2. ∎

Heapsort has sometimes been described as the "⧄" algorithm, because of the motion of l and r. The upper triangle represents the heap creation phase, when $r = N$ and l decreases to 1; and the lower triangle represents the selection phase, when $l = 1$ and r decreases to 1. Table 2 shows the process of heapsorting our sixteen example numbers. (Each line in that table shows the state of affairs after step H2, and brackets indicate the position l and r.)

24	2H	J1P	1B	P	*H2. Decrease l or r.*
25		LDA	INPUT+1,2	$N - 1$	If $l = 1$, set $R \leftarrow R_r$, $K \leftarrow K_r$.
26		LDX	INPUT+1	$N - 1$	
27		STX	INPUT+1,2	$N - 1$	$R_r \leftarrow R_1$.
28		DEC2	1	$N - 1$	$r \leftarrow r - 1$.
29		J2P	3B	$N - 1$	To H3 if $r > 1$.
30		STA	INPUT+1	1	$R_1 \leftarrow R$. ∎

This program is only about twice as long as Program S, but it is much more efficient when N is large. Its running time depends on

$P = N + \lfloor N/2 \rfloor - 2$, the number of sift-up passes;

A, the number of sift-up passes in which the key K finally lands in an interior node of the heap;

B, the total number of keys scanned during sift-ups;

C, the number of times $j \leftarrow j + 1$ in step H5; and

D, the number of times $j = r$ in step H4.

These quantities are analyzed below; in practice they show comparatively little fluctuation about their average values,

$$A \approx 0.349N, \qquad B \approx N\log_2 N - 1.87N,$$
$$C \approx \tfrac{1}{2}N\log_2 N - 0.9N, \qquad D \approx \ln N. \tag{7}$$

For example, when $N = 1000$, four experiments on random input gave $(A, B, C, D) = (371, 8055, 4056, 12)$, $(351, 8072, 4087, 14)$, $(341, 8094, 4017, 8)$, $(340, 8108, 4083, 13)$, respectively. The total running time, $7A + 14B + 4C + 20N - 2D + 15\lfloor N/2 \rfloor - 28$, is therefore approximately $16N\log_2 N + 0.2N$ units on the average.

A glance at Table 2 makes it had to believe that heapsort is very efficient; large keys shift to the left before we stash them at the right! It is indeed a strange way to sort, when N is small; the sorting time for the 16 keys in Table 2 is $1068u$, while the simple method of straight insertion (Program 5.2.1S) takes only $514u$. Straight selection (Program S) takes $853u$.

For larger N, Program H is more efficient. It invites comparison with Shell's diminishing increment sort (Program 5.2.1D) and Hoare's quicksort (Program 5.2.2Q), since all three programs sort by comparisons of keys and use little or no auxiliary storage. When $N = 1000$, the approximate average running times are

$160000u$ for heapsort,

$130000u$ for Shell's sort,

$80000u$ for quicksort.

(MIX is typical of most present-day computers, but particular machines will of course yield somewhat different relative values.) As N gets larger, heapsort will be superior to Shell's sort, but the asymptotic formula $16N\log_2 N \approx 23.08N\ln N$ will never beat quicksort's $12.67N\ln N$. A modification of heapsort discussed in exercise 18 will speed up the process on many computers, but even this improvement falls short of quicksort.

On the other hand, quicksort is efficient only on the average, and its worst case is of order N^2. Heapsort has the interesting property that its worst case isn't much worse than the average: We always have

$$A \le 1.5N, \qquad B \le N\lfloor\log_2 N\rfloor, \qquad C \le N\lfloor\log_2 N\rfloor, \tag{8}$$

so Program H will take no more than $18N\lfloor\log_2 N\rfloor + 38N$ units of time, regardless of the distribution of the input data. Heapsort is the first sorting method we have seen which is *guaranteed* to be of order $N\log N$. Merge sorting, discussed in Section 5.2.4 below, also has this property, but it requires more memory space.

Largest in, first out. We have seen in Chapter 2 that linear lists can often be classified in a meaningful way by the nature of the insertion and deletion operations performed on them. A *stack* has "last in, first out" behavior, in the sense that every deletion removes the youngest item in the list (the item which was inserted most recently of all items currently present). A simple *queue* has

"first in, first out" behavior, in the sense that every deletion removes the oldest remaining item. In more complex situations, such as the elevator simulation of Section 2.2.5, we want a "smallest in, first out" list, where every deletion removes the item having the smallest key. Such a list may be called a *priority queue*, since the key of each item reflects its relative ability to get out of the list quickly. Selection sorting is a special case of a priority queue in which we do N insertions followed by N deletions.

Priority queues arise in a wide variety of applications. For example, some numerical iterative schemes are based on repeated selection of an item having the largest (or smallest) value of some test criterion; parameters of the selected item are changed, and it is reinserted into the list with a new test value, based on the new values of its parameters. Operating systems often make use of priority queues for the scheduling of jobs. Exercises 15, 29, and 36 mention other typical applications of priority queues, and many other examples will appear in later chapters.

How shall we implement priority queues? One of the obvious methods is to maintain a sorted list, containing the items in order of their keys. Inserting a new item is then essentially the same problem we have treated in our study of insertion sorting, Section 5.2.1. Another even more obvious way to deal with priority queues is to keep the list of elements in arbitrary order, selecting the appropriate element each time a deletion is required by finding the largest (or smallest) key. The trouble with both of these obvious approaches is that they require on the order of N steps either for insertion or deletion, when there are N entries in the list, so they are very time-consuming when N is large.

In his original paper on heapsorting, Williams pointed out that heaps are ideally suited to large priority queue applications, since we can insert or delete elements from a heap in $O(\log N)$ steps; furthermore, all elements of the heap are compactly located in consecutive memory locations. The selection phase of Algorithm H is a sequence of deletion steps of a *largest-in-first-out* process: to delete the largest element K_1 we remove it and "sift-up" K_N into a new heap of $N - 1$ elements. (If we want a smallest-in-first-out algorithm, as in the elevator simulation, we can obviously change the definition of heap so that "$\geq$" becomes "$\leq$" in (3); for convenience, we shall consider only the largest-in-first-out case here.) In general, if we want to delete the largest item and then insert a new element x, we can do the sift-up procedure with $l = 1$, $r = N$, and $K = x$. If we wish to insert an element x without a prior deletion, we can use the "bottom-up" procedure of exercise 16.

A linked representation for priority queues. An efficient way to represent priority queues as linked binary trees was discovered in 1971 by Clark A. Crane. His method requires two link fields and a small count field in every record, but it has the following advantages over a heap:

1) When the priority queue is being treated as a stack, the insertion and deletion operations are more efficient (they take a fixed time independent of the queue size).

2) The records never move, only the pointers change.

3) It is possible to merge two disjoint priority queues, having a total of N elements, into a single priority queue, in only $O(\log N)$ steps.

Crane's original method, slightly modified, is illustrated in Fig. 27, which shows a special kind of binary tree structure. Each node contains a KEY field, a DIST field, and two link fields LEFT and RIGHT. The DIST field is always set equal to the length of the shortest path from that node to a leaf (i.e., an empty Λ node) of the tree. If we regard DIST(Λ) = 0 and KEY(Λ) = $-\infty$, the KEY and DIST fields in the tree satisfy the following properties:

$$\texttt{KEY(P)} \geq \texttt{KEY(LEFT(P))}, \qquad \texttt{KEY(P)} \geq \texttt{KEY(RIGHT(P))}; \tag{9}$$

$$\texttt{DIST(P)} = 1 + \min(\texttt{DIST(LEFT(P))}, \texttt{DIST(RIGHT(P))}); \tag{10}$$

$$\texttt{DIST(LEFT(P))} \geq \texttt{DIST(RIGHT(P))}. \tag{11}$$

Relation (9) is analogous to the heap condition (3), it guarantees that the root of the tree has the largest key; and relation (10) is just the definition of the DIST fields as stated above. Relation (11) is the interesting innovation: It implies that a shortest path to a leaf may always be obtained by moving to the right. We shall say that a binary tree with this property is a *leftist tree*, because it tends to "lean" so heavily to the left.

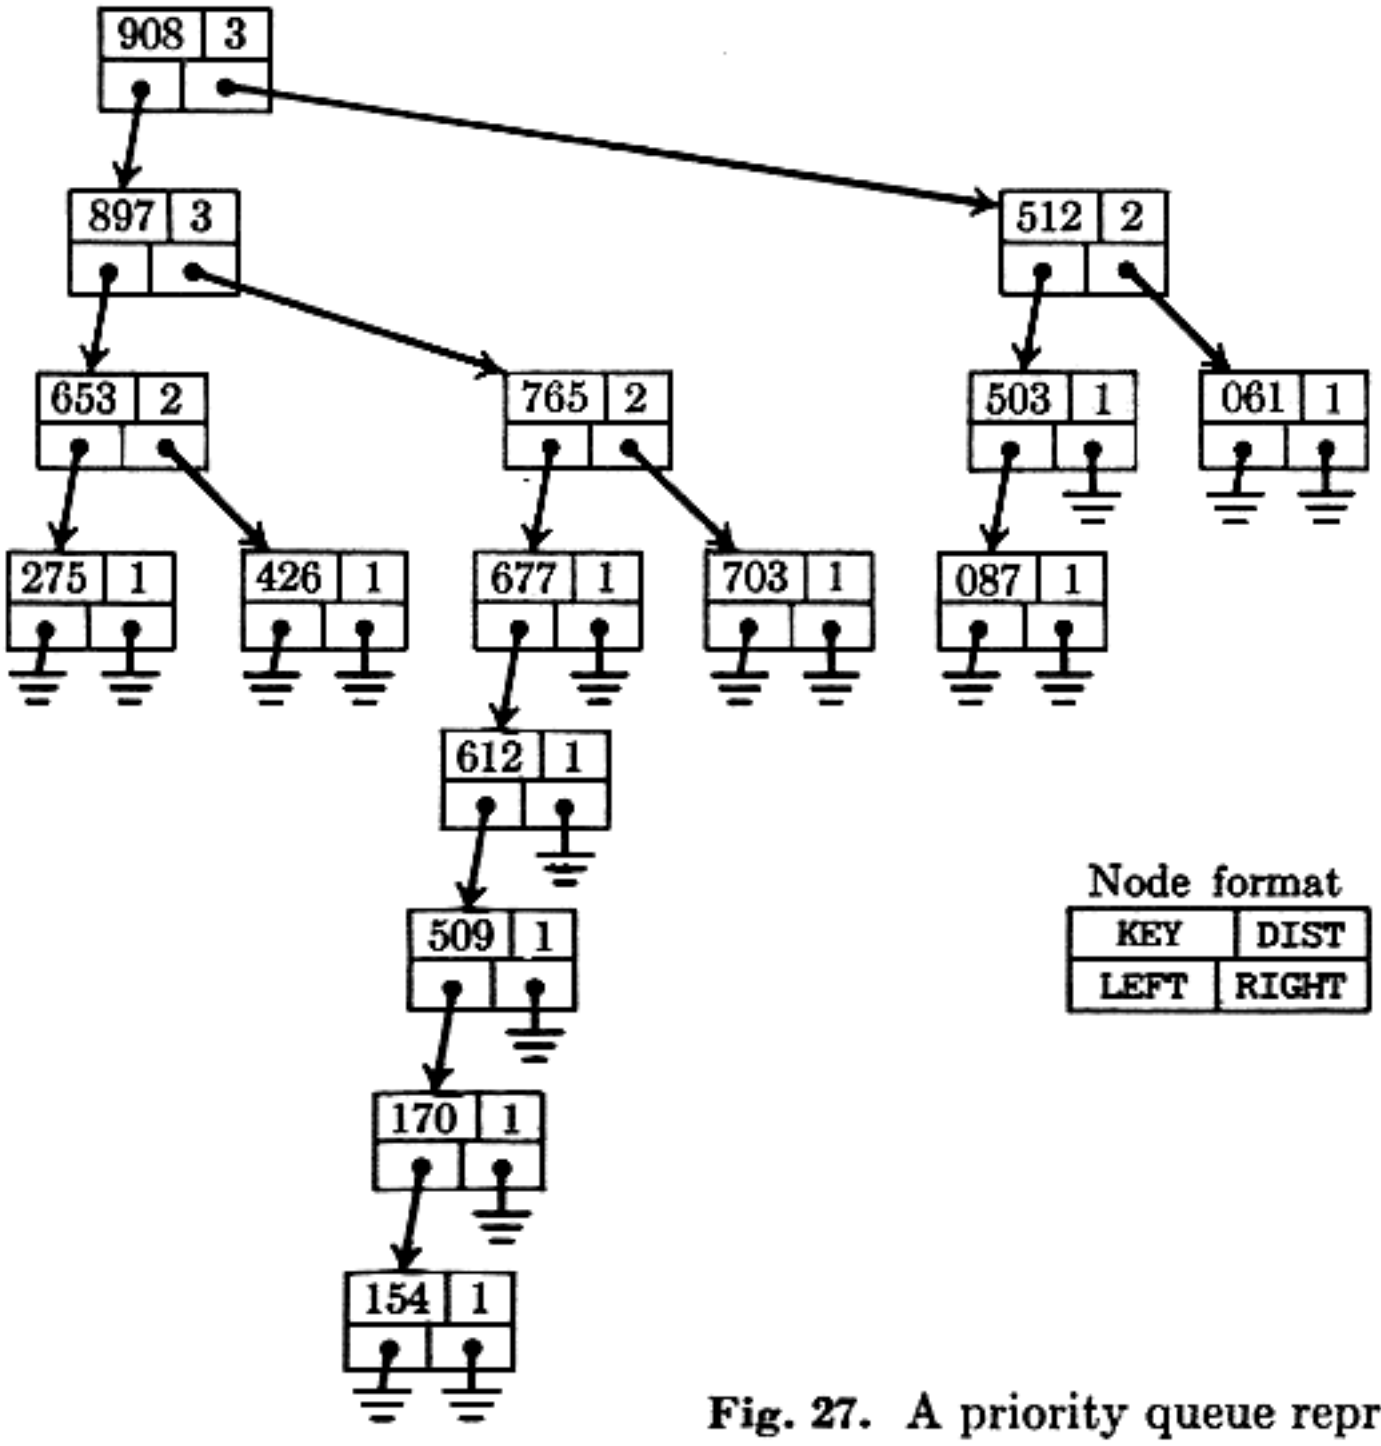

Fig. 27. A priority queue represented as a leftist tree.

It is clear from these definitions that DIST(P) $= n$ implies the existence of at least 2^n leaf nodes below P; otherwise there would be a shorter path from P to a leaf. Thus, if there are N nodes in a leftist tree, the path leading downward from the root towards the right contains at most $\lfloor \log_2 (N + 1) \rfloor$ nodes. It is possible to insert a new node into the priority queue by traversing this path (see exercise 32); hence only $O(\log N)$ steps are needed in the worst case. The best case occurs when the tree is linear (all RIGHT links are Λ), and the worst case occurs when the tree is perfectly balanced.

To remove the node at the root, we simply need to merge its two subtrees. The operation of merging two disjoint leftist trees, pointed to respectively by P and Q, is conceptually simple: If KEY(P) $\geq$ KEY(Q) we take P as the root and merge Q with P's right subtree; then DIST(P) is updated, and LEFT(P) is interchanged with RIGHT(P) if necessary. A detailed description of this process is not difficult to devise (see exercise 32).

Comparison of priority queue techniques. When the number of nodes, N, is small, it is best to use one of the straightforward linear list methods to maintain a priority queue; but when N is large, a $\log N$ method is obviously much faster. Therefore large priority queues are generally represented as heaps or as leftist trees. We shall discuss another way to represent linear lists in Section 6.2.3, via *balanced trees*, and this leads to a third $\log N$ method suitable for representing priority queues. It is therefore appropriate to compare these three techniques.

We have seen that leftist tree operations tend to be slightly faster than heap operations, although heaps take less memory space. Balanced trees take about the same space as leftist trees, perhaps slightly less; the operations are slower than heaps, and the programming is more complicated, but the balanced tree structure is considerably more flexible in several ways. When using a heap or a leftist tree we cannot predict very easily what will happen to two items with equal keys; it is impossible to guarantee that items with equal keys will be treated in a last-in-first-out or first-in-first-out manner, unless the key is extended to include an additional "serial number of insertion" field so that no equal keys are really present. With balanced trees, on the other hand, we can easily stipulate consistent conventions about equal keys, and we can also do things such as "insert x immediately before (or after) y." Balanced trees are symmetrical so that we can delete either the largest or the smallest element at any time, while heaps and leftist trees must be oriented one way or the other. (See exercise 31, however, which shows how to construct *symmetrical* heaps.) Balanced trees can be used for searching as well as for sorting; and we can rather quickly remove consecutive blocks of elements from a balanced tree. But two balanced trees cannot be merged in less than $O(N)$ steps, while leftist trees can be merged in only $O(\log N)$ steps.

In summary, heaps use minimum memory; leftist trees are great for merging disjoint priority queues; and the flexibility of balanced trees is available, if necessary, at reasonable cost.

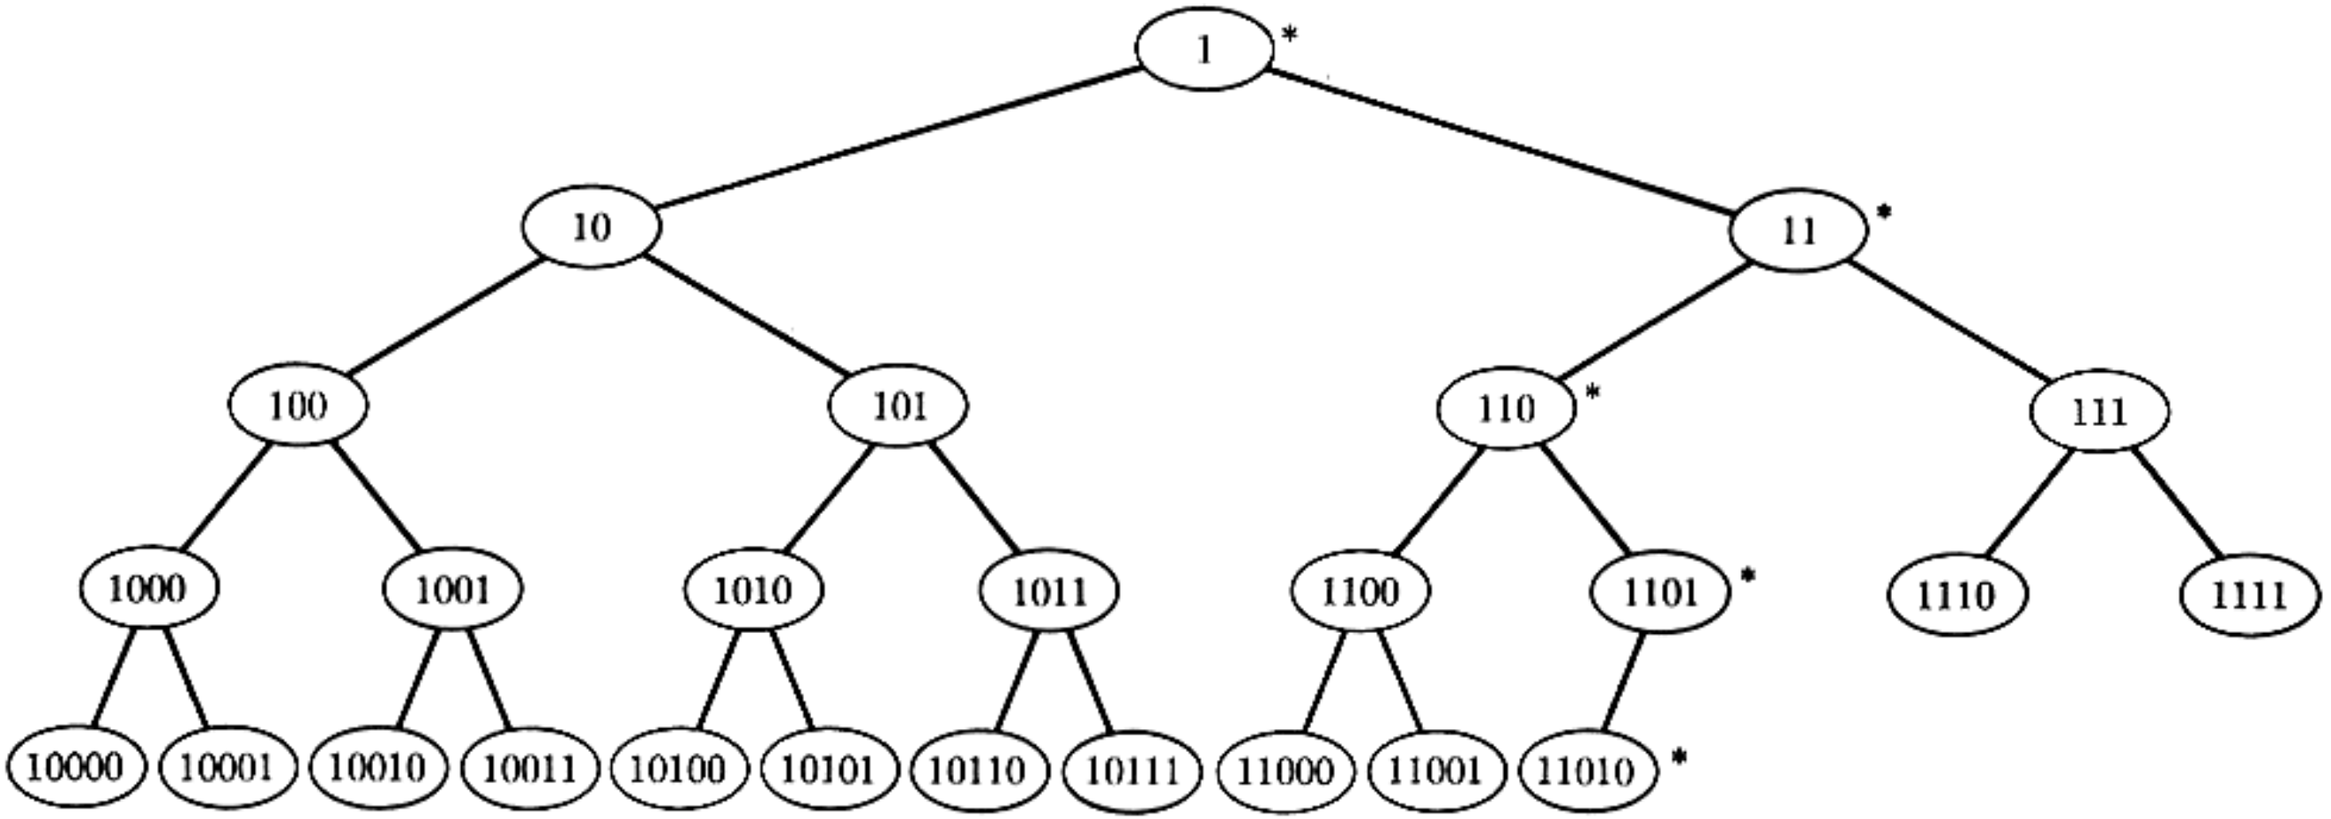

Fig 28. A heap of $26 = (11010)_2$ elements looks like this.

***Analysis of heapsort.** Algorithm H has not yet been analyzed completely, but several of its properties can be deduced without great difficulty. Therefore we shall conclude this section by studying the anatomy of a heap in some detail.

Figure 28 shows the shape of a heap with 26 elements; each node has been labeled in binary notation corresponding to its subscript in the heap. Asterisks in this diagram denote the so-called *special nodes*, which lie on the path from 1 to N.

One of the most important attributes of a heap is the collection of its subtree sizes. For example, in Fig. 28 the sizes of the subtrees rooted at 1, 2, . . . , 26 are, respectively,

$$26^*,\ 15,\ 10^*,\ 7,\ 7,\ 6^*,\ 3,\ 3,\ 3,\ 3,\ 3,\ 3,\ 2^*,\ 1,\ 1,\ 1,\ 1,\ 1,\ 1,\ 1,\ 1,\ 1,\ 1,\ 1,\ 1,\ 1^*. \tag{12}$$

Asterisks denote *special subtrees*, rooted at the special nodes; exercise 20 shows that if the binary representation of N is

$$N = (b_n b_{n-1} \ldots b_1 b_0)_2, \qquad n = \lfloor \log_2 N \rfloor, \tag{13}$$

the special subtree sizes are always

$$(1b_{n-1} \ldots b_1 b_0)_2,\ (1b_{n-2} \ldots b_1 b_0)_2,\ \ldots,\ (1b_1 b_0)_2,\ (1b_0)_2,\ (1)_2. \tag{14}$$

Nonspecial subtrees are always perfectly balanced, so their size is always of the form $2^k - 1$. Exercise 21 shows that the nonspecial sizes consist of exactly

$$\begin{gathered} \lfloor (N-1)/2 \rfloor \text{ 1's}, \qquad \lfloor (N-2)/4 \rfloor \text{ 3's}, \\ \lfloor (N-4)/8 \rfloor \text{ 7's}, \qquad \ldots, \qquad \lfloor (N - 2^{n-1})/2^n \rfloor \ (2^n - 1)\text{'s}. \end{gathered} \tag{15}$$

For example, Fig. 28 contains twelve nonspecial subtrees of size 1, six of size 3, two of size 7, and one of size 15.

Let s_l be the size of the subtree whose root is l, and let M_N be the multiset $\{s_1, s_2, \ldots, s_N\}$ of all these sizes. We can calculate M_N easily for any given N by using (14) and (15). Exercise 5.1.4–20 tells us that the total number of ways to arrange the integers $\{1, 2, \ldots, N\}$ into a heap is

$$N! \,/\, s_1 s_2 \ldots s_N \;=\; N! \,/ \prod_{s \in M_N} s. \tag{16}$$

For example, the number of ways to place the 26 letters $\{A, B, C, \ldots, Z\}$ into Fig. 28 so that vertical lines preserve alphabetic order is

$$26!/(26 \cdot 10 \cdot 6 \cdot 2 \cdot 1 \cdot 1^{12} \cdot 3^6 \cdot 7^2 \cdot 15^1).$$

We are now in a position to analyze the heap-creation phase of Algorithm H, namely, the computations which take place before the condition $l = 1$

occurs for the first time in step H2. Fortunately we can reduce the study of heap creation to the study of independent sift-up operations, because of the following theorem.

Theorem H. *If the input to Algorithm H is a random permutation of* $\{1, 2, \ldots, N\}$, *then each of the* $N!/(\Pi_{s\in M_N} s)$ *possible heaps is an equally likely outcome of the heap creation phase. Moreover, each of the* $\lfloor N/2 \rfloor$ *sift-up operations performed during this phase is "uniform," in the sense that each of the* s_l *possible values of* i *is equally likely when step H8 is reached.*

Proof. We can apply what numerical analysts might call a "backwards analysis"; given a possible result $K_1 \ldots K_N$ of the sift-up operation rooted at l, we see that there are exactly s_l prior configurations $K'_1 \ldots K'_N$ of the file which will siftup to that result. Each of these prior configurations has a different value of K'_l; hence, working backwards, there are exactly $s_l s_{l+1} \ldots s_N$ input permutations of $\{1, 2, \ldots, N\}$ which yield the configuration $K_1 \ldots K_N$ after the siftup at position l has been completed.

The case $l = 1$ is typical: Let $K_1 \ldots K_N$ be a heap, and let $K'_1 \ldots K'_N$ be a file which is transformed by siftup into $K_1 \ldots K_N$ when $l = 1$, $K = K'_1$. If $K = K_i$, we must have $K'_i = K_{\lfloor i/2 \rfloor}$, $K'_{\lfloor i/2 \rfloor} = K_{\lfloor i/4 \rfloor}$, etc., while $K'_j = K_j$ for all j not on the path from 1 to i. Conversely, for each i this construction yields a file $K'_1 \ldots K'_N$ such that (a) sift-up transforms $K'_1 \ldots K'_N$ into $K_1 \ldots K_N$, and (b) $K_{\lfloor j/2 \rfloor} \geq K_j$ for $2 \leq \lfloor j/2 \rfloor < j \leq N$. Therefore exactly N such files $K'_1 \ldots K'_N$ are possible, and the sift-up operation is uniform. (An example of the proof of this theorem appears in exercise 22.) ∎

Referring to the quantities A, B, C, D in the analysis of Program H, we can see that a uniform sift-up operation on a subtree of size s contributes $\lfloor s/2 \rfloor/s$ to the average value of A; it contributes

$$\frac{1}{s}(0 + 1 + 1 + 2 + \cdots + \lfloor \log_2 s \rfloor) = \frac{1}{s}\Bigg(\sum_{1\leq k\leq s} \lfloor \log_2 k \rfloor\Bigg)$$
$$= \frac{1}{s}\left((s+1)\lfloor \log_2 s \rfloor - 2^{\lfloor \log_2 s \rfloor + 1} + 2\right)$$

to the average value of B (see exercise 1.2.4–42); and it contributes either $2/s$ or 0 to the average value of D, according as s is even or odd. The corresponding contribution to C is somewhat more difficult to determine, so it has been left to the reader (see exercise 26). Summing over all sift-ups, we find that the average value of A during heap creation is

$$A'_N = \sum_{s\in M_N} \lfloor s/2 \rfloor/s, \tag{17}$$

and similar formulas hold for B, C, and D. It is therefore possible to compute these average values exactly without great difficulty, and the following table shows typical results:

N	A'_N	B'_N	C'_N	D'_N
99	19.18	68.35	42.95	0.00
100	19.93	69.39	42.71	1.84
999	196.16	734.66	464.53	0.00
1000	196.94	735.80	464.16	1.92
9999	1966.02	7428.18	4695.54	0.00
10000	1966.82	7429.39	4695.06	1.97
10001	1966.45	7430.07	4695.84	0.00
10002	1967.15	7430.97	4695.95	1.73

Asymptotically speaking, we may ignore the special subtree sizes in M_N, and we find for example that

$$A'_N = \frac{N}{2}\cdot\frac{0}{1} + \frac{N}{4}\cdot\frac{1}{3} + \frac{N}{8}\cdot\frac{3}{7} + \cdots + O(\log N) = (1 - \tfrac{1}{2}\alpha)N + O(\log N), \tag{18}$$

where

$$\alpha = \sum_{k\ge 1}\frac{1}{2^k - 1} = 1.60669\ 51524\ 15291\ 76378\ 33015\ 23190\ 92458\ 04805\text{—}. \tag{19}$$

(This value has been computed by J. W. Wrench, Jr., using the series transformation of exercise 27.) For large N, we may use the approximate formulas

$$\begin{aligned} A'_N &\approx 0.1967N + 0.3\ (N \text{ even}), \qquad 0.1967N - 0.3\ (N \text{ odd});\\ B'_N &\approx 0.74403N - 1.3\ln N;\\ C'_N &\approx 0.47034N - 0.8\ln N;\\ D'_N &\approx 1.8 \pm 0.2\ (N \text{ even}), \qquad 0\ (N \text{ odd}). \end{aligned} \tag{20}$$

The minimum and maximum values are also readily determined. Only $O(N)$ steps are needed to create the heap (cf. exercise 23).

This essentially disposes of the heap creation phase of Algorithm H. But the selection phase is another story, which remains to be written! Let A''_N, B''_N, C''_N, and D''_N denote the average values of A, B, C, and D during the selection phase when N elements are being heapsorted. The behavior of Algorithm H on random input is subject to comparatively little fluctuation about the empirically-determined average values

$$\begin{aligned} A''_N &\approx 0.152N;\\ B''_N &\approx N\log_2 N - 2.61N;\\ C''_N &\approx \tfrac{1}{2}N\log_2 N - 1.4N;\\ D''_N &\approx \ln N \pm 2; \end{aligned} \tag{21}$$

but no adequate theoretical explanation for these constants has yet been found. It is not hard to deduce the upper bounds stated in (8), by considering individual sift-up operations, but the upper bound for C should probably be lowered to about $\frac{1}{2}N \log_2 N$ when the algorithm as a whole is considered.

EXERCISES

1. [*10*] Is straight selection (Algorithm S) a "stable" sorting method?

2. [*15*] Why does it prove to be more convenient to select the largest key, then the second-largest, etc., in Algorithm S, instead of first finding the smallest, then the second-smallest, etc.?

3. [*M21*] (a) Prove that if Algorithm S starts with a random permutation of $\{1, 2, \ldots, N\}$, the first iteration of steps S2 and S3 yields a random permutation of $\{1, 2, \ldots, N-1\}$ followed by N. (In other words, the presence of each permutation of $\{1, 2, \ldots, N-1\}$ in $K_1 \ldots K_{N-1}$ is equally likely.) (b) Therefore if B_N denotes the average value of the quantity B in Program S, given randomly ordered input, we have $B_N = H_N - 1 + B_{N-1}$. [*Hint:* Cf. Eq. 1.2.10–16.]

▸ **4.** [*M25*] Step S3 of Algorithm S accomplishes nothing when $i = j$; is it a good idea to test whether or not $i = j$ before doing step S3? What is the average number of times the condition $i = j$ will occur in step S3 for random input?

5. [*20*] What is the value of the quantity B in the analysis of Program S, when the input is $N \ldots 3\ 2\ 1$?

6. [*M29*] (a) Let $a_1\, a_2 \ldots a_N$ be a permutation of $\{1, 2, \ldots, N\}$ having C cycles, I inversions, and B changes to the right-to-left maxima when sorted by Program S. Prove that $2B \leq I + N - C$. [*Hint:* See exercise 5.2.2–1.] (b) Show that $I + N - C \leq \lfloor n^2/2 \rfloor$; hence B can never exceed $\lfloor n^2/4 \rfloor$.

7. [*M46*] Find the variance of the quantity B in Program S, as a function of N, assuming random input.

▸ **8.** [*24*] Show that if the search for $\max(K_1, \ldots, K_j)$ in step S2 is carried out by examining keys in left-to-right order $K_1, K_2, \ldots, K_j$, instead of $K_j, \ldots, K_2, K_1$ as in Program S, it is often possible to reduce the number of comparisons needed on the next iteration of step S2. Write a MIX program based on this observation.

9. [*M25*] What is the average number of comparisons performed by the algorithm of exercise 8, for random input?

10. [*12*] What will be the configuration of the tree in Fig. 23 after 14 of the original 16 items have been output?

11. [*10*] What will be the configuration of the tree in Fig. 24 after the element 908 has been output?

12. [*M20*] How many times will $-\infty$ be compared with $-\infty$ when the "bottom up" method of Fig. 23 is used to sort a file of 2^n elements into order?

13. [*20*] (J. W. J. Williams.) Step H4 of Algorithm H distinguishes between the three cases $j < r$, $j = r$, and $j > r$. Show that if $K \geq K_{r+1}$ it would be possible to simplify step H4 so that only a two-way branch is made. How could the condition $K \geq K_{r+1}$ be ensured throughout the heapsort process, by modfying step H2?

14. [*10*] Show that simple queues are special cases of priority queues. (Explain how keys can be assigned to the elements so that a largest-in-first-out procedure is equivalent to first-in-first-out.) Is a stack also a special case of a priority queue?

▶**15.** [*M22*] (B. A. Chartres.) Design a high-speed algorithm which builds a table of the prime numbers $\leq N$, making use of a *priority queue* to avoid division operations. [*Hint:* Let the smallest key in the priority queue be the least odd nonprime number greater than the last odd number considered as a prime candidate. Try to minimize the number of elements in the queue.]

16. [*20*] Design an efficient algorithm which inserts a new key into a given heap of n elements, producing a heap of $n + 1$ elements.

17. [*20*] The algorithm of exercise 16 can be used for heap creation, instead of the "decrease l to 1" method used in Algorithm H. Do both methods create the same heap when they begin with the same input file?

▶**18.** [*21*] (R. W. Floyd.) During the selection phase of heapsort, the key K tends to be quite small, so that nearly all of the comparisons in step H6 find $K < K_j$. Show how to modify the algorithm so that K is not compared with K_j in the main loop of the computation.

19. [*21*] Design an algorithm which deletes a given element of a heap of length N, producing a heap of length $N - 1$.

20. [*M20*] Prove that (14) gives the special subtree sizes in a heap.

21. [*M24*] Prove that (15) gives the nonspecial subtree sizes in a heap.

▶**22.** [*20*] What permutations of {1, 2, 3, 4, 5} are transformed into 5 3 4 1 2 by the heap creation phase of Algorithm H?

23. [*M28*] (a) Prove that the length of scan, B, in a sift-up algorithm never exceeds $\lfloor \log_2 (r/l) \rfloor$. (b) According to (8), B can never exceed $N\lfloor \log_2 N \rfloor$ in any particular application of Algorithm H. Find the maximum value of B as a function of N, taken over all possible input files. (You must prove that an input file exists such that B takes on this maximum value.)

24. [*M24*] Derive an exact formula for the standard deviation of B'_N (the total length of scan during the heap-creation phase of Algorithm H).

25. [*M20*] What is the average value of the contribution to C made during the sift-up pass when $l = 1$ and $r = N$, if $N = 2^{n+1} - 1$?

26. [*M30*] Solve exercise 25, (a) for $N = 26$, (b) for general N.

27. [*M25*] (J. W. Wrench, Jr.) Prove that $\sum_{n\geq 1} x^n/(1 - x^n) = \sum_{n\geq 1} x^{n^2}(1 + x^n)/(1 - x^n)$. (Setting $x = \frac{1}{2}$ gives a very rapidly converging series for evaluating (19).)

28. [*35*] Explore the idea of *ternary heaps*, based on complete ternary trees instead of binary trees. Do ternary heaps sort faster than binary heaps?

29. [*26*] (W. S. Brown.) Design an algorithm for multiplication of polynomials or power series $(a_1x^{i_1} + a_2x^{i_2} + \cdots)(b_1x^{j_1} + b_2x^{j_2} + \cdots)$, in which the coefficients of the answer $c_1x^{i_1+j_1} + \cdots$ are generated in order as the input coefficients are being multiplied. [*Hint:* Use an appropriate priority queue.]

30. [*M48*] Can C ever exceed $\frac{1}{2}N \log_2 N$ when a file is heapsorted? What is the maximum value of C? What is the minimum value?

31. [*37*] (J. W. J. Williams.) Show that if two heaps are placed "back to back" in a suitable way, it is possible to maintain a structure in which either the smallest or the largest element can be deleted at any time in $O(\log n)$ steps. (Such a structure may be called a *priority deque*.)

32. [*21*] Design an algorithm which merges two disjoint priority queues, represented as leftist trees, into one. (In particular, if one of the given queues contains a single element, your algorithm will insert it into the other queue.)

▸**33.** [*15*] In a priority queue represented as a leftist tree, why is the operation of removing the root done by merging the two subtrees, instead of by "promoting" nodes toward the top as in a heap?

34. [*M47*] How many leftist trees with N nodes are possible, ignoring the KEY values? [The sequence begins 1, 1, 2, 4, 8, 17, 38, . . . ; is there a simple asymptotic formula?]

35. [*26*] If UP links are added to a leftist tree (cf. the discussion of triply-linked trees in Section 6.2.3), it is possible to delete an arbitrary node P from within the priority queue as follows: Replace P by the merger of LEFT(P) and RIGHT(P); then adjust the DIST fields of P's ancestors until either reaching the root or reaching a node whose DIST is unchanged.

Prove that this process never requires changing more than $O(\log N)$ of the DIST fields, if there are N nodes in the tree, even though the tree may contain very long upward paths.

36. [*18*] (*Least-recently-used page replacement.*) Many operating systems make use of the following type of algorithm: A collection of nodes is subjected to two operations, "using" a node, and replacing the least-recently-"used" node by a new node. What data structure makes it easy to ascertain the least-recently-"used" node?

5.2.4. Sorting by Merging

Merging (or *collating*) means the combination of two or more ordered files into a single ordered file. For example, we can merge the two files 503 703 765 and 087 512 677 to obtain 087 503 512 677 703 765. A simple way to accomplish this is to compare the two smallest items, output the smallest, and then repeat the same process. Starting with

$$\begin{cases} 503 & 703 & 765 \\ 087 & 512 & 677 \end{cases}$$

we obtain

$$087 \begin{cases} 503 & 703 & 765 \\ 512 & 677 & \end{cases},$$

then

$$087 \quad 503 \begin{cases} 703 & 765 \\ 512 & 677 \end{cases},$$

and so on. Some care is necessary when one of the two files becomes exhausted; a detailed description of the process appears in the following algorithm:

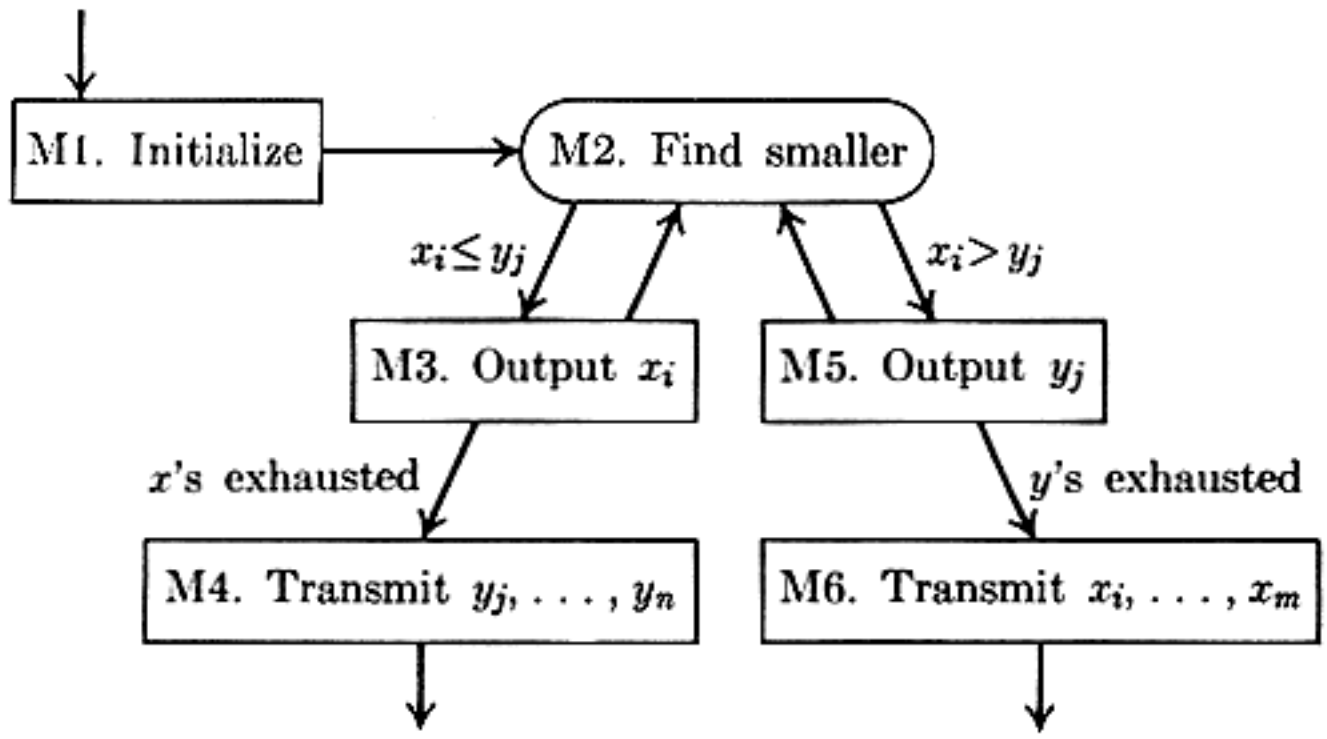

Fig. 29. Merging $x_1 \le \cdots \le x_m$ with $y_1 \le \cdots \le y_n$.

Algorithm M (*Two-way merge*). This algorithm merges the ordered files $x_1 \le x_2 \le \cdots \le x_m$ and $y_1 \le y_2 \le \cdots \le y_n$ into a single file $z_1 \le z_2 \le \cdots \le z_{m+n}$.

M1. [Initialize.] Set $i \leftarrow 1$, $j \leftarrow 1$, $k \leftarrow 1$.

M2. [Find smaller.] If $x_i \le y_j$, go to step M3, otherwise go to M5.

M3. [Output x_i.] Set $z_k \leftarrow x_i$, $k \leftarrow k + 1$, $i \leftarrow i + 1$. If $i \le m$, return to M2.

M4. [Transmit $y_j, \ldots, y_n$.] Set $(z_k, \ldots, z_{m+n}) \leftarrow (y_j, \ldots, y_n)$ and terminate the algorithm.

M5. [Output y_j.] Set $z_k \leftarrow y_j$, $k \leftarrow k + 1$, $j \leftarrow j + 1$. If $j \le n$, return to M2.

M6. [Transmit $x_i, \ldots, x_m$.] Set $(z_k, \ldots, z_{m+n}) \leftarrow (x_i, \ldots, x_m)$ and terminate the algorithm. ∎

We shall see in Section 5.3.2 that this straightforward procedure is essentially the "best possible" way to merge on a conventional computer, when $m \approx n$. (On the other hand, when m is much smaller than n, it is possible to devise more efficient merging algorithms, although they are rather complicated in general.) Algorithm M could be made slightly simpler without much loss of efficiency by placing artificial "sentinel" elements $x_{m+1} = y_{n+1} = \infty$ at the end of the input files, stopping just before ∞ is output. For an analysis of Algorithm M, see exercise 2.

The total amount of work involved in Algorithm M is essentially proportional to $m + n$, so it is clear that merging is a simpler problem than sorting. Furthermore, we can reduce the problem of sorting to merging, for it is possible to continue merging longer and longer subfiles until everything is in sort. We may consider this to be an extension of the idea of insertion sorting: inserting a new element into a sorted file is the special case $n = 1$ of merging! If we want to speed up the insertion process we can consider inserting several elements at a time, "batching" them, and this leads naturally to the general idea of merge sorting. From a historical point of view, merge sorting is one of the very first

methods proposed for computer sorting; it was suggested by John von Neumann as early as 1945 (see Section 5.5).

We shall study merging in considerable detail in Section 5.4, with regard to external sorting algorithms; in the present section, we shall focus only on the question of merge sorting within a high-speed random-access memory.

Table 1 shows a merge sort which "burns the candle at both ends" in a manner similar to the scanning procedure we have used in quicksort, radix exchange, etc.: we examine the input from the left and from the right, working towards the middle. Ignoring the top line of the table for a moment, let us consider the transformation from line 2 to line 3. At the left we have the ascending run 503 703 765; at the right, reading leftwards, we have the run 087 512 677. Merging these two sequences leads to 087 503 512 677 703 765, which is placed at the left of line 3. Then the keys 061 612 908 in line 2 are merged with 170 509 897, and the result (061 170 509 612 897 908) is recorded at the *right* end of line 3. Finally, 154 275 426 653 is merged with 653 (the overlap is discovered before it causes any harm), and the result is placed at the left. Line 2 of the table was formed in the same way from the original input in line 1.

Table 1

NATURAL TWO-WAY MERGE SORTING

503	087	512	061	908	170	897	275	653	426	154	509	612	677	765	703
503	703	765	061	612	908	154	275	426	653	897	509	170	677	512	087
087	503	512	677	703	765	154	275	426	653	908	897	612	509	170	061
061	087	170	503	509	512	612	677	703	765	897	908	653	426	275	154
061	087	154	170	275	426	503	509	512	612	653	677	703	765	897	908

Vertical lines in Table 1 represent the boundaries between runs. They are the so-called "step-downs," where a smaller element follows a larger one. In the middle of the file we generally have an ambiguous situation where we read the same key from both directions; this causes no problem if we are a little bit careful as in the following algorithm. The method is traditionally called a "natural" merge because it makes use of the runs which occur "naturally" in its input.

Algorithm N (*Natural two-way merge sort*). Records $R_1, \ldots, R_N$ are sorted using two areas of memory, each of which is capable of holding N records. For convenience, we shall say that the records of the second area are R_{N+1}, $\ldots$, R_{2N}, although it is not really necessary that R_{N+1} be adjacent to R_N. The initial contents of $R_{N+1}, \ldots, R_{2N}$ is immaterial. After sorting is complete, the keys will be in order, $K_1 \leq \cdots \leq K_N$.

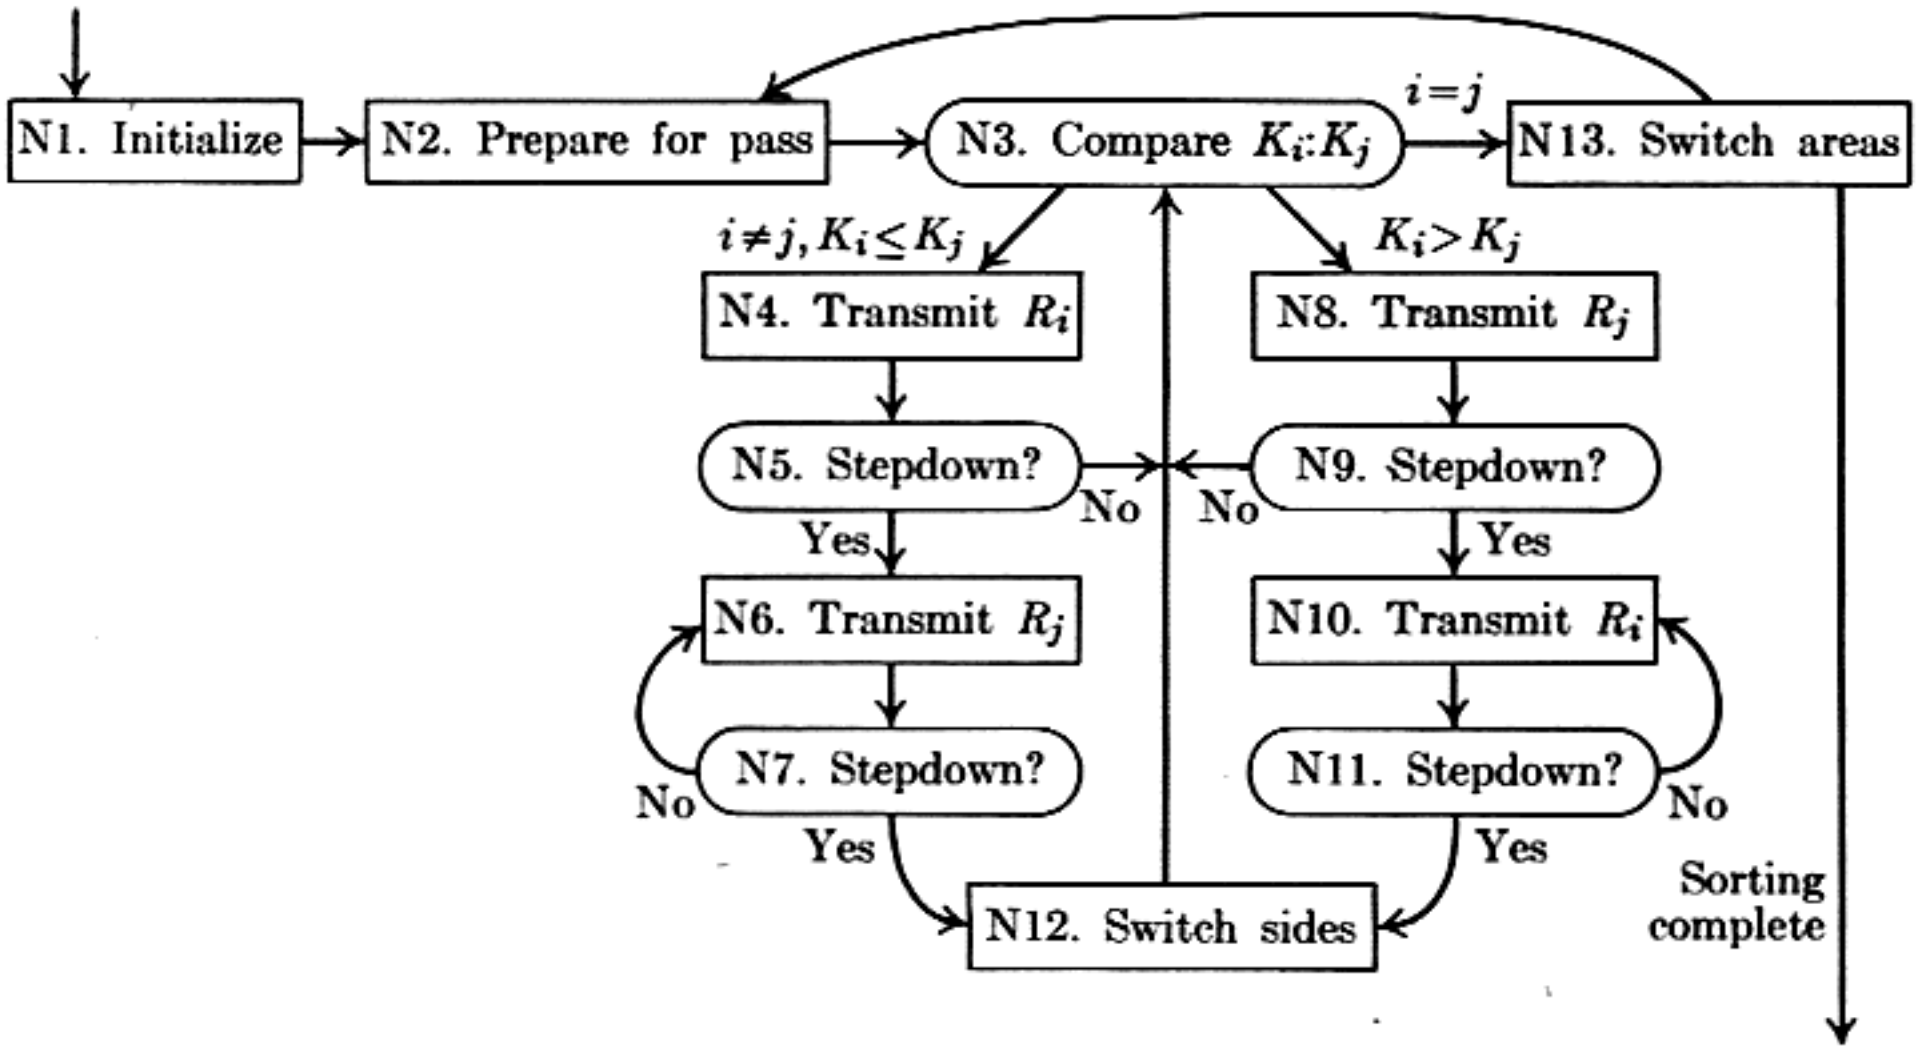

Fig. 30. Merge sorting.

N1. [Initialize.] Set $s \leftarrow 0$. (When $s = 0$, we will be transferring records from the $(R_1, \ldots, R_N)$ area to the $(R_{N+1}, \ldots, R_{2N})$ area; when $s = 1$, we will be going the other way.)

N2. [Prepare for pass.] If $s = 0$, set $i \leftarrow 1$, $j \leftarrow N$, $k \leftarrow N + 1$, $l \leftarrow 2N$; if $s = 1$, set $i \leftarrow N + 1$, $j \leftarrow 2N$, $k \leftarrow 1$, $l \leftarrow N$. (Variables i, j, k, l point to the current positions in the "source files" being read and the "destination files" being written.) Set $d \leftarrow 1$, $f \leftarrow 1$. (Variable d gives the current direction of output; f is set to zero if future passes are necessary.)
